ABSTRACT

We investigate the burstiness of star formation and the ionizing efficiency of a large sample of galaxies at 0.7 < z < 1.5 using HST grism spectroscopy and deep ultraviolet (UV) imaging in the GOODS-N and GOODS-S fields. The star formation history (SFH) in these strong emission line low-mass galaxies indicates an elevated star formation rate (SFR) based on the H\textalpha emission line at a given stellar mass when compared to the standard main sequence. Moreover, when comparing the H\textalpha and UV SFR indicators, we find that an excess in SFR\textsubscript{H\textalpha} compared to SFR\textsubscript{UV} is preferentially observed in lower-mass galaxies below 10\textsuperscript{9} M\textsubscript{\odot}, which are also the highest-EW galaxies. These findings suggest that the burstiness parameters of these strong emission line galaxies may differ from those inferred from hydrodynamical simulations and previous observations. For instance, a larger burstiness duty cycle would explain the observed SFR\textsubscript{H\textalpha} excess. We also estimate the ionizing photon production efficiency \( \xi_{\text{ion}} \), finding a median value of \( \log(\xi_{\text{ion}}/\text{erg}^{-1}\text{Hz}) = 24.80 \pm 0.26 \) when adopting a Galactic dust correction for H\textalpha and an SMC one for the stellar component. We observe an increase of \( \xi_{\text{ion}} \) with redshift, further confirming similar results at higher redshifts. We also find that \( \xi_{\text{ion}} \) is strongly correlated with EW\textsubscript{H\textalpha}, which provides an approach for deriving \( \xi_{\text{ion}} \) in early galaxies. We observe that lower-mass, lower-luminosity galaxies have a higher \( \xi_{\text{ion}} \). Overall, these results provide further support for faint galaxies playing a major role in the reionization of the Universe.

1 INTRODUCTION

There is a growing interest in the study of low-mass galaxies at all epochs, both on the theoretical and observational fronts. Until recently, most of the efforts were dedicated to characterizing massive galaxy populations out to the highest redshifts, and little was known about high-\( z \) star-forming galaxies with stellar masses below 10\textsuperscript{10} M\textsubscript{\odot}. Near-infrared spectroscopic surveys from space, such as 3D-HST (Brammer et al. 2012) and WISPS (Atek et al. 2010), and subsequent follow-ups with ground-based multi-object spectrographs (e.g., Wisnioski et al. 2015; Kriek et al. 2015), have given access to the main rest-frame optical emission lines, which enable us to derive the physical properties of the ISM in high-redshift galaxies. In particular, various studies have recently focused on investigating the star formation histories of low-mass galaxies and how they compare to their massive counterparts (e.g., Guo et al. 2016; Sparre et al. 2017; Flores Velázquez et al. 2020).

In the classic picture of galaxy evolution in which the SFR varies smoothly with time, star-forming galaxies follow a well known relation between the SFR and the stellar mass \( M_\ast \) (e.g., Brinchmann et al. 2004; Elbaz et al. 2007; Wuyts et al. 2011b; Whitaker et al. 2014). It is believed that such a relation is shaped by the complex interplay between several physical mechanisms that operate over long timescales (Giga years). For instance, the current SFR depends on the gas accretion and the merger history of the galaxy and star-formation suppression by the AGN feedback. While
this relation is expected to hold for relatively massive galaxies (> $10^{10}$ $M_\odot$), it is unlikely that star formation quenching from AGN remains very efficient in low-mass galaxies. Supernova explosions become the most significant source of feedback processes. At a given redshift, low-mass galaxies appear to have a higher specific star formation rate (sSFR, which is the SFR per unit of stellar mass) than “normal” galaxies, and can double their total stellar mass on a very short timescale of 100 Myr (Rodighiero et al. 2011; Atek et al. 2014; Boogaard et al. 2018). Star formation is expected to occur mostly through a stochastic process in these galaxies as a result of two competing processes: gas accretion feeding intense bursts of star formation and feedback from supernova explosions. Such variations are expected to occur on short time scales (∼ 10 Myr) and imply that galaxy observables might not be representative of the averaged properties of galaxies (Domínguez et al. 2015). Bursty star formation also has important implications on galaxy formation and evolution, as it may be responsible for altering dark matter density profiles (Chan et al. 2015; Read et al. 2016; Pelliccia et al. 2020).

The burstiness of star formation can be investigated by comparing SFR(Hα) and SFR(UV), two indicators that trace different timescales: while the Hα nebular emission traces the ionizing radiation from short-lived massive O stars over few to ten Myr, the UV continuum traces a population of longer-lived O, B and A stars over ∼ 100 Myr (see Kennicutt & Evans 2012, for a review). In the case of a constant star formation, the ratio between these two indicators will be close to unity after 100 Myr, whereas deviations are to be expected for rapidly varying star formation. Hydrodynamical simulations have shown that burstiness increases towards lower-mass galaxies (e.g. Shen et al. 2014; Flores Velázquez et al. 2020), which leads to a decreasing SFR$_{H\alpha}$/SFR$_{UV}$ ratio with decreasing stellar mass.

This is due to the relatively rapid response of SFR(Hα) to the change in instantaneous SFR compared to SFR(UV) in the same burst period. This is why the ratio between these two SFRs is an indicator of burstiness. It means that, within a 10 Myr period of an instantaneous SF burst, SFR(Hα) will increase rapidly, following closely the “true” SFR, whereas SFR(UV) will slowly increase, falling behind the “true” SFR. In this phase we will have SFR$_{H\alpha}$/SFR$_{UV}$ above unity (see for example Sparre et al. 2017). After the burst, The FUV emission will decrease slowly, whereas the Hα emission fades quickly. Therefore, the SFR$_{H\alpha}$/SFR$_{UV}$ goes below unity after the burst episode. Similar results were also observed in local and high-redshift galaxies (Weisz et al. 2012; Guo et al. 2016; Emami et al. 2019), whereas no sign of burstiness was found by Smit et al. (2016). Faisst et al. (2019) also find that more than half of their sample of $z \sim 4.5$ galaxies have an SFR$_{H\alpha}$/SFR$_{UV}$ ratio above unity.

Low-mass galaxies are also suspected to be major contributors to cosmic reionization. According to the very steep slope ($\alpha \sim -2$) of the faint-end of the UV luminosity function at $z > 6$ (e.g. Atek et al. 2015; Bouwens et al. 2015; Livermore et al. 2017; Ishigaki et al. 2018; Atek et al. 2018), the UV radiation budget is dominated by galaxies fainter than $M_{UV} = -17$ mag. One needs to convert this non-ionizing UV radiation to the ionization emission below 912 Å, which can be achieved by estimating the ionizing efficiency $\xi_{ion}$. The measurement of a ionization production rate relative to the UV luminosity density at 1500 Å. The primary method to compute $\xi_{ion}$ is to use a nebular recombination line such Hα to infer the ionizing photon production rate, which is then compared to UV luminosity. Therefore, this $\xi_{ion}$ estimate is based on the same Hα/UV ratio used to investigate the star formation burstiness. Indirect measurements of Hα have been obtained through the photometric excess in Spitzer IRAC bands to infer $\xi_{ion}$ in $z \sim 4$ galaxies (e.g. Smit et al. 2016; Lam et al. 2019). Spectroscopic measurements of Hα or Hβ lines have also been conducted to infer $\xi_{ion}$ of $z \sim 2$ – 3 galaxies. However, these studies either focused on relatively massive galaxies ($M_\star = 10^9 - 10^{11} M_\odot$; Shivaei et al. 2018), a relatively small sample of galaxies (Emami et al. 2020), or SED fitting to infer the UV properties in bright Lyα emitters (Nakajima et al. 2016). At higher redshift, Stark et al. (2015) used stellar population and photoionization models to fit rest-frame UV spectra of $z \sim 7$ galaxies and infer $\xi_{ion}$ from the best-fit SED model.

In this work, we use a large sample of galaxies at $0.7 < z < 1.5$ reaching down to a stellar mass of $\sim 10^8 M_\odot$, with both spectroscopic measurements of Hα emission and deep UV imaging to investigate the star formation burstiness. We used rest-frame optical spectra from 3DHST grism survey in the GOODS-S and GOODS-N fields and rest-frame UV imaging around 1500 Å from HUDUV program. Nebular attenuation was inferred from a subsample of galaxies with Balmer decrement measurements and the mass-attenuation relation. The continuum attenuation was computed from the UV continuum slope $\beta$. We also used these quantities to directly compute the ionizing efficiency.

The paper is structured as follows. In Section 2, we present the observational data used in the paper. In Section 3, we describe how the galaxy sample was selected and how dust attenuation was derived. The star formation burstiness is discussed in Section 4. We investigate its impact on the location of galaxies in the SFR-M$_\star$ plane and how the ratio of SFR indicators SFR$_{H\alpha}$/SFR$_{UV}$ evolves towards low-mass galaxies. The method for deriving the ionizing efficiency is described in Section 5. We also discuss the impact of dust attenuation on the final $\xi_{ion}$ results. Finally, we compare our estimate with a compilation of literature results and derive the redshift-evolution of $\xi_{ion}$. In Section 6, we explore the evolution of $\xi_{ion}$ with the Hα end [OIII] equivalent widths and the galaxies properties, such as the stellar mass and the UV magnitude. In Section 7, we discuss the implications of star formation burstiness and $\xi_{ion}$ estimates on the contribution of galaxies to cosmic reionization, before presenting our summary and conclusions in Section 8. Throughout the paper, magnitudes are in the AB system (Oke & Gunn 1983) and we adopt a cosmology with $H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1}$, $\Omega_M = 0.7$, and $\Omega_{\Lambda} = 0.3$.

2 OBSERVATIONS

The spectroscopic data used in this paper were obtained from the data release v4.1.5 of the 3D-HST survey (Brammer et al. 2012; Momcheva et al. 2016). The program uses about 250 orbits of the Hubble Space Telescope (HST) to observe a total of 124 pointings in four of the CANDELS fields (Grogin et al. 2011). The release also include similar observations in the fifth field (GOODS-N) obtained by the AGHAST program (GO-11600). Observations consist of slitless spectra obtained with the GI41 grism on the Wide Field Camera 3 (WFC3) and short direct imaging observations with the F140W filter. The near-infrared (NIR) spectra cover the wavelength range 1.1 to 1.65 μm at an instrumental resolution of R=130. For more details about the data reduction, we refer the reader to Momcheva et al. (2016). We also use matched photometric catalogs constructed on the CANDELS and 3D-HST observations, which are complemented with ancillary data between 0.3 and 8 μm (cf. Skelton et al. 2014, for details).

The matched emission line catalogs include multiple quality flags down to an AB magnitude of $JH = 24$. Beyond this magnitude
Bursty star formation in low-mass galaxies

3 THE GALAXY SAMPLE

The combination of the grism spectroscopy and the UV imaging provides us with the opportunity to explore the star formation activity on different timescales and measure the ionizing efficiency of star forming galaxies at $z \sim 1$ as a function of their physical parameters. We have selected our sample based on high-significance Hα emission lines (above SNR=3) and equivalent widths higher than 80 Å in the spectroscopic data, and SNR>3 continuum detection in the F336W filter of the UV data. The final sample contains a total of 1167 objects in the redshift range $0.7 < z < 1.5$.

The NIR grism spectroscopy is particularly sensitive to strong nebular emission lines. Most of the objects in this sample will have relatively high equivalent widths, and in some cases, their continuum will remain undetected. Therefore, equivalent width measurements will be highly uncertain. We have re-computed the equivalent width of all the emission lines using the line flux and the broadband magnitude in the $JH_{140}$ images, correcting for the contribution of line flux to the observed magnitudes:

$$EW_{cor} = \frac{F_{line}}{f_{\lambda,140} - \int f_{\lambda,140}md\lambda}$$

where $f_{line}$ is the line flux and $f_{\lambda,140}$ is the flux density in the F140W filter. While continuum-selected samples are limited by the depth of the imaging data, our emission-line selection favors high equivalent width galaxies showing enough contrast between the line and the continuum. The left panel of Figure 1 shows the impact of this selection on the completeness in Hα flux as a function of magnitude. While the faint-end limits of both continuum and line fluxes are represented by the shaded area, the line flux limit increases towards brighter magnitudes. Beyond a magnitude $JH \sim 24$, the sample is defined not only by the equivalent width, but also by the Hα flux limit. For these faint galaxies, we will only select bright Hα emitters relative to their continuum magnitude. This impact of this selection bias will be in Section 4. Comparing the stellar mass distribution for the Hα sample and the parent sample, we can see on the right panel of Figure 1 that the selected sample becomes incomplete towards low stellar masses, typically around $\log(M_*/M_\odot)=8$, and at high masses around $\log(M_*/M_\odot)=9.5$. This is due to our sample selection, which is based on SNR cuts on both Hα and UV emission, on one hand, and EW(Hα), on the other hand.

| Emission | Curve | E(B-V) | Correction Factor |
|----------|-------|--------|------------------|
| Hα       | Cardelli | 0.14   | 1.40             |
| Hα       | Calzetti | 0.12   | 1.50             |
| UV       | SMC     | 0.10   | 3.3              |
| UV       | Calzetti | 0.23   | 11.3             |

Table 1. The importance of dust correction for the Hα and UV emissions. We list the reddening estimates and the correction factors for the different extinction/attenuation laws considered in this work. The E(B-V) values represent the nebular and the stellar reddening for the Hα and UV fluxes, respectively.

3.1 Dust attenuation correction

To correct the parameter measurements for dust attenuation, we consider the Hα and UV continuum emission independently. First, we compute the nebular attenuation from the Balmer decrement Hα/Hβ for a subsample of 10 galaxies over a restricted redshift range of $1.3 < z < 1.5$, where both Hα and Hβ lines are visible in the G141 grism, and we examine the trends as a function of stellar mass and Hα luminosity. Figure 2 shows a good agreement with the results of Domínguez et al. (2013) who used a stack of 0.75 < z < 1.5 emission-line spectra to derive Balmer decrements as a function of stellar mass. It also follows the trend derived for local galaxies (Brinchmann et al. 2004; Garn & Best 2010) with no sign of evolution with redshift, which was also observed at z > 1 (e.g. Sobral et al. 2012; Domínguez et al. 2013). We apply the relation derived by Domínguez et al. (2013) to the entire galaxy sample to estimate the nebular attenuation.

As for the UV luminosity, we compute the UV slope over a rest-frame spectral range of 1300 – 3300 Å by performing a multi-band fitting to the relation $f_\lambda \propto \lambda^\beta$. Then we derive the attenuation by adopting an intrinsic UV slope of $\beta_0 = -2.62$ (Reddy et al. 2018a). The intrinsic UV slope is sensitive to the star formation history (SFH) of galaxies, which in turns affects the computed stellar attenuation. Galaxies with higher specific star formation rate have bluer UV colors due to a lower contribution of older stellar populations. The present sample has relatively high sSFRs and strong emission lines, with median values of sSFR=$10^{-9.4} \text{ yr}^{-1}$ and EW$_{rest}(H\alpha)$=160 Å (cf. Fig. 4). We show in Appendix C the effects of adopting the standard value of $\beta_0 = -2.23$ of Meurer et al. (1999).

Many efforts have been undertaken to investigate the attenuation law in high-redshift galaxies. There has been some evidence for a different calibration compared to local galaxies, possibly due to their younger age, lower metallicities or their different emission line properties in general (de Barros et al. 2014; Price et al. 2014; Reddy et al. 2015; Smit et al. 2016; Cowie et al. 2016). In Section 4 we adopt the Cardelli et al. (1989) curve for Hα emission and the SMC extinction curve (Gordon et al. 2003) for the UV continuum. When computing absolute values such as the ionizing efficiency (Section 5) we explore the effects of adopting two laws for the nebular attenuation, namely the Calzetti et al. (2000) and Cardelli et al. (1989) curves. Regarding the stellar continuum, we also compare the SMC extinction curve (Gordon et al. 2003) with the Calzetti et al. (2000) attenuation curve in computing E(B-V)$_g$, keeping the same intrinsic slope $\beta_0 = -2.62$. Table 1 shows the resulting correcting factors for Hα and UV luminosities when adopting different dust laws. We also show in Figure 3 the relation between E(B-V)$_g$ and E(B-V)$_{stars}$. An important dispersion is observed, with most of
the sample lying between the 1:1 ratio and the 0.44 factor of Calzetti et al. (2000).

4 STAR FORMATION BURSTINESS IN LOW-MASS GALAXIES

While star formation is expected to proceed smoothly in massive galaxies, it becomes highly stochastic in lower mass galaxies, with short-lived intense bursts of star formation. These bursts are marked by high Hα equivalent but also high \( \xi_{\text{ion}} \) as shown by hydrodynam-
Bursty star formation in low-mass galaxies

4.1 SFR-M∗ relation

Observations from the local universe to high-redshift galaxies show a tight correlation between the star formation rate and stellar mass (e.g. Brinchmann et al. 2004; Noeske et al. 2007; Whitaker et al. 2014). The underlying picture is that galaxies accrete gas and build up their stellar mass in a gradual and smooth process, with constant SFR averaged over hundreds of Myrs. However, during the last decade, observations of low-mass galaxies, primarily selected upon their strong emission lines, have painted a different picture of star formation processes. In particular, extreme emission line galaxies (EELGs) experience short episodes of intense star formation, leading to excursions from the SFR-M∗ main sequence (Weisz et al. 2012; Atek et al. 2014; Guo et al. 2016; Faust et al. 2019; Emami et al. 2019), although, the averaged SFR over cosmic time, would match a steady star formation scenario. Several hydrodynamical simulations also unveiled the stochastic processes at play in low-mass galaxies compared to their massive counterparts (Shen et al. 2014; Domínguez et al. 2015; Sparre et al. 2017), as a result of episodes of gas accretion that trigger star formation followed by stellar feedback and gas outflows, which hampers gas infall into the galaxy.

We first use the Hα emission to compute the SFR following the Kennicutt & Evans (2012) calibration, assuming a solar metallicity and a Chabrier (2003) IMF, and a Cardelli dust attenuation correction. The SED fitting procedure used to constrain the stellar mass also assumes a Chabrier IMF (Skelton et al. 2014). In Figure 5, we plot the correlation between the SFR and M∗ for our sample of galaxies together with the best-fit relations in the literature at similar redshifts, which combined the observed UV and reprocessed IR light to derive the total SFR. Whitaker et al. (2014) derived the total IR luminosity using a luminosity-independent conversion factor from the Spitzer/MIPS 24 µm based on a single SED template (Wuyts et al. 2011a). Schreiber et al. (2015) compute the total IR luminosity by fitting SED templates from Chary & Elbaz (2001) to the Herschel flux densities and measure L_IR in the best-fit template. A significant fraction of the sample lies above the main sequence relations. We can see that the departure from the main sequence is associated with an increase in $EW_{Hα}$. In fact, only galaxies with $EW_{Hα}$ around a hundred Å follow the main sequence. As explained earlier, this is the result of the elevated instantaneous SFR, probed by Hα, following a recent burst of star formation. The observed flattening of the slope towards low-mass galaxies is likely the result of Hα flux incompleteness, as we reach SFRs below $1 M_\odot$ yr$^{-1}$. However, it is clear that the deviation from the main sequence is much larger at low mass, as the highest $EW_{Hα}$ values are observed at lower masses.

Regardless of the SFR limit, the scatter seems to increase...
The blue points follow the expected MS trend, but below this area represents the SFR\(\alpha\) excluded by the \(H\alpha\) and scatter of Whitaker et al. (2014). The light-blue points are the galaxies with a factor of 3 higher than the one observed at higher masses. This discrepant fraction of galaxies (red points) below Log(M\(\star\)/M\(_\odot\)) is indicated by the gray shaded region. In our observations, we are still detecting a significant fraction of galaxies (red points) below Log(M\(\star\)/M\(_\odot\))~ 9, most probably because of an increased scatter towards lower masses. A good agreement between the simulations and observations in the mass range below Log(M\(\star\)/M\(_\odot\))~ 9 is achieved by using a scatter factor of 3 higher than the one observed at higher masses. This stands in contrast with other studies based on UV-selected samples or SED-based SFR indicators, which found no evidence of increasing scatter towards lower masses (Kurczynski et al. 2016), nor evidence for an enhanced \(H\alpha\) luminosity compared to UV (Guo et al. 2016). Boogaard et al. (2018) also explored the low-mass end of the main sequence at 0.1 < z < 0.9 by using Balmer lines to measure the SFR, finding an intrinsic scatter similar to Kurczynski et al. (2016) and a shallower slope compared to massive galaxy samples.

In Figure 6, we show how our sample fits in the main sequence diagram when the SFR is derived from the UV. When compared to Figure 5, the galaxies follow more closely the MS, although these relations are extrapolated here (dashed lines) at lower masses (mainly below 10\(^9\) M\(_\odot\)). This follows the scenario where, recent star formation traced by \(H\alpha\), likely causes the excursion of galaxies out of the MS. In the same figure, we also compare the dust-corrected SFR\(\text{UV}\) with the total SFR (represented by gray points), which was estimated by adding up the uncorrected SFR\(\text{UV}\) and the SFR\(\text{IR}\) derived from the IR luminosity at 8 ~ 1000 \(\mu\)m measured from Spitzer/MIPS 24 \(\mu\)m photometry (Skelton et al. 2014). Although about 20% of the sample is missing because they are not detected in the Spitzer data, we can see the dust corrected SFR is globally in fair agreement with the total SFR.

4.2 \(H\alpha\) and UV SFR indicators

The ratio between SFR\(H\alpha\) and SFR\(\text{UV}\) is often used as an indicator of the star formation burstiness in galaxies (e.g., Meurer et al. 2009; Weisz et al. 2012; Guo et al. 2016; Broussard et al. 2019). At the onset of a burst, the \(H\alpha\) flux increases over a very short timescale of \(~10\) Myr, whereas UV bright and less massive stars will run on a longer period \(~100\) Myr) (e.g. Leitherer et al. 1999; Hao et al. 2011; Kennicutt & Evans 2012; Calzetti 2013). Therefore, important variations in SFR\(H\alpha\)/SFR\(\text{UV}\) ratio are expected when the star formation is non-steady and out of equilibrium. For instance, Weisz et al. (2012) produced a set of SFH history models to match the observations of a sample of local galaxies. They find that low-mass galaxies experience a bursty star formation, with burst episodes lasting less than 10 Myr and a period of 250 Myr between bursts. Those models appear to reproduce the observed variations of the \(f(H\alpha)/f(\text{UV})\) ratio, which are mostly below unity. Emami et al. (2019) improved this analysis with a larger parameter space with exponentially rising and declining SFH and find similar results, albeit with a larger burst duration. In their analysis, they find the star formation burstiness by comparing the \(L(H\alpha)/L(\text{UV})\) with \(\Delta L(H\alpha)\), which are correlated, in particular at lower stellar masses. The bursty nature of star formation in low-mass galaxies has been confirmed by hydrodynamical simulations. In the FIRE simulations, Sparre et al. (2017) show that the SFR probed on a short timescale by \(H\alpha\) can vary by an order of magnitude compared to the UV indicator. They also find a significant fraction of galaxies with SFR\(H\alpha\)/SFR\(\text{UV}\) ratios well below unity.

In general, the explanation for the decline of the SFR\(H\alpha\)/SFR\(\text{UV}\) ratio observed in those studies is based on the different timescales of these emissions. At the onset of the burst, the \(H\alpha\) emission is brighter than the FUV. The stars responsible for the FUV emission have a longer lifetime. This means that the FUV emission will gradually take over, and the SFR\(H\alpha\)/SFR\(\text{UV}\) will decline steadily below unity over the course of the burst in the first ~ 50 Myr. After the end of the burst, the \(H\alpha\) emission from massive stars becomes negligible, as the stars responsible for this emission die after ~ 10 Myr. Over the next 100 ~ 200 Myr, the FUV emission in turn starts to fade, as the less massive stars start to disappear, leading to a steady increase in the SFR\(H\alpha\)/SFR\(\text{UV}\) ratio. Around 300 Myr, the SFR\(H\alpha\)/SFR\(\text{UV}\) returns to its equilibrium value of unity, which marks the end of the burst cycle (Weisz et al. 2012; Dominguez et al. 2015; Emami et al. 2019). According to this scenario, the observed SFR\(H\alpha\)/SFR\(\text{UV}\) ratio is below unity during most of the burst cycle.

In Figure 8, we plot the SFR\(H\alpha\)/SFR\(\text{UV}\) ratio as a function of stellar mass for our sample, assuming a SMC dust correction for the UV continuum. At high masses (> 10\(^9\) M\(_\odot\)), the ratio of SFR indicators is mainly close or below unity. For galaxies with M\(_\star\) < 10\(^9\) M\(_\odot\), the ratio is around unity or higher. From the same figure, we can see a similar trend with EW\(H\alpha\), as galaxies with EW\(H\alpha\) of a few hundreds to a thousand Å are the ones with higher SFR ratios. The main result is that we observe an SFR\(H\alpha\)/SFR\(\text{UV}\) ratio above unity mainly in low-mass galaxies (M\(_\star\) ~ 10\(^8\) M\(_\odot\)) rather than in more massive galaxies (M\(_\star\) > 10\(^9\) M\(_\odot\)). This result

\(^\dagger\) \(\Delta L(H\alpha)\) is the deviation of the \(H\alpha\) luminosity from the best fit to the main sequence of \(L(H\alpha)\) vs M\(_\star\).
is different from what is observed in the studies mentioned earlier and the associated scenario, where SFR$_{H\alpha}$/SFR$_{UV}$ is observed to be mainly below unity. Of course, because of our H$\alpha$ flux selection (see Section 3 and Figure 7), we might be missing SFR$_{H\alpha}$/SFR$_{UV}$ lower than unity at M$^\star < 10^8$M$_\odot$. However, the observation of elevated SFR$_{H\alpha}$/SFR$_{UV}$ in low-mass galaxies still stands, and is not observed in more massive galaxies.

For comparison, the other notable studies along these findings are Shim et al. (2011) and Faist et al. (2019) who analyze a sample of z ~ 4 galaxies for which they measure H$\alpha$ through the IRAC 3.6μm excess. Shim et al. (2011) find an SFR ratio of SFR$_{H\alpha}$/SFR$_{UV}$ = 6.1 ± 4.1, even higher than our result. Not surprisingly, their sample also has a very high H$\alpha$ equivalent width distribution (E$W_{H\alpha}$ ~ 140-1700 Å), due to the IRAC selection, which is sensitive to H$\alpha$ emitters with E$W_{H\alpha}$ higher than 70-350 Å. This effect is clearly visible in Fig. 8, where high-E$W_{H\alpha}$ galaxies have the highest SFR$_{H\alpha}$/SFR$_{UV}$. Similarly, Faist et al. (2019) find that more than 50% of their sample has SFR$_{H\alpha}$ in excess compared to SFR$_{UV}$, particularly in low-mass galaxies. They also find an anti-correlation between E$W_{H\alpha}$ and stellar mass. The trend and SFR ratios observed at low masses differ from the results of some previous studies summarized above (Weisz et al. 2012; Sparre et al. 2017). This was already observed in Figure 5 where the scatter of the main sequence (i.e. ΔL(Hα)) is larger at lower masses. We note that Emami et al. (2019) also find a larger scatter in the (L(Hα) vs M$^\star$) relation towards lower mass galaxies.

Given the timescales traced by H$\alpha$ and UV, the distribution of SFR$_{H\alpha}$/SFR$_{UV}$ and its dispersion provides an indication on the SFH parameters. As discussed earlier, since SFR$_{UV}$ runs on hundreds Myr, while SFR$_{H\alpha}$ on 10 Myr, the distribution of observed galaxies should be centered on the low side of SFR$_{H\alpha}$/SFR$_{UV}$. However, a variation in the following two parameters will increase the prevalence of galaxies with higher SFR ratios like the ones observed here: (i) a larger τ in the exponential SF; or (ii) a higher duty cycle, i.e. a shorter period between successive SF bursts.

In this context, the results of Guo et al. (2016) are also shown in Fig. 5. They selected a sample of 165 galaxies at $0.4 < z < 1$ with SNR(H$\beta$) > 3 and SNR(F275W) > 5. They derived SFR$_{H\alpha}$ using the H$\beta$ flux, the case B recombination ratio of 2.86, and the calibration of Kennicutt & Evans (2012). They derived SFR$_{UV}$ using the UV luminosity at 1500 Å and the same calibration of Kennicutt & Evans (2012). Both determinations assume a Chabrier IMF and solar metallicity. We used the same calibration and parameters to derive the SFRs of the present sample. Guo et al. (2016) also showed that dust correction is negligible for these SFR determinations and apply a correction only for galaxies with SFR$_{UV}$/SFR$_{1500\AA} > 20$. They do not find the mass-dependent trend observed in our sample, but rather an increase in the SFR ratio with increasing mass. Again, it is possible that these differences are partially due to selection effects, since their sample has a median E$W_{H\beta}$ = 15 Å, a factor of two lower than our sample. We argue that if this were only due to selection effects, these high-E$W$ lines should also be present in higher-mass systems. Our sample most likely probes a low-mass galaxy population caught during a burst of star formation, rather than its decline as seen in those studies. Theoretical models of bursty star formation also predict an increase of this mode in low-mass galaxies (e.g. Faucher-Giguère 2018) due to shorter dynamical timescales and probably higher gas fractions.

Another possible source for the variations in the SFR$_{H\alpha}$/SFR$_{UV}$ ratio in low-mass galaxies is a stochastic sampling of the IMF. In the case of low-mass galaxies with a low SFR, massive stars could form less frequently than assumed, leading to deviations of SFR$_{H\alpha}$/SFR$_{UV}$ from equilibrium even in the case of a steady star formation. Numerous studies have explored the effects on IMF sampling (Pflamm-Altenburg et al. 2009; Fumagalli et al. 2011; Weisz et al. 2012; Guo et al. 2016; Emami et al. 2019). Overall, the resulting variations in SFR indicators were insufficient to reproduce the observed decline of SFR$_{H\alpha}$/SFR$_{UV}$. The discrepancy is even larger for our results, where we observe a clear increase towards lower masses, which makes the IMF sampling an unlikely scenario.

Finally, several uncertainties remain regarding the determination of the SFR$_{H\alpha}$/SFR$_{UV}$ ratio and its evolution as a function of galaxy parameters. Both SFR indicators use conversion factors from H$\alpha$ and UV luminosities assuming a constant star formation. Of course, we expect important deviations from these assumptions for different SFHs, particularly in the case of bursty star formation. If both SFR calibrations were correct, we would expect the SFR$_{H\alpha}$ and SFR$_{UV}$ to be equal. This is precisely why such a ratio can reveal deviations from steady star formation scenarios and trace bursty SFH. In addition to SFH, the inclusion of binary stars in stellar population models and a higher mass end (300 M$_\odot$) for the IMF (Wilkins et al. 2019) can increase SFR$_{UV}$ by 0.15-0.2 dex, and SFR$_{H\alpha}$ by 0.35 dex. Castellano et al. (2014) also showed that SFR$_{UV}$ tend to underestimate the true SFR of z ~ 3 Lyman break galaxies with sub-solar metallicity by a factor of a few. It is unclear whether this underestimate would also apply to lower-mass galaxies at lower redshifts. Furthermore, if the attenuation curve for the stellar continuum is different in lower-mass galaxies (e.g., Salim & Narayanan 2020), it will also affect the SFR ratio. One scenario that would contribute to the increase of SFR$_{H\alpha}$/SFR$_{UV}$ ratio towards lower mass galaxies is the one where the dust attenuation law becomes steeper towards low-mass galaxies.

Figure 8. The ratio of H$\alpha$ and UV SFR indicators as a function of stellar mass. SFR$_{H\alpha}$ is corrected for dust attenuation using the Cardelli law and SFR$_{UV}$ with the SMC curve. Data points are also color-coded with E$W_{H\alpha}$. The horizontal line indicates a one-to-one ratio. The results of Guo et al. (2016) and the associated scenario, where SFR$_{H\alpha}$ is different from what is observed in the studies mentioned earlier are shown with green squares. Note that these points represent the ratio SFR$_{H\alpha}$/SFR$_{UV}$. The prevalence of galaxies with higher SFR ratios like the ones observed at low masses differ from the results of some previous studies summarized above (Weisz et al. 2012; Sparre et al. 2017). This was already observed in Figure 5 where the scatter of the main sequence (i.e. ΔL(Hα)) is larger at lower masses. We note that Emami et al. (2019) also find a larger scatter in the L(Hα) vs M$^\star$ relation towards lower mass galaxies.

| Log(M/M$_\odot$) | Log(SFR$_{H\alpha}$/SFR$_{UV}$) | 0.7 < z < 1.6 This work | 0.4 < z < 1.0 Guo et al. 2016 |

5 IONIZING EFFICIENCY

We compute the ionizing efficiency \( \xi_{\text{ion}} \), which is defined as the ratio between the ionizing (Lyman continuum) photon production \( N_{\text{ion}} \) and the observed non-ionizing UV luminosity density \( L_{\text{UV}} \) estimated at 1500 \( \AA \):

\[
\xi_{\text{ion}} = \frac{N_{\text{ion}}}{L_{\text{UV}}} \text{ [erg}^{-1} \text{Hz]} \tag{2}
\]

In the framework of the case B recombination theory (Osterbrock 1989), \( N_{\text{ion}} \) can be estimated from Hydrogen recombination lines (Leitherer & Heckman 1995):

\[
L(H\alpha) \text{ [erg s}^{-1}] = 1.36 \times (1 - f_{\text{esc}}) \times 10^{-12} N_{\text{ion}} \text{ [s}^{-1}] \tag{3}
\]

where \( L(H\alpha) \) is the H\( \alpha \) luminosity and \( f_{\text{esc}} \) is the escape fraction of Lyman continuum radiation from galaxies. Most results in the literature indicate a wide range of \( f_{\text{esc}} \) values, both in low- and intermediate-redshift galaxies. Recent spectroscopic measurements in \( z \approx 0.3 \) compact star-forming galaxies reported by Izotov et al. (2016, 2018) indicate an escape fraction between 2 and 70%. Imaging campaigns at higher redshifts reported a few robust detections with escape fraction exceeding \( f_{\text{esc}} \approx 50\% \) (e.g., Shapley et al. 2016; Vanzella et al. 2016; Bian et al. 2017; Vanzella et al. 2018; Rivera-Thorsen et al. 2019). On the other hand, Rutkowski et al. (2017) estimate an upper limit of \( f_{\text{esc}} < 15\% \) in emission-line galaxies at \( z \approx 2.5 \), using partly the 3DHST G141-grism data in GOODS-N and UVDVF fields. For the sake of consistency with literature results, here we assume a zero escape fraction of LyC radiation. Accounting for \( f_{\text{esc}} \) will result in a higher \( \xi_{\text{ion}} \).

According to equations 2 and 3, \( \xi_{\text{ion}} \) is equivalent to the ratio \( SFR_{H\alpha}/SFR_{UV} \), modulo a factor of \( 1.3 \times 10^{26} (1 - f_{\text{esc}}) \). Therefore, in the case where we assume a zero escape fraction, this burstiness indicator is a direct probe of the ionizing efficiency and its evolution with galaxy parameters. The ionizing efficiency will be subject to the same uncertainties discussed earlier for the SFR ratio.

In Figure 9, we demonstrate how our sample selection translates into \( \xi_{\text{ion}} \) completeness. We plot the H\( \alpha \) luminosity as a function of UV luminosity for our \( \xi_{\text{ion}} \) sample, together with their respective limits (gray shaded regions) derived from the depth of the observations. Combining the \( EW_{H\alpha} \) cut and H\( \alpha \) flux limit, and using the observed correlation between the UV and IR magnitudes, we computed the \( \xi_{\text{ion}} \) limit (red-shaded area), assuming a redshift range of \( 0.7 < z < 1.5 \) in the simulations (cf. Appendix A). Overall, these simulations will be helpful in assessing the limits of the correlations we explore in Section 6.

5.1 Ionizing efficiency results

The results of the dust-corrected estimates of \( \xi_{\text{ion}} \) are shown in Figure 10. Adopting standard attenuation corrections using the Cardelli et al. (1989) law for H\( \alpha \) emission and the SMC curve for UV continuum, we obtain a median ionizing efficiency of \( Log(\xi_{\text{ion}}/\text{erg}^{-1} \text{Hz}) = 24.80 \pm 0.26 \). Adopting the Calzetti law for the nebular attenuation has little effect on the ionizing efficiency, except when deriving the nebular attenuation by applying a factor of 1/0.44 to the stellar attenuation (Calzetti et al. 2000). The \( \xi_{\text{ion}} \) estimates are more sensitive to the attenuation curve in the UV domain. The derived \( \xi_{\text{ion}} \) are lower by 0.45 dex if we assume the Calzetti attenuation curve rather than the SMC curve for dust-correcting the UV luminosity density. The scatter in the \( \xi_{\text{ion}} \) distribution increases by 0.11 dex in this case.

Figure 9. The H\( \alpha \) luminosity as a function of rest-frame UV luminosity for the \( \xi_{\text{ion}} \) sample. The red-shaded region represents the \( \xi_{\text{ion}} \) limit imposed by our equivalent width cut (cf. Figure 1). The associated range of values account for the redshift range \( 0.7 < z < 1.5 \) and the relationship between the IR and UV magnitudes (cf. text for details). Shaded regions along both axes indicate the detection limits in L(H\( \alpha \)) and L(UV), calculated at the mean redshift of the sample.

Table 1 summarizes the relative importance of dust correction to the H\( \alpha \) and UV emissions. We can see that the correction factor applied to the UV emission is much larger than the one for H\( \alpha \). Also, the choice of an attenuation law is more critical for the UV emission. In figure 11, we show the \( \xi_{\text{ion}} \) distribution in four mass bins to highlight the dependence on stellar mass discussed later in Section 6.

These values are in general significantly lower than what has been found in previous studies and the canonical value of \( Log(\xi_{\text{ion}}) = 25.2 \) widely used in computing the ionizing budget of galaxies (e.g., Robertson et al. 2013). As a comparison, Emami et al. (2020) report an average \( Log(\xi_{\text{ion}}) = 25.47 \pm 0.09 \) in a sample of lensed galaxies at \( z \approx 2 \), which is almost an order of magnitude higher. At a similar redshift, Shivaei et al. (2018) find \( Log(\xi_{\text{ion}}) = 25.34 \). Both values are derived with an SMC extinction correction of the UV luminosity.

We list below a literature compilation of \( \xi_{\text{ion}} \) determinations at different redshifts.

- The results of Emami et al. (2020) are based on spectroscopic observations of \( 28 z \approx 2 \) lensed galaxies, with a similar stellar mass range probed by our sample \( (8 \leq Log(M_*/M_\odot) \leq 10) \). The study follows the same approach used here for \( \xi_{\text{ion}} \) estimates and dust correction. However, their results are based on stacked spectra, in bins of physical properties (stellar mass, UV magnitude, UV continuum slope).
- Shivaei et al. (2018) used spectroscopic and UV imaging data from the MOSDEF survey to measure \( \xi_{\text{ion}} \) in a large sample of 673 galaxies at \( 1.4 < z < 2.6 \). They use the Balmer decrement H\( \alpha \)/H\( \beta \) to measure nebular attenuation, whereas it is available for only a sub-sample of our galaxies (cf. Section 3.1). Stellar attenuation is derived from SED fitting. Importantly, that work probes stellar masses above \( Log(M_*/M_\odot) > 9 \), which is significantly higher than the present sample.
- Using spectroscopic observations to measure H\( \beta \) emission and SED fitting to infer the UV continuum emission, Nakajima et al. (2016) measured \( \xi_{\text{ion}} \) in sample of 15 Ly\( \alpha \) Emitters and Lyman...
In addition, several studies have used the broad-band excess between the 3.6μm and 4.5μm Spitzer/IRAC channels to derive the Hα flux of z > 4 galaxies. Based on this method, Bouwens et al. (2016) derived \( \xi_{\text{ion}} \) for galaxies at \( z \sim 4.4 \) and \( z \sim 5.25 \). These values were corrected for dust using a stellar attenuation derived from SED fitting. The results of two attenuation laws (Calzetti and SMC) are shown in the Figure. Their stellar mass range is also comparable to this work, with an average value around Log\( (M_*/M_\odot) \sim 9 \).

- Similarly, Lam et al. (2019) used stacked IRAC colors to measure Hα emission and infer \( \xi_{\text{ion}} \) in sample of 300 galaxies at 3.8 < \( z < 5.3 \) with spectroscopic redshifts. The dust correction is based on UV continuum slope measurements and the SMC curve. We here report the average \( \xi_{\text{ion}} \) value computed in sub-sample over a stellar mass range of \( 8 \leq \log(M_*/M_\odot) \leq 10 \).
- At higher redshifts, Stark et al. (2015) obtained rest-frame UV spectroscopy of \( z \sim 7 \) lensed galaxies and used stellar population and photo-ionization models to infer the ionizing efficiency of one of them. As the authors note, the intense radiation field of this galaxy is not necessarily representative of the galaxy population at \( z > 6 \) because of the strong equivalent width selection and the bright Lyα emission.

Within this list of studies, only Emami et al. (2020) has both spectroscopic measurements of the Hα flux and UV imaging to accurately infer \( \xi_{\text{ion}} \) for galaxies in the same range of stellar mass as probed in this study. The main differences are the lower redshift range and the much larger sample size used in the present study. In figure 12, we keep only the studies that probe a similar stellar mass range and use the same dust prescriptions as our study. We observe a clear evolution of \( \xi_{\text{ion}} \) as a function of lookback time \( t_L \), ranging from Log\( (\xi_{\text{ion}}) = 24.70 \) at \( t_L \sim 8.3 \) Gyr to Log\( (\xi_{\text{ion}}) = 25.54 \) at \( t_L \sim 12.7 \) Gyr. We perform a linear fit to all the data points by computing the maximum likelihood using Markov Chain Monte Carlo (MCMC) simulations using emcee (Foreman-Mackey et al., 2013). In Figure 12, we plot the best-fit relation and 95% confidence interval of the fit. We find a best-fit relation of Log\( (\xi_{\text{ion}}) = 0.21 t_L + 22.82 \). Such evolution is expected since galaxy physical properties are known to evolve with redshift. For instance, the emission-line selection naturally favors high equivalent widths for the Hα line and the average Hα equivalent width of emission-line galaxies is known to increase with redshift (e.g., Atek et al. 2011; Smit et al. 2014; Faist et al. 2016; Reddy et al. 2018). These effects can explain the higher \( \xi_{\text{ion}} \) values observed at higher redshifts (see also Section 6).

### 6 Evolution of \( \xi_{\text{ion}} \) with Galaxy Properties

We now explore the evolution of \( \xi_{\text{ion}} \) as a function of the galaxy physical properties.

#### 6.1 The Relation between \( \xi_{\text{ion}} \) and \( EW_{H\alpha} \)

As previously noted, \( \xi_{\text{ion}} \) is directly related to the Balmer recombination lines, but also the UV luminosity of galaxies. It is a measure of the contribution of young massive stars as traced by Hα relative to a slightly older stellar population as traced by the non-ionizing stellar continuum. A good proxy for this ratio is the Hα equivalent width, which is a good indicator of the age of the stellar population. In Figure 13, we show the clear correlation found between \( \xi_{\text{ion}} \) and \( EW_{H\alpha} \). The best fit relation is given by:

\[
\log(\xi_{\text{ion}}) = 0.6^{+0.1}_{-0.1} \times \log(EW_{H\alpha}) + 23.47^{+0.26}_{-0.25}
\]

(4)
Log\[\xi_{ion}\] \(\sim\) (Calzetti) curves are used to correct for dust. The dotted horizontal line indicates the canonical value of \(\log(\xi_{ion}) = 25.20\). The gray line and the shaded area show our best-fit results and associated 95% confidence interval. The fit is performed on all the data points shown here.

The fitting procedure is similar to the one used in Figure 12. On average, the \(H\alpha\) equivalent width is well correlated with \(\xi_{ion}\) because it is directly related to the star formation activity and the age of the stellar population. However, part of this tight correlation can also be explained by the fact that the \(H\alpha\) luminosity is also used is computing \(\xi_{ion}\) (cf. Equation 3.2).

Similarly, this strong relationship between \(\xi_{ion}\) and \(EW_{H\alpha}\) has been found at other redshifts. Combining a spectroscopic follow-up of strong line emitters and SED fitting, Tang et al. (2019) finds a similar relation at \(z \sim 2\), albeit with a steeper slope of 0.87. We can also appreciate the effect of adopting different prescriptions for the dust correction. This is even more apparent in the case of Matthee et al. (2017) results, where a significant offset is observed between dust corrections based on the \(\beta\) slope or the dust-\(M_*\) relation of Garn & Best (2010). Emami et al. (2020) find a shallower slope of 0.53 although with a higher dispersion. Finally, (Reddy et al. 2018b) also explored the relation between \(\xi_{ion}\) and Balmer lines in the MOSDEF survey, over a lightly higher stellar mass range of \((M_* > 10^9 M_\odot)\). They find a strong correlation between \(\xi_{ion}\) and \(EW_{H\alpha}\).

Most of the \(\xi_{ion}\) determinations in the literature are based on samples that preferably select strong emission line galaxies (but see Reddy et al. 2018b). The extrapolation of these trends to low equivalent widths (below 200\AA\) was first questioned by Tang et al. (2019). We don’t find any significant flattening of the relation towards lower EWs, even though the sample becomes less complete below \(EW = 80 \ \text{\AA}\). This result also confirms the findings of Emami et al. (2020) and Matthee et al. (2017).

### 6.2 Ionizing efficiency vs stellar mass and UV magnitude

As we have seen, \(\xi_{ion}\) appears to correlate well with the \(H\alpha\) equivalent width. At the same time, \(EW_{H\alpha}\) is anti-correlated with the stellar mass (cf. Figure 14). Similar results have been observed in galaxy samples at different redshifts (e.g. Reddy et al. 2018b; Faisst et al. 2019). It is therefore expected that \(\xi_{ion}\) will correlate with the stellar mass. However, several studies have found that \(\xi_{ion}\) is generally independent of the stellar mass. In particular, over the same mass range as our sample, Emami et al. (2020) find no evolution.
Figure 15. $\xi_{\text{ion}}$ as a function of the stellar mass. Our $\xi_{\text{ion}}$ measurements are represented with filled blue stars. These $\xi_{\text{ion}}$ estimates are derived by correcting H\beta line flux for nebular attenuation using the Cardelli curve and UV continuum luminosity for stellar extinction using SMC curve. Green filled (open) circles show the results of Emami et al. (2020) using the effective (standard) stacking method. The red filled (open) triangles show $\xi_{\text{ion}}$ estimates by Shivaei et al. (2018) corrected for dust using Calzetti (SMC) curves. The results of Matthee et al. (2017) are shown with open, light-filled, and filled squares with dust corrections based on the $\beta$ slope, the mass-to-dust relation, and E(B-V) from SED fitting, respectively. More details on these literature results are given in Section 5.1 of $\xi_{\text{ion}}$ between their two stacks binned in mass. At higher masses, Shivaei et al. (2018) find a small increase of 0.23 dex towards lower masses in the case of a Calzetti et al. (2000) attenuation curve for Shivaei et al. (2018) find a small increase of 0.23 dex towards lower masses. Because of the redshift-evolution we have seen before, the general trend is slightly offset from the $z \sim 2$ results. The observed trend is unlikely the result of mass completeness (cf. Section 3). However, while the sample is generally limited by the equivalent width selection of EWs $= 80$ Å, it starts to be purely H\alpha-flux limited below $10^8 M_{\odot}$ (cf. Fig. 1). Such incompleteness could favor high $\xi_{\text{ion}}$ values in lower-mass galaxies. Yet, we do not find high $\xi_{\text{ion}}$ values in galaxies with stellar masses higher than $10^8 M_{\odot}$, which is not affected by incompleteness. Deeper spectroscopic surveys of low-mass galaxies are required in order to confirm this trend.

The largest uncertainty remains the dust correction, as small variation in the dust content or the attenuation law has a large impact on the derived $\xi_{\text{ion}}$, mainly because of the correction in the UV. We also over-plot the results of Matthee et al. (2017) with different dust correction methods, all of which show a trend of increase of $\xi_{\text{ion}}$ towards lower masses, and highlight the dust-correction uncertainties. Note that, the $\beta$-based dust correction of Matthee et al. (2017) assumes $\beta_0 = -2.21$ (Meurer et al. 1999), which contributes to the observed offset relative to our results.

We also investigate the relation between $\xi_{\text{ion}}$ and the absolute UV magnitude, for which most studies do not report a clear correlation. As shown in Figure 16, Shivaei et al. (2018) and Emami et al. (2020) report no evolution with $M_{\text{UV}}$, while Matthee et al. (2017) show an increase towards fainter magnitudes. Similarly to our previous result regarding the stellar mass, faint galaxies show significantly higher ionizing efficiency. At even fainter magnitudes than our sample, a stacking analysis of a sample of LAEs at $z = 4-5$ by Maseda et al. (2020) shows $\xi_{\text{ion}}$ falling along this trend.

7 IMPLICATIONS FOR REIONIZATION

Early star-forming galaxies are currently the best candidates for driving cosmic reionization (Robertson et al. 2015; Bouwens et al. 2015; Atek et al. 2015). Given the most recent observational constraints on the shape of the UV luminosity function at $z > 6$, low-mass galaxies could provide the bulk of the ionization budget (Livermore et al. 2017; Atek et al. 2018; Ishigaki et al. 2018; Finkelstein et al. 2019). However, precise knowledge of the ionizing properties of early galaxies and the escape fraction of ionizing radiation is still required to infer their exact contribution to reionization. Since such investigations are still challenging at $z > 6$, many studies rely on lower-redshift galaxies, with the underlying assumption that they have the same properties as early galaxies. Therefore, it is important to focus on low-mass galaxies that are more representative of the galaxy population at the epoch of reionization.

It is clear that many physical properties and the SFH of low-mass galaxies are different from what is seen in their massive counterpart. The prevalence of intense emission lines, for instance, is much higher in low-mass galaxies, and increases with redshift. Star formation proceeds in successive bursts in low-mass galaxies, rather than a steady and constant star formation rate. Figure 8 shows how...
the relative increase in the recent SFR, as traced by Hβ relative to the averaged past SFR, as traced by the UV, indicate a recent burst of star formation in low-mass galaxies. While these observations cannot reveal successive SF bursts, many hydrodynamical simulations show that bursty star formation indeed happens mostly in low-mass galaxies, and can reproduce the observed variations of Hβ/UV luminosity ratios. (Shen et al. 2014; Domínguez et al. 2015; Sparre et al. 2017; Emami et al. 2019).

Confronting numerical simulations to the present observations is out of the scope of this paper and will be investigated in future work. Overall, understanding the burstiness parameters in these galaxies is crucial for several reasons:

- While the canonical value of Log(ξion) = 25.2, based on a constant star formation, might be adequate for massive galaxies, such assumptions do not hold in low-mass galaxies. Hydrodynamical simulations have shown that bursty star formation history leads to large variations in ξion compared to constant SFH (e.g. Domínguez et al. 2015), which means the observed LyC photon production is not necessarily representative of the average value in these galaxies. For instance, these galaxies may remain undetected in LyC following a burst of star formation, although their average LyC production is high, and even if they have a high escape fraction. This is because it takes about 5 Myr for LyC emission to decrease by an order of magnitude after the burst, whereas the escape fraction will be significant only after 10 Myr, which corresponds to the supernovae timescale. However, accounting for binary stars in stellar population models (e.g. Stanway & Eldridge 2018) lead to a significant increase in the number of ionizing photons produced over a larger range of masses, which result in a significant ionizing emission beyond 10 Myr (e.g. Chisholm et al. 2019).

- Bursty star formation also means that star formation feedback, which is responsible for disrupting the neutral ISM and clearing sight lines, will have significant impact on the LyC escape fraction. Hydrodynamical simulations also find large time variations of the escape fraction in low-mass galaxies, driven by supernovae explosions of massive stars (Kimm & Cen 2014; Trebitsch et al. 2017).

We note that in estimating ξion, we assumed fesc = 0. This is only a convention to ensure a fair comparison with literature results and the redshift-evolution of ξion. The most recent observing campaigns show a wide range of values for fesc at different redshifts (Izotov et al. 2016, 2018; Shapley et al. 2016; Vanzella et al. 2018; Flury et al. 2022). While empirically constraining the evolution of fesc remains challenging, hydrodynamical simulations find correlations with galaxy properties. For example, fesc increases with increasing star formation efficiency (or sSFR) and decreasing metallicity (e.g. Kimm et al. 2019).

These two quantities are pivotal in estimating the total ionizing power of galaxies. In addition to their dependency with galaxy physical parameters, these quantities might also be intertwined, as a higher ionizing photon production is likely followed by an increase in the escape fraction. Both their average values seem to increase with redshift, indicating a higher ionizing power in early galaxies than their low-z analogs.

8 CONCLUSIONS

In this work, we used a combination of HST grism spectroscopy from the 3DHST survey and UV imaging from the HUDUV survey for a large sample of 1167 galaxies across a redshift range of 0.7 < z < 1.5. This represents a unique sample with its combination of direct measurements of Hα down to an emission line flux limit of 1.5 × 10^{-17} erg s^{-1} cm^{-2} and deep UV imaging down to M ∼ 28 mag. This combination enables us to probe star formation and UV output down to low stellar masses between ∼ 10^6 and 10^{10} M_☉. We have explored the star formation histories of these low-mass galaxies and estimated their ionizing efficiency ξion. In an attempt to extrapolate these findings to higher-redshift galaxies, we also explored how these parameters evolve with the physical properties of galaxies and with redshift.

We used the Hα emission to infer the ionizing photon production rate, which in turn was combined with the UV luminosity at 1500 Å to compute the ionizing efficiency ξion. For removing the attenuation due to dust, we used the Cardelli curve to correct the Hα flux and the SMC curve to correct the UV luminosity. With this combination, we obtained a median ionizing efficiency of Log(ξion/erg⁻¹ Hz⁻¹) = 24.80 ±0.26. While adopting different curves, the nebular attenuation has little impact on ξion, the UV attenuation is a source of significant uncertainty. For example, adopting Calzetti et al. (2000) law for the UV attenuation reduces the above median ξion by 0.54 dex. Overall, our determination is significantly lower than literature results at higher redshifts. We find a clear evolution with lookback time, ranging from Log(ξion) = 24.70 at t_e ∼ 8.3 Gyr to Log(ξion) = 25.54 at t_e ∼ 12.7 Gyr. This evolution can be explained by higher star formation efficiency and higher emission line EWs on average at higher redshifts.

Investigating the relation between ξion and galaxy properties:

- We observe a strong correlation with the Hα equivalent width, consistent with the previous findings at different redshifts (Tang et al. 2019; Matthee et al. 2017; Reddy et al. 2018b; Emami et al. 2019).

- We found that ξion is anti-correlated with stellar mass. This result should not be surprising since we also observe a strong anti-correlation between EW_{Hα} and stellar mass. However, incompleteness at the low-mass end likely affects the slope of the correlation. Previous studies found that ξion is mostly independent of the stellar mass (Shivaei et al. 2018; Emami et al. 2019).

- Similarly, there is an evolution with absolute UV magnitude where fainter galaxies show higher ξion values. Studies by Matthee et al. (2017) and Maseda et al. (2020) show results consistent with this trend.

When considering the SFR-M_* relation, we find that a significant fraction of our sample lies above the main sequence, established at a similar redshift (Whitaker et al. 2014; Schreiber et al. 2015). Only galaxies around EW_{Hα} ∼ 100 Å follow the MS, while higher EW_{Hα} galaxies depart from the MS, presumably because of an elevated instantaneous SFR following a recent burst. This is particularly true for lower-mass galaxies, below 10^9 M_☉, where high EWs are more common and contribute to a larger dispersion in the MS relation.

This result is confirmed when comparing the Hα and UV continuum SFR indicators as a function of mass. We observe high SFR_{Hα}/SFR_{UV} ratios in galaxies with 10^9 M_☉. Unsurprisingly, these galaxies also show the highest EW_{Hα}. Given the selection bias towards strong Hα emitters in low-mass galaxies, these results can also be characterized as a higher scatter in the SFR_{Hα}/SFR_{UV} distribution in lower-mass galaxies, as it has been observed in previous studies (Weisz et al. 2012; Guo et al. 2016; Sparre et al. 2017; Emami et al. 2019). Faisst et al. (2019) results show that 50% of galaxies show a significant excess (more than a factor of 2) in SFR derived from Hα with respect to the equilibrium. These galaxies also show the highest Hα equivalent widths. In general, there is a large scatter around the equilibrium value of SFR_{Hα}/SFR_{UV}.
On the other hand, Broussard et al. (2019) compare theoretical predictions from semi-analytical models and hydrodynamical simulations to 3D-HST observations to infer the SF burstiness. They define the burstiness parameter \( \eta \) as the logarithm of the ratio between SFR_{[\alpha]} and SFR_{UV}. They find a positive correlation between the average of \( \eta \) and stellar mass, and the scatter appears to be independent of the stellar mass. They note however that this correlation could be due to systematics in 3D-HST data that are not implemented in mock galaxies or to the dust prescriptions used. Our findings are in disagreement with those results, since we find that (i) the SFR_{[\alpha]}/SFR_{UV} increases towards lower masses, even when using the same dust prescription to correct the H\(\alpha\) and the UV emissions (Bottom-right panel of Figure B1); or (ii) given the selection effects (see Section 4.2) the scatter of SFR_{[\alpha]}/SFR_{UV} ratio increases towards lower masses. This disagreement could be due to differences in both the sample selection and the methodology. Firstly, it is unclear whether the population of low-mass galaxies (fainter than H=24 AB mag) used in Broussard et al. (2019) has gone through additional checks including visual inspection, as it has been done in the present study. Indeed, this sub-sample of galaxies in the 3D-HST catalog is prone to uncertain measurements and spurious spectral identifications. Secondly, theSED fitting procedure and parameters used to derive their stellar population properties are different from the ones used in our study.

Some theoretical studies also show that burstiness is common in high-redshift galaxies across a wide mass range, whereas others show that only low-mass galaxies remain bursty all the way down to \( z = 0 \) (Muratov et al. 2015; Flores Velázquez et al. 2020)). Our results suggest that burstiness parameters such as the duration of the burst or the duty cycle can differ from theoretical predictions. The prevalence of galaxies with enhanced H\(\alpha\) relative to UV emission requires star formation variation on short time scales (less than 10 Myr) and/or short idle time between burst episodes on a rapid duty cycle. Direct implications on models of galaxy formation include modifications in the balance between the infall of gas, on one hand, and the ejection of gas or photoionization by the UV background, on the other hand.

Finally, a realistic model of reionization requires the convolution of the galaxy UV LF with physically-motivated ionization properties of galaxies. Recent attempts based on current observations lead to a variety of conclusions regarding the nature of galaxies contributing the most to reionization (e.g. Finkelstein et al. 2019; Naidu et al. 2020). A better understanding of the burstiness of galaxies and an accurate assessment of the volumetric escape fraction of galaxies (e.g. as a function of stellar mass) through deep LyC and rest-frame optical observations are needed to improve on this front.

Future NIR spectroscopic observations with the upcoming JWST will help obtain accurate measurements of the SFR and dust attenuation through the Balmer decrement for a large sample of galaxies across a wide range of redshifts to investigate in details the SF burstiness in galaxies down to even lower masses.

ACKNOWLEDGEMENTS

We thank Irene Shivaei, Najmeh Emami, and Jorryt Matthee for sharing their tabulated data. HA thanks Dan Stark and Brian Siana for useful discussions. This work is supported by CNES. It is based on observations with the NASA/ESA Hubble Space Telescope, obtained from the Mikulski Archive for Space Telescopes at the Space Telescope Science Institute, which is operated by the Association of Universities for Research in Astronomy, Inc., under NASA contract NAS 5-26555. These observations are associated with programs 12177, 11600, 12534, and 13872. PAO acknowledges support from the Swiss National Science Foundation through the SNSF Professorship grant 190079 ‘Galaxy Build-up at Cosmic Dawn’. The Cosmic Dawn Center (DAWN) is funded by the Danish National Research Foundation under grant No. 140.

APPENDIX A: LUMINOSITY COMPLETENESS

In section 5, in order to estimate the completeness of our sample in terms of ξUV measurements, we combined the Hα flux limit and the EWHα. We simulated a sample of EWHα following the observed distribution, applying the same selection cut at 80Å. A combination with the Hα flux limit gives a distribution in F140W magnitudes (rest-frame optical continuum). For the second term LUV, we use the observed correlation between the UV (F336W) and NIR (F140W) magnitudes and its associated dispersion. Figure A1 shows this relation, with a correlation of UV mag = (0.68 ± 0.012) × Hmag + (9.22 ± 0.29)

APPENDIX B: DUST CORRECTIONS

To explore how the choice of dust laws affects the burstiness results, we computed the SFRHα/SFRUV ratio as a function of stellar mass for four different combinations of nebular/stellar corrections. The results are shown in Figure B. We first adopt the Calzetti attenuation law for both the SFRHα and SFRUV (Top-left panel). As we have explained in Section 3.1 (see also Table 1), changing the dust law leads to significant difference in the correction factors mainly in the UV domain. Therefore, the adoption of the Calzetti law for the UV makes the SFRUV significantly larger, especially for the more massive galaxies, which makes the SFRHα/SFRUV much lower. The
net result is a stronger dependence of the burstiness with stellar mass. We also investigate the following combinations: SMC/SMC and the Calzetti/Calzetti, but this time deriving the nebular attenuation from the stellar one, assuming a ratio of \( E_{B-V, \text{star}}/E_{B-V, \text{gas}} = 0.44 \). The fiducial combination Cardelli/SMC is also shown. These two combinations have little impact on the general trend of the SFR ratio, apart from slightly elevating the normalization of the bulk of the sample.

**APPENDIX C: INTRINSIC UV SLOPE**

In computing the dust extinction of the UV stellar continuum, we have measured and compared the observed UV slope \( \beta \) with the intrinsic slope \( \beta_0 \). We adopted a value of \( \beta_0 = -2.62 \) derived by Reddy et al. (2018a). This value is derived for a sample of \( z \sim 2 \) galaxies, assuming a stellar population model with an age of 100 Myr, \( Z = 0.14Z_\odot \) metallicity and a constant star formation history. To investigate the importance of this parameter choice, we also used the canonical value of \( \beta_0 = -2.23 \) (Meurer et al. 1999) for comparison, which assumes a constant star formation history and a solar metallicity. In Figure C1, we show the effect on the \( \text{SFR}_{H\alpha}/\text{SFR}_{UV} \) ratio as a function of stellar mass. We observe a slight elevation of the global values, with no noticeable impact on the overall trend. In Meurer et al. (1999), it is also shown that variations of the stellar populations properties, including instantaneous bursts of star formation, IMF and metallicity lead to variations between \( \beta_0 = -2.0 \) and \( \beta_0 = -2.6 \).

Similarly, we also show in Figure C2 the impact of adopting a different intrinsic UV slope on the \( \xi_{\text{ion}} \) distribution. First, adopting \( \beta_{\text{int}} = -2.23 \) results in a median value of Log\( (\xi_{\text{ion}}/\text{erg}^{-1} \text{ Hz}) = 25.12 \pm 0.26 \), adopting the fiducial dust correction combination Cardelli/SMC. For reference, we found Log\( (\xi_{\text{ion}}/\text{erg}^{-1} \text{ Hz}) = 24.80 \pm 0.26 \) when using \( \beta_{\text{int}} = -2.62 \). We also included a dispersion in the intrinsic UV slope by uniformly sampling the range \( -2.62 < \beta < -2.23 \), resulting in the right panel of Figure C2. We find a median value of Log\( (\xi_{\text{ion}}/\text{erg}^{-1} \text{ Hz}) = 24.89 \pm 0.27 \). A slight increase of 0.05 dex in the dispersion of the \( \xi_{\text{ion}} \) distribution is notably observed for the Cardelli/Calzetti dust correction.

This paper has been typeset from a \TeX/\LaTeX\ file prepared by the author.
Figure B1. Effects of dust laws on the variations of the SFR$_{H\alpha}$/SFR$_{UV}$ as a function of stellar mass. Four combinations for nebular/stellar dust are tested here. Top-left: Calzetti/Calzetti, top-right: SMC/SMC, Bottom-left: Cardelli/SMC, Bottom-right: Calzetti/Calzetti assuming $E_{B-V,\text{stars}}=0.44E_{B-V,\text{gas}}$. The color code is the same as in Figure 8.

Figure C1. The impact of the intrinsic UV slope $\beta_{\text{int}}$ on the correlation between the SFR$_{H\alpha}$/SFR$_{UV}$ and the stellar mass. We compare, in the left panel, the value adopted in this study $\beta_0 = -2.62$ (Reddy et al. 2018a) and, in the right panel, the canonical value of $\beta_0 = -2.21$ (Meurer et al. 1999). We used the Calzetti et al. (2000) attenuation curve for both the stellar and nebular dust correction (cf. fig. B1).
Figure C2. The impact of the intrinsic UV slope $\beta_{\text{int}}$ on $\xi_{\text{ion}}$ distribution. The left panel shows the same distributions shown in figure 10 but adopting $\beta_{\text{int}} = -2.23$ (Meurer et al. 1999) instead of $\beta_{\text{int}} = -2.62$ (Reddy et al. 2018a). The right panel shows the result of using a dispersion in $\beta_{\text{int}}$ in the range defined by these two values.
