Abstract. Background/Aim: Poly (ADP-ribose) polymerase (PARP) inhibition could enhance the efficacy of temozolomide and prolong survival in patients with glioblastoma. The aim of this study was to evaluate the combination of the PARP inhibitor olaparib with temozolomide in the treatment of glioblastoma. Materials and Methods: The in vitro and in vivo antitumor effects of the PARP inhibitor olaparib together with temozolomide were evaluated. The in vitro experimental glioblastoma model involved O6-methylguanine methyltransferase (MGMT) promoter-methylated (U87MG, U251MG) and MGMT promoter-unmethylated (T98G) glioblastoma cell lines using in this model cell viability and apoptosis were assessed. For the in vivo studies, nude mice bearing orthotopically xenografted glioblastoma cell lines (U87MG) were randomized to four experimental groups: i) the untreated, ii) temozolomide alone, iii) olaparib alone and iv) olaparib and temozolomide combination groups. Mice were treated daily for 4 weeks and monitored for tumor growth and survival. Results: In vitro we found that the combination of olaparib with temozolomide enhanced temozolomide-induced cytotoxicity in all glioblastoma cell lines regardless of the status of MGMT promoter methylation. In vivo, mice treated with temozolomide alone or in combination with olaparib showed greater survival than those untreated or with the olaparib monotherapy, as well as significantly decreased tumor volume. There was no significant difference in survival and tumor volume between temozolomide alone and the combination treatment. Conclusion: The combination of the PARP inhibitor olaparib with temozolomide could be promising candidates for combination therapy of glioblastoma regardless of the MGMT promoter methylation status.

Key Words: Glioblastoma, olaparib, temozolomide, combination chemotherapy.
differentiation, metastatic abilities, unlimited proficiency, and high DNA repair capacity (6, 7). Among the properties of GSCs, their high DNA repair capacity is widely believed to participate in their resistance against chemotherapy and radiotherapy. In GSCs, proteins that respond to DNA damage, such as checkpoint kinase 1 (CHK1), ATR serine/threonine kinase (ATR), ATM serine/threonine kinase (ATM), and poly (ADP-ribose) polymerase 1 (PARP1), are upregulated (6, 8). It can, therefore, be appreciated that both GSCs and their DNA repair mechanisms could be considered as targets for future therapeutic strategies.

TMZ, which is essentially used in conventional chemotherapy for glioblastoma, is a monoalkylating agent that methylates DNA bases. The main cytotoxic lesions induced by TMZ are N$_3$-methyladenine (N$_3$MeA), N$_7$-methylguanine (N$_7$-MeG), and O$_6$-methylguanine (O$_6$-MeG) (9). N$_3$MeA and N$_7$-MeG are repaired by base-excision repair (BER), whereas O$_6$-MeG generated by TMZ is repaired by O$_6$-methylguanine-DNA-methyltransferase (MGMT). Inhibition of either repair pathway can sensitize glioblastoma cells to TMZ cytotoxicity, but BER is naturally potent in GSCs; thus, it contributes minimally to overall TMZ responsiveness. In contrast, MGMT expression has been suppressed by promoter methylation in approximately 40% of glioblastomas; thus, the amount of MGMT expressed in tumor cells determines whether the tumor cells are susceptible or resistant to TMZ (9, 10). In tumors that show insufficient MGMT expression, persistent O$_6$-MeG lesions are incorrectly paired with thymidine and trigger replicative stress of mismatch repair (MMR), resulting in replication fork-associated DNA double-strand breaks (DSBs) and cytotoxicity (11). On the other hand, in patients who have tumors with an abundant expression of MGMT, even TMZ could not improve their prognosis (9, 11).

Poly (ADP-ribose) polymerase (PARP) is an important family of enzymes that contribute to repairing DNA damage, achieving genomic stability of tumor cells to promote survival (7, 9, 11). Therefore, inhibiting PARP has been considered to enhance the potency of cytotoxic agents. PARP inhibitors in combination with TMZ were first used in clinical trials against advanced tumors in 2003 (12). Since the introduction of the concept of synthetic lethality by Bryant et al. (13) and Farmer et al. (14) in 2005, which appeared in homologous recombination-deficient cells exposed to PARP inhibitors, there is a large number of studies on PARP inhibitors as potential antitumor sensitizing agents (7, 11).

In this study, we evaluated whether combination therapy of the PARP inhibitor olaparib with the alkylating agent temozolomide could be a promising treatment for glioblastoma in preclinical models. We tested cell viability and used an orthotropic xenograft model to determine the efficacy of the treatment.

**Materials and Methods**

**Cell culture.** The human glioma cell lines used in the studies were selected based on their MGMT expression, which is related to temozolomide sensitivity. The MGMT promoter-methylated cell lines (U87MG, U251MG) and the MGMT promoter-unmethylated cell line (T98G) were all purchased from the American Type Culture Collection (ATCC, Manassas, VA, UAS) in 2019. Cells were cultured in complete media with Dulbecco’s modified Eagle’s medium (DMEM, Sigma-Aldrich, Germany) supplemented with 10% heat-inactivated fetal bovine serum (FBS) and incubated at 37°C and 5% CO$_2$. We used differentiated cell cultures (FBS-supported monolayers) instead of undifferentiated cell cultures (neurospheres) based on a previous study, which found that there were no significant differences between the two cell culture systems in TMZ-induced DNA damage (16).

**Cell viability test.** We conducted cytotoxicity tests of olaparib. All cells (U87MG, U251MG, T98G) were seeded in 96-well plates (5x10$^3$ cells/well) and incubated for 24 h. The media used during incubation were discarded and replaced with 200 μl of complete media mixture containing serial increasing concentrations of olaparib (1 nM, 10 nM, 100 nM, 1 μM, 10 μM, 100 μM, and 1 mM). The cytotoxicity of olaparib, TMZ and a combination of olaparib and TMZ was measured in each cell line. The concentration of TMZ was chosen experimentally after several tests to determine the proper concentration that showed a definite inhibition (minimum inhibitory concentration). All groups of cells were plated first in triplicate and then in quadruplicate for statistical analysis.

Cell viability was tested using CCK-8 assays (Dojindo Molecular Technologies, Inc., Tokyo, Japan) according to the manufacturer’s protocol. We replaced the treatment solution with 200 μl of complete media mixture containing serial increasing concentrations of olaparib (1 nM, 10 nM, 100 nM, 1 μM, 10 μM, and 1 mM). The cytotoxicity of olaparib, TMZ and a combination of olaparib and TMZ was measured in each cell line. The concentration of TMZ was then in quadruplicate for statistical analysis.

**Apoptosis analysis.** The apoptosis assay was carried out using the FITC Annexin V Apoptosis Detection Kit I (BD Pharmingen™, Cat. 556547) according to the manufacturer’s protocol. U87MG cells (1x10$^6$) were seeded in seven 100 mm petri dishes and incubated in complete media for 24 h. Further incubation was carried out for 48 h after replacing the media with the following: i) serum-free DMEM (four dishes, control groups), ii) 500 μM TMZ in serum-free DMEM (TMZ group), iii) 10 μM olaparib in serum-free DMEM (Ola group) and iv) 500 μM TMZ+10 μM olaparib in serum-free DMEM (TMZ+Ola group). Subsequently, the cells were harvested.
and incubated with 5 μl of FITC Annexin V and 5 μl PI for 15 min in the dark at RT. The number of apoptotic cells was evaluated by manually counting four random microscopic fields (400× original magnification) per subject. Cells were analyzed using a FACS Canto II (Becton Dickinson) flow cytometer.

**Mouse glioblastoma xenograft model.** This study was approved by the Institutional Animal Care and Use Committee of the Medical Science Research Institute, Seoul National University Bundang Hospital (Gyeonggi-do, Republic of Korea; authorization No. BA-1906-274-033-08). Twenty-two six-week-old BALB/c nude mice were used for the orthotopic xenograft model ( Orient Bio, Seongnam-si, Korea; distributor for Charles River, Wilmington, MA, USA). After anesthetizing them by 30 mg/kg/intraperitoneal (i.p.) Zoletil and 10 mg/kg/i.p. Rompun, we used a stereotactic frame (Kopf Instruments, Tujunga, CA) to fix them during implantation. Using a 10 μl Hamilton syringe, we injected 2×10^5 U87MG cells resuspended in 2 μl of Dulbecco’s phosphate buffered solution (PBS) intracranially at an identical site (0.5 mm anterior and 2.0 mm right lateral from bregma). Injection lasted for 4 min (0.5 μl/min), and the needle was removed after exactly 4 min at a speed of 1 mm/min. The hole made after the injection in the skull was blocked by dental cement (Prime Dental Manufacturing, Chicago, IL, USA).

**Treatment Preparation.** The weight/volume percentage concentration of the treatment solutions was 10%. A 10% hydroxypropyl-β-cyclodextrin (HBC) solution was prepared with 0.1 g HBC powder/10 ml of PBS. First, we vortexed a solution of 100 mg of TMZ powder in 17 ml of 10% HBC solution, and then a 3 ml solution of dimethyl sulfoxide (DMSO) was then vortexed to optimally solubilize TMZ. Olaparib solution was prepared in the reverse order with the 10% HBC solution being vortexed after DMSO was added. This procedure ensured that the substrates were sufficiently dissolved. The prepared treatment solutions were then aliquoted in PCR tubes and cryopreserved for later use. When required, the olaparib and TMZ solutions were thawed for two min in a 37°C water bath before the i.p. injection.

**Treatment protocol and evaluation.** Tumor-bearing mice were randomly allocated to four groups and treated differently after a week of implantation: i) untreated (control group, n=6), ii) TMZ alone (TMZ group, n=6), iii) olaparib alone (Ola group, n=5), and iv) combination with olaparib and TMZ (combination group, n=5). The dosages for olaparib and TMZ were 50 mg/kg. The mice were received an i.p. injection for 4 consecutive days per week, and the treatment cycle was conducted for 4 weeks. Then, the animals were monitored for 2 months to analyze their survival before sacrifice and measurement of the tumor volume. The humane endpoint was defined as a weight reduction of >20% of the initial weight. If weight loss in all mice remained above this threshold, all surviving mice were anaesthetized and humanely sacrificed at the end of the study. Following sacrifice, the brains of the mice were removed following vascular perfusion with a solution containing PBS and fixed with 4% formaldehyde for 1 week. Then, the brains were embedded in paraffin and sectioned coronally into slices of 5 μm thickness using a microtome (RM2255, Leica Biosystems, Richmond, IL, USA). The slices were mounted on individual slides and stained with hematoxylin and cosin. The maximal length (L), width (W), and height (H) of each tumor were measured, and tumor volume was calculated using the following formula: tumor volume (V)=4/3 π (L/2×W/2×H/2).

**Results**

**Cell viability test of olaparib.** Since the cytotoxicity of olaparib is unknown in glioma cell lines, it was initially assessed by the cell viability test. The half maximal inhibitory concentration (IC50) of olaparib seemed similar in all three cell lines and was between 0.1 and 1 mol/l: i) 228 mol/l for U87MG, ii) 177 mol/l for U251MG, and iii) 260 mol/l for T98G. The IC50 values of the three cell lines were similar in terms of olaparib toxicity regardless of the MGMT promoter methylation, and the viability patterns overlapped (Figure 1).

The efficiency of the PARP inhibitor olaparib to sensitize cells to TMZ and help suppress glioblastoma was evaluated in a cell viability test. We found that the degree of viability decreased in the order of i) control, ii) olaparib, iii) temozolomide, and iv) their combination (Figure 2A-C). Olaparib enhanced the TMZ-induced cytotoxicity in all glioblastoma models regardless of the MGMT promoter methylation status. In addition, the difference in cell viability between the Ola and the combination group in T98G, the MGMT promoter-unmethylated cell line, was larger compared to the other two groups (Figure 2C).

**Apoptosis analysis.** Apoptosis is a natural course of DNA-damaged cells. Since TMZ is a monoaalkylating agent that affects DNA, apoptosis instead of necrosis should occur after treatment. Our FACS data showed that after 48 h of TMZ and olaparib treatment, there were few cells that underwent necrosis (0.93% of 10,000 cells in the TMZ+Ola group), while a considerable number of cells underwent apoptosis (early apoptosis 3.69% vs. late apoptosis 12.24% in the TMZ+Ola group) (Figure 3A). Comparing the 3h to the 48h treatment group, we found that there were more cells undergoing early apoptosis in the first group (3 h, 7.61%, 48 h, 12.24%) (Figure 3). In summary, olaparib and temozolomide cotreatment led glioblastoma tumor cells to undergo apoptosis rather than necrosis.

**Cotreatment efficacy in vivo.** An orthotopic xenograft model was used to identify the efficacy of PARP inhibitors in sensitizing TMZ to mimic the clinical situation. Animals were treated for 4 weeks with TMZ or PARP inhibitor or both. The inhibitory effects on tumor growth were evaluated by tumor volume assessment. We obtained the mean tumor volume from each group, including the untreated control.
animals. The mean tumor volume in the TMZ (14.02±5.53 mm$^3$) and the combination group (13.35±7.03 mm$^3$) was significantly smaller than both the control (45.20±7.67 mm$^3$) and the Ola group (45.06±3.88 mm$^3$). The mean tumor volume in the combination group was a bit smaller than that of the TMZ group, however, there was no statistical significance ($p=0.865$) (Figure 4A and B).

Figure 4C shows the survival analysis on the orthotopic mouse model. The mean survival period of the i) control, ii) Ola, iii) TMZ, and iv) combination group was: i) 55, ii) 52, iii) 77, and iv) 77 days, respectively. The overall survival in both the TMZ ($p=0.018$) and the combination group ($p=0.030$) was significantly high compared to the control group. There was no significant difference between the TMZ and combination groups.

Discussion

Olaparib enhanced the cytotoxicity of TMZ on glioblastoma in our in vitro studies. All the glioblastoma cell lines tested were more vulnerable to mixed conditions of TMZ and olaparib than TMZ alone. However, the orthotopic glioblastoma mouse model treated with mixed therapy had no evidence of a survival gain compared to the one offered by TMZ monotherapy. This result shows that combination therapy with a PARP inhibitor and TMZ has promising effects even on glioblastoma, as previous studies have proved its efficiency on BRCA-mutant tumors (12), still with some hurdles in in vivo studies and real clinical settings.

The combined effect of PARP inhibitors and TMZ could be understood at a molecular level. As mentioned above, the resistance of glioblastoma stem cells to TMZ arises from their potent repair system, represented by BER and MGMT. Several components are needed to activate their repair systems, such as PARPs. PARP1, which can be inhibited by olaparib, detects the presence of DNA lesions and then activates signaling pathways to promote relevant cell responses for DNA repair, including BER. When DNA single-strand breaks (SSBs) are detected, they recruit and activate several BER factors as a necessary scaffold to repair SSBs before replication (17, 18). Thus, inhibiting PARP1 could prevent GSCs from activating the repair system, making them vulnerable to temozolomide.

In 2015, Erice et al. (19) reported that MGMT expression predicts PARP-mediated resistance to temozolomide. The study verified the sensitizing effect of PARP inhibitors in...
Figure 2. The anti-tumor effect of olaparib, temozolomide, or their combination on the viability of the different cell lines. These cell lines (A: U87MG, B: U251MG, C: T98G) were seeded in 96-well-plates and treated with olaparib only, temozolomide only, or a combination of the two. Olaparib enhanced the TMZ-induced cytotoxicity in all cell lines. CTR: Control; TMZ: temozolomide. *p<0.05, and **p<0.001.
temozolomide-resistant cell lines, especially in the most commonly temozolomide-treated tumors (melanoma, colorectal cancer, and glioblastoma cancer). In their study, PARP inhibitors showed sensitizing effects only in MGMT-overexpressing cell lines, which are TMZ-resistant. The authors noted that cell lines that do not express MGMT by promoter methylation did not change their response following the addition of a PARP inhibitor to temozolomide therapy.

According to a previous paper of Erice et al. (19), we assessed the viability of each cell line used in that study to the combination therapy before implanting them into the xenograft model. We found that both MGMT promoter-methylated as well as -unmethylated cells were sensitive to the treatment of PARP inhibitors with TMZ. As cell line of MGMT promoter methylation status does not matter, we generated an orthotopic xenograft model by U87MG as previously described (20).

MGMT is a “suicide” DNA repair enzyme whose level is important to maintain genomic stability (21). When MGMT is overexpressed, DNA alkylation formed by chemotherapeutics could be easily repaired, resulting in high resistance (10). However, because PARP inhibitors participate in different DNA repair pathways, base excision repair could make MGMT-overexpressing cell lines vulnerable to temozolomide. This is a great advantage of PARP inhibitors against glioblastoma; however, it does not mean that PARP inhibitors are only effective in MGMT promoter-unmethylated-derived glioblastoma. Given our results, a PARP inhibitor can also enhance the effect of TMZ in MGMT promoter-methylated-derived glioblastoma, which is another advantage of PARP inhibitor use against glioblastoma.

The difference in the coverage of PARP inhibitors between other and our studies could be hidden by proportional statistics. In Erice’s study (19), the researchers used half maximal growth inhibition concentration (GI50) as a sensitization marker. This marker could proportionally evaluate how the susceptibility of a cell line changed by a sensitizer. Since GI50 is the concentration for half the maximal inhibition of cell proliferation, this value could rise substantially for agents to which there is resistance, resulting in a significant difference between sensitized and non-sensitized lines. Importantly, in already sensitive lines, this method could underestimate the effect of the agent, although there could be a significant enhancement of reactivity. In our study, we compared the viability of different cell lines under the same temozolomide concentration. This procedure has the benefit that this fixed dose of TMZ, since efficient, could be used for glioblastoma patients. In addition, analysis of cell viability showed that a sufficient amount of PARP inhibitor could enhance the cytotoxicity of TMZ.

Interestingly, against our expectations, we failed to demonstrate the survival gain of olaparib and TMZ combination treatment compared to TMZ monotherapy in the in vivo study. This could be partly explained based on the assumption of an ineffective drug penetration into the brain due to the blood-brain barrier. According to Parrish et al., the PARP inhibitor rucaparib does not potentiate TMZ in the orthotopic GBM models (22), which does not agree with the findings of an in vivo study in flank tumor models (23). Blood-brain barrier remains a hurdle to most chemotherapeutics in tumors of the central nervous system, and olaparib is not an exception. Besides, we could not evaluate the tumor model before treatment. Despite the fact that each treatment group showed no difference in mouse weight or general health status, there might have been a difference in tumor volume, which can affect the efficacy of drugs.

Recently, two phase I trials use olaparib in glioblastoma patients and their results appear to be promising. In the first trial olaparib combined with radiotherapy was well tolerated in newly diagnosed glioblastoma patients (24). In the second

Figure 3. Apoptosis assay of combination treatment in U87MG cell line. FACS data (A; 48h, B; 3h) of Annexin V/PI apoptosis analysis showed that using Olaparib (O) and Temozolomide (T) induces apoptosis, not necrosis. UL: Upper left; UR: upper right; LL: lower left LR: lower right.
Figure 4. The tumor volume and survival in the glioblastoma xenograft model. (A) Hematoxylin and eosin-stained coronal histological section of mouse brain of each group analyzed 1 month after treatment. (B) The mean tumor volume of the TMZ group and the combination treatment group was significantly lower than the control group, however, between them, there was no statistical significance. (C) Survival of the glioma xenograft mouse model. Most of the control group and the Olaparib (Ola) group mice died within 40 days. However, mice in the remaining groups lived to the end of the experiment. In addition, there was no difference between the TMZ group and the combination group. TMZ: Temozolomide.
trial, olaparib and temozolomide combination therapy was conducted in patients with relapsed glioblastoma, and the researchers found that olaparib penetrates the core and margins of recurrent glioblastoma, with good tolerance (25).

Only a handful of studies have assessed the use of PARP inhibitors in glioblastoma. In 2017, Ohmoto et al. (26) indicated four research tasks needed to apply PARP inhibitors in specific tumor treatments. First, the most suitable drugs should be determined among several PARP inhibitors. Second, a new treatment target should be found in cases of homologous recombination repair (HHR)-proficient tumors. Third, the regimen that could increase the overall survival and progression-free survival should be decided, and fourth, proper biomarkers that could measure the efficacy, side effects, and clinical resistance should be found.

Our study has some limitations. First, we could not evaluate the penetration or accumulation of olaparib or temozolomide, which would affect the efficacy of treatment. Many other studies have noted the limited role of olaparib due to the blood brain barrier, limiting the exact role of novel drugs. Second, the initial tumor volume was not considered due to technical limitations. The initial tumor volume could confound the interpretation of the results. Additional studies with different cell lines or other PARP inhibitors and further evaluation of drug distribution in brain tumors would be beneficial to determine the effect of PARP inhibitors in patients with glioblastoma.

Conflicts of Interest
