Abstract
We show the photodetachment cross sections of H\(^{−}\) near a metal surface can be modified using a weak static electric field. The modification is possible because the oscillatory part of the cross section near a metal surface is directly connected with the transit time and the action of the detached electron closed-orbit which can be changed systematically by varying the static electric field strength. Photodetachment cross sections for various photon energies and electric field values are calculated and displayed.

1. Introduction
Great interest in the photodetachment of negative ions in electric and magnetic fields has grown since the 1980s when scientists observed oscillatory photodetachment cross sections for negative ions in a static electric field [1–16]. In the same time, energy level shifts and other interesting dynamics for Rydberg atoms near a metal surface have also been studied [17–21]. Recently Yang et al studied the photodetachment process of H\(^{−}\) near an interface [22]. Inspired by these studies, the photodetachment process of a negative ion near a metal surface has been proposed and studied recently by Zhao and Du [23, 24]. They showed that the image charge inside the metal induces an oscillation in the photodetachment cross section above threshold. Furthermore, it was predicated that the oscillation exists only when the detached electron energy is less than \(\frac{1}{4}d\), where \(d\) is the distance between the initial negative ion and the metal surface. Below photodetachment threshold the quantum tunnelling effect makes the photodetachment cross section finite.

In this paper, we consider the coherent control of the photodetachment process of a negative ion such as H\(^{−}\) near a metal surface by using an additional static electric field. We will show by adding a static electric field that the photodetachment cross section will become oscillatory above threshold and the energy limit mentioned above for the oscillation in the presence of only a metal surface will be removed. In addition, when the static electric field is applied, the photodetachment cross section is controlled by the transit time and the action of one detached electron closed-orbit. Because the static electric field can systematically change the transit time and the action of the closed-orbit, it can modify the photodetachment cross section in a systematic way. Atomic units will be used unless specified otherwise.

2. Hamiltonian and closed-orbit
The system is shown schematically in figure 1. A negative ion H\(^{−}\) is near a metal surface. An external static electric field \(F\) perpendicular to the metal surface is applied. We assume that the \(z\)-axis is away from the metal surface and the photon polarization direction is also in the \(z\)-direction. Using the image method [17, 24], the Hamiltonian for the detached electron in cylindrical coordinates can be written as

\[
H = \frac{1}{2}(p_\rho^2 + p_z^2) - \frac{1}{4(d + z)} + \frac{1}{4d} + Fz. \tag{1}
\]

The first four terms in equation (1) describe the motion of the detached electron near a metal surface [23, 24]. The last term is new and it represents the static electric field. Note that the constant term \(\frac{1}{4d}\) does not change the dynamics. It is added to set the value of the total potential to zero at the origin.

According to the closed-orbit theory [25, 26], the photodetachment process can be described as follows. The negative ion H\(^{−}\) is initially in an s state and the active electron is loosely bound by the hydrogen atom. When the laser is on, the negative ion may absorb a photon of energy \(E_{\text{ph}}\) and the active electron becomes an outgoing p-wave. The wave then propagates away from the hydrogen atom in all directions. When the distance between the detached electron and the hydrogen atom is large, a semiclassical description for the electronic motion is appropriate. If there are closed-orbits in
the system, the detached electron wave can follow the closed-orbits and returns to the initial negative ion region. When this happens, the returning waves will interfere with the initial outgoing wave to produce oscillations in the photodetachment cross section. Following the earlier study, it is assumed that the metal absorbs the electron when the electron hits the metal [23, 24]. In figure 2 the photodetachment process and the potential for the Hamiltonian in equation (1) are illustrated. Previously we have demonstrated that very close to the photodetachment threshold the metal surface acts like an effective electric field of strength \( F_{\text{eff}} \) defined by [24]

\[
F_{\text{eff}} = \frac{1}{4d^2},
\]

(2)

where \( d \) is the distance between the metal surface and the negative ion. In this paper we will first fix \( d = 60a_0 \) and discuss the modifications in the cross sections by varying the static electric field. The effect of changing the distance will be briefly discussed later. In figure 2 the potentials in equation (1) are displayed for static electric field \( F = 0F_{\text{eff}}, 0.3F_{\text{eff}}, 0.6F_{\text{eff}} \) and \( 0.9F_{\text{eff}} \) respectively. The heavy black curve labelled by \( F = 0F_{\text{eff}} \) is the image potential of the metal surface without the electric field considered previously [24]. In this case, we found that if the detached electron energy is less than \( \frac{1}{2d} \), there is a closed-orbit in the system. If the detached electron energy is greater than \( \frac{1}{2d} \), there is no closed-orbit. According to the closed-orbit theory, the photodetachment cross section is oscillatory when the detached electron is above threshold and less than \( \frac{1}{2d} \). The oscillatory cross section merges to a smooth cross section for detached electron energy equal to \( \frac{1}{2d} \). When the static electric field is present, the potential keeps increasing as \( z \) is increased. We find there is always one closed-orbit above threshold. As illustrated in figure 2, this closed-orbit leaves the negative ion in the \( z \)-direction and finally returns to the negative ion after it is turned around by the image potential of the metal surface and the static electric field. Figure 2 also suggests that the transit time of the closed-orbit decreases as the static electric field \( F \) is increased. Numerical calculations will confirm this observation later.

3. Formulae for the photodetachment cross section

When the static electric field is on, the same procedure [24] can be used to derive the photodetachment cross section. We will briefly summarize the results. For the detached electron energy \( E \geq 0 \), the photodetachment cross section is a sum of two terms:

\[
\sigma(E, d, F) = \sigma_0(E) + \sigma_r(E, d, F), \quad E \geq 0,
\]

(3)

where

\[
\sigma_0(E) = \frac{16\pi^2\sqrt{2}E^{3/2}}{3c(E_b + E)^3} T(E, d, F)\]

(4)

is the smooth background and is equal to the cross section of free negative ion without the metal surface and the static electric field, and \( \sigma_r(E, d, F) \) is the oscillating part of the cross section given by

\[
\sigma_r(E, d, F) = \frac{8\pi^2B^2\sqrt{2E}}{c(E_b + E)^3} T(E, d, F) S(E, d, F)
\]

(5)

where \( T(E, d, F) \) and \( S(E, d, F) \) are respectively the transit time and the action of the closed-orbit. The transit time and the action can be calculated using the following integrals:

\[
T(E, d, F) = 2 \int_0^{E_{\text{c}}} \frac{1}{p_z} \, dz, \\
S(E, d, F) = 2 \int_0^{E_{\text{c}}} p_z \, dz.
\]

(6)
The momentum $p_z$ in the $z$-direction is readily obtained from equation (1) as

$$p_z = \sqrt{2\left(E - \frac{1}{4d} + \frac{1}{4(d+z)} - Fz\right)}.$$ \hspace{1cm} (7)

$z_m$ is the turning point of the closed-orbit and can be obtained by setting $p_z$ to zero. If we denote the parameter $A = E - \frac{1}{4\pi}$, then

$$z_m = \frac{1}{2F}\left[-(Fd - A) + \sqrt{(Fd + A)^2 + F}\right].$$ \hspace{1cm} (8)

In both equations (4) and (5) $B = 0.31552$, $E_b$ is the binding energy of $\text{H}^-$ and is approximately $0.754$ eV, $c$ is approximately equal to $137$ au \cite{[5]}. Both integrals for $T(E,d,F)$ and $S(E,d,F)$ can be expressed analytically using special functions as \cite{[27]}

$$T = \frac{2\sqrt{2}}{\sqrt{F}}\left[\sqrt{z_m - z_n}E(\gamma,\lambda) + \frac{d + z_n}{\sqrt{z_m - z_n}}F(\gamma,\lambda)\right]$$ \hspace{1cm} (9)

and

$$S = \frac{4\sqrt{2F}}{3}\left[\sqrt{z_m - z_n}(\frac{z_m + z_n + 2d}{\sqrt{z_m - z_n}})E(\gamma,\lambda) - (z_n + d)F(\gamma,\lambda) - \sqrt{-z_m z_n d}\right].$$ \hspace{1cm} (10)

where $z_n < 0$ is another point corresponding to $p_z = 0$ in equation (7) and is given by

$$z_n = \frac{1}{2F}\left[-(Fd - A) - \sqrt{(Fd + A)^2 + F}\right].$$ \hspace{1cm} (11)

$F(\gamma,\lambda)$ and $E(\gamma,\lambda)$ (this function should not be confused with the energy $E$) are, respectively, the elliptic integrals of the first kind and the second kind \cite{[27]}. The two parameters are defined as

$$\gamma = \arcsin\sqrt{\frac{z_m}{z_m + d}}, \quad 0 \leq \gamma \leq \frac{\pi}{2};$$

$$\lambda = \sqrt{\frac{z_m + d}{z_m - z_n}}, \quad 0 \leq \lambda \leq 1.$$ \hspace{1cm} (12)

Although the analytical expressions for $T(E,d,F)$ and $S(E,d,F)$ are derived above, in practice, we find it is easier to evaluate the integrals in equations (6) numerically. For the detached electron energy $E < 0$, the cross section is finite because of a quantum tunneling effect. Following the earlier work \cite{[24]}, the above threshold photodetachment cross section joins to the following formula below threshold:

$$\sigma(E,d,F) = \frac{\pi^2 B^2 (1 + 4F^2d^2)}{cd^2(E_b + E)^3} \exp[-2S_t(E,d,F)],$$ \hspace{1cm} (13)

where

$$S_t(E,d,F) = \int_{z_t}^{0} \left(2\left(Fz - \frac{1}{4(d+z)} + \frac{1}{4d} - E\right)dz, \quad E \leq 0\right.$$ \hspace{1cm} (14)

and the formula for $z_t$ has the same expression as $z_m$ in equation (8) except the energy $E$ is negative.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{image.png}
\caption{The transit time $T$ and the action $S$ of the closed-orbit. The distance between the negative ion and the metal surface is $60\text{a}_0$. The electric fields are respectively $0\text{F}_{\text{eff}}, 0.3\text{F}_{\text{eff}}, 0.6\text{F}_{\text{eff}}$ and $0.9\text{F}_{\text{eff}}$.}
\end{figure}

4. Modifying cross sections

We have expressed the cross section in terms of the transit time and the action of the only closed-orbit for the system in equation (1). We now fix the distance $d$ between the negative ion and the metal surface to be $60\text{a}_0$ and study how the static electric field modifies the transit time and the action of the closed-orbit. In figure 3 we show the dependence of $T(E,d,F)$ and $S(E,d,F)$ on the detached electron energy for static electric fields $F = 0\text{F}_{\text{eff}}, 0.3\text{F}_{\text{eff}}, 0.6\text{F}_{\text{eff}}$ and $0.9\text{F}_{\text{eff}}$, respectively. We calculated the transit time $T(E,d,F)$ and the action $S(E,d,F)$ independently. The numerical results were checked against the following relationship \cite{[26]}:

$$\frac{\partial S}{\partial E} = T.$$ \hspace{1cm} (15)

As the electric field strength is increased, both the transit time and the action of the closed-orbit decrease. The changes in the transit time and the action of the closed-orbit are directly reflected in the total photodetachment cross section. Simple analysis of the formula in equation (5) suggests the oscillation amplitude is increased but the oscillation frequency is decreased as the static electric field strength $F$ in equation (1) is increased. In figure 4 we display the calculated cross sections corresponding to $F = 0\text{F}_{\text{eff}}, 0.3\text{F}_{\text{eff}}, 0.6\text{F}_{\text{eff}}$ and $0.9\text{F}_{\text{eff}}$, respectively. The results are consistent with our expectations. In the presence of the static electric field the photodetachment cross section is oscillatory above threshold. The oscillation amplitude becomes larger while the oscillation frequency becomes smaller as the electric field is increased.
Regarding the variation of the action $S$ with respect to the static electric field in the present system, we can apply a theorem [26] to get

$$\frac{\partial S}{\partial F} = -\int z \, dt. \quad (16)$$

The integral on the right-hand side of equation (16) is along the closed-orbit. The first derivative $\frac{\partial S}{\partial F}$ is therefore negative because the right-hand side is negative for this closed-orbit. As a result, when the static electric field $F$ is increased, the action of the closed-orbit always decreases. This dependence of action on the static electric field can be used to modify the cross section. For selected photon energies, we show in figure 5 the variations of the cross sections as the static electric field is increased. The selected photon energies correspond to the minima in the cross section when the static electric field is zero. The photon energies for the dotted curve, the dashed curve and the heavy black curve are respectively 0.8533 eV, 0.8564 eV and 0.8585 eV, for example. Figure 5 demonstrates that for any fixed photon energy, the cross section varies in a simple pattern as the static electric field is increased. Therefore we can get the desired cross section by choosing proper values of static electric field. For example, when the photon energy is 0.8585 eV, the cross section reaches a large value if the static electric field is close to 5 kV cm$^{-1}$ and the cross section reaches a small value if the static electric field is close to 3 kV cm$^{-1}$. In fact, we find that the valleys and peaks of the oscillation in the cross section are primarily determined by the action $S$. To demonstrate this point, in figure 6 we show $\cos(S)$ as a function of both energy and electric field. The brightest points correspond to the maxima of $\cos(S)$. For the purpose of comparison, we find the cross section represented by the black line in figure 5 is similar to the brightness along the dotted line in figure 6. The three peaks indicated by the circles in the cross section in figure 5 coincide well with the three brightest spots indicated by the three circles in figure 6. Because of this correspondence, figure 6 can be used as a map for the modification of the photodetachment cross section.

Finally we emphasize that although the above analysis is made for a distance $d = 60\alpha_0$ between the negative ion...
Figure 7. The photodetachment cross sections for three different distances between the negative ion and the metal surface. The static electric field is 107 kV cm\(^{-1}\) which is equal to 0.3\(F_{\text{eff}}\) in figure 4. The light solid curve in this figure is the same as the light solid curve in figure 4.

and the metal surface, similar phenomena occur at other distances. Figure 7 shows the photodetachment cross sections for three distances with the same static electric field at 107 kV cm\(^{-1}\). Similar analysis for the interference patterns in the cross sections can be carried out for each distance to find the positions of the minima and maxima in the cross sections.

5. Conclusions

We have investigated the effects of an additional weak static electric field on the photodetachment of H\(^{-}\) near a metal surface. When the static electric field is applied, the photodetachment cross section becomes oscillatory in the whole energy region above threshold. The cross section can be expressed in terms of the transit time and the action of the only closed-orbit. By increasing the static electric field, one can systematically change the transit time and the action of the closed-orbit to modify the cross section. The landscape of the function \(\cos(S)\) can serve as a map for the modification of the photodetachment cross section.
