Orthostatic hypertension (OHT) is a condition characterized by an increase in blood pressure after assuming the standing position.[1] Nowadays no consensus definition exists, thus OHT prevalence varies among studies (4%–20.3%).[2–6] Studies considering a broad OHT definition (i.e., either a systolic or a diastolic blood pressure increase upon standing) demonstrated the highest prevalence of OHT.[1] However, when any rise in orthostatic blood pressure (without cut-offs) is considered as OHT, people with a normal orthostatic response could be wrongly classified as affected by this pathologic condition. On the contrary, definitions including only a systolic or a diastolic increase in blood pressure could miss some cases of OHT.

The tests used to perform the diagnosis are: active standing, ambulatory blood pressure monitoring and tilt-table.[1] Notwithstanding the lack of validated methods creates uncertainty. In the clinical setting the active standing examination could be biased by the “white coat effect”.[1] Automated sphygmomanometers, though widely used, are less sensible than mercury sphygmomanometers in measuring orthostatic blood pressure variations.[7] The level of orthostatic stress applied can be more or less intense (from lying to standing or from sitting to standing); in the last case, some affected people may not be identified. Finally, the recording time after the orthostatic stress (immediately after the stress, one minute or three minutes after the stress) markedly differed across studies. A pre-conscious increase in blood pressure which is not sustained over time may not bear the same consequences of a prolonged adrenergic activation.

OHT is frequently overlooked in routine clinical practice because many clinicians ignore this condition. Unfortunately, OHT under-diagnosis is not free of potential serious consequences. The pathophysiologic mechanisms that underpin OHT, seem to be implied also in the development of its adverse effects. The sympathetic overdrive [4,5,8,9] responsible for the excessive compensatory reaction to orthostatic stress [4] when associated with blood pressure variability enhances endothelium shear stress. This could favour thrombotic events and cardiovascular morbidity. OHT has been considered as a form of pre-hypertension and has been related to hypertension target organ damage (higher urinary albumin/creatinine ratio and higher BNP levels, higher BNP/ANP ratio, electrocardiographic signs of left ventricular hypertrophy and silent cerebrovascular disease).[5,8,9] Target organ damage is a risk factor for premature cardiovascular events and death. Indeed, OHT has been linked to adverse clinical outcomes,[2,3,6,10–36] thought without a robust evidence.[1] The main source of inconsistency across studies is the absence of a uniform definition of OHT, which also makes the comparison tricky.

Studies on OHT related mortality are extremely heterogeneous. Three studies found that OHT was associated with an increased mortality.[6,19,31] The strongest evidence comes from the study by Veronica who described a higher all cause and cardi-
OHT was found to be associated with non-fatal cardiovascular events leading to hospitalization or to a specific long-term new treatment in institutionalized older individuals. OHT was also linked to stroke (though with conflicting results) myocardial infarction and peripheral arterial disease.

Eventually, OHT has been related to poor cognitive performance. Bad blood pressure control promotes cerebral small vessel disease which predisposes to micro-bleedings and subcortical lacunar infarctions. These alterations in critical or associative areas of the brain can contribute to the impairment of cognitive performance.

To sum up, it seems that OHT is related to hypertension, abnormal blood pressure patterns and masked hypertension, which can all predispose to future cardiovascular events. Indeed, an association with some cardiovascular comorbidities, cognitive impairment and mortality has been found, though with some conflicting results.

We need to develop a clear and widely accepted definition of OHT to perform prospective longitudinal studies to clearly assess OHT related adverse outcomes. If future studies confirmed the associations of OHT with adverse clinical outcomes it would be advisable to recommend routine postural change measurement during routine clinical practice to obtain information of prognostic clinical significance.
