Abstract. We consider the generic problem of suddenly changing the geometry of an integrable, one-dimensional many-body quantum system. We show how the physics of an initial quantum state released into a bigger system can be completely described within the framework of the algebraic Bethe ansatz, by providing an exact decomposition of the initial state into the eigenstate basis of the system after such a geometric quench. Our results, applicable to a large class of models including the Lieb–Liniger gas and Heisenberg spin chains, thus offer a reliable framework for the calculation of time-dependent expectation values and correlations in this nonequilibrium situation.

Keywords: integrable spin chains (vertex models), quantum integrability (Bethe ansatz), spin chains, ladders and planes (theory)

ArXiv ePrint: 1006.3741
Integrable models have provided a wealth of valuable information on the equilibrium thermodynamics of strongly correlated systems during the last few decades (see [1]–[3] and references therein). More recently, much progress has also been made on their dynamical properties. On the other hand, the field of out-of-equilibrium dynamics is only now starting to become accessible to comparably exact methods [4]–[8], in particular in the study of so-called quantum quenches (see [9]–[25], for example). In those studies the quench is defined as a sudden change of a local parameter of the Hamiltonian, typically the interaction strength or an external field. In this short letter, we consider the case where a global parameter is abruptly changed, namely the size of the system before and after the quench. For the purpose of this letter, we call this the geometric quench. Earlier studies of such a set-up, using numerical techniques, include [26,27]. The case where a Lieb–Liniger gas on a finite interval is released to an infinite interval is covered in [28]–[30]. Another related case is when the initial state is a completely filled (polarized) state [31]–[33], [8]. It is worth mentioning that a geometric quench can be viewed as something in between a global quench [9]–[22] and a local quench [23,24,18].

In this letter, we highlight an interesting feature of the wavefunctions of integrable one-dimensional models of quantum many-body physics, opening the door to a large class of possible calculations of nonequilibrium dynamical effects in these systems due to a sudden change of their geometry. We start with a simple explanation using the coordinate representation of wavefunctions and provide an algebraic version of the reasoning thereafter. This letter ends with some perspectives and suggestions for further work.

1. Coordinate Bethe ansatz

We consider a quantum system initially defined within a finite space interval $0 \leq x < L_1$ (for clarity, we use notations appropriate for a model defined on the continuum, such as the Lieb–Liniger model [34]; our reasoning also applies to lattice models such as spin chains by trivial modifications). We suppose that the initial Hamiltonian can be written as the integral of a Hamiltonian density:

$$H_1 = \int_0^{L_1} dx \mathcal{H}(x)$$

and that specific boundary conditions (e.g. periodic or twisted; the reasoning for the open case is slightly different, and is discussed in section 2) labeled by $\alpha_1$ are imposed on the wavefunctions. In the case of integrable systems, a complete set of orthonormalizable eigenfunctions is explicitly given in each $N$-particle sector by a Bethe ansatz; individual wavefunctions

$$\Psi^{(1)}(\{x\}|\{\lambda\}_{\alpha^1_1}^{L_1}), \quad 0 \leq x_i < L_1$$

are labeled by their cardinality-$N$ set $\{\lambda\}_{\alpha^1_1}^{L_1}$ of rapidities, a solution to the Bethe equations associated with quantization in the space $0 \leq x < L_1$ under boundary conditions $\alpha_1$. Completeness ensures that the number of allowable solutions coincides with the dimensionality of the Hilbert space. One important observation, reflected in our notation, is that the eigenfunctions $\Psi(\{x\}|\{\lambda\})$ do not explicitly depend on the length $L_1$ or boundary conditions $\alpha_1$; rather, these dependences are carried only implicitly by the sets of rapidities. This simple observation forms the basis of what we propose here.

The generic experiment we have in mind can be described as follows. Suppose that we initially prepare the system in a specific eigenstate $\Psi(\{x\}, t = 0^-) \equiv \Psi^{(1)}(\{x\}|\{\lambda\}_{\alpha^1_1}^{L_1})$. At time $t = 0$, we glue a new, empty region onto the original system, thereby changing its size from $L_1$ to $L_2 > L_1$, a process we call a geometric quench. From this point onwards, to control the subsequent time evolution exactly, all calculations must be done in the basis of eigenstates of the new Hamiltonian

$$H_2 = \int_0^{L_2} dx \mathcal{H}(x)$$

defined by integrating the same Hamiltonian density as before (so all interaction parameters remain unchanged) over the larger space interval up to $L_2$. The eigenstates of $H_2$ (choosing boundary conditions labeled by $\alpha^2_2$) are functions of the form

$$\Psi^{(2)}(\{x\}|\{\mu\}_{\alpha^2_2}^{L_2}), \quad 0 \leq x_i < L_2,$$

where the sets of rapidities $\{\mu\}_{\alpha^2_2}^{L_2}$ now solve the Bethe equations associated with quantization in the space $0 \leq x < L_2$ under boundary conditions $\alpha_2$.

At first sight, the gluing of the wavefunctions before and after the geometric quench is not simple. This gluing condition can be written as the nonlinear condition:

$$\Psi(\{x\}, t = 0^+) = \left\{ \begin{array}{ll} \Psi^{(1)}(\{x\}|\{\lambda\}_{\alpha^1_1}^{L_1}), & 0 \leq x_i < L_1, \\ 0, & \text{if } \exists x_i \in [L_1, L_2[. \end{array} \right. $$

Decomposing this into the basis of eigenstates of $H_2$ can now be achieved by relying on the crucial observation made above, namely that the wavefunctions of $H_2$ do not depend explicitly on $L_1, \alpha_1$ (respectively $L_2, \alpha_2$). This allows us to make the identifications

$$\Psi^{(2)}(\{x\}|\{\mu\}_{\alpha^2_2}^{L_2})|_{0 \leq x_i < L_1} = \Psi^{(1)}(\{x\}|\{\mu\}_{\alpha^2_2}^{L_2})|_{0 \leq x_i < L_1}.$$
eigenfunction of $H_2$ is thus given by the well-known Slavnov formula [36] (associated with the original domain):

$$\frac{\langle \Psi^{(1)}(\{\mu\}_{\alpha^2})|\Psi^{(1)}(\{\lambda\}_{\alpha^1})\rangle}{\sqrt{\langle \Psi^{(1)}(\{\lambda\}_{\alpha^1})|\Psi^{(1)}(\{\lambda\}_{\alpha^1})\rangle\langle \Psi^{(2)}(\{\mu\}_{\alpha^2})|\Psi^{(2)}(\{\mu\}_{\alpha^2})\rangle}} = F_1(\{\mu\}_{\alpha^2};\{\lambda\}_{\alpha^1}).$$

(7)

The exact decomposition of our initial state onto the wavefunctions of $H_2$ is simply written as

$$\Psi(\{x\}, t = 0^+) = \sum_{\{\mu\}_{\alpha^2}} F_1(\{\mu\}_{\alpha^2}, \{\lambda\}_{\alpha^1}) \Psi^{(2)}(\{x\}|\{\mu\}_{\alpha^2}).$$

(8)

The subsequent time evolution is now trivial to build back in, since $\Psi^{(2)}$ are exact eigenstates of $H_2$. This simple expression is the central result of our letter.

2. Algebraic Bethe ansatz

2.1. Geometric quench overlap: periodic boundary conditions

From the previous analysis we clearly see that the dynamics of the geometric quench problem is encoded in the overlaps $F_1$ defined by (7). The natural framework for computing norms and overlaps of Bethe eigenstates is the algebraic Bethe ansatz. This approach is based on the construction of a monodromy matrix $T(\lambda)$, which leads to an algebraic formulation of the problem, see, for instance, [2]. The monodromy matrix, $T \in V_0 \otimes \mathcal{H}$ with $V_0$ an auxiliary space and $\mathcal{H}$ the Hilbert space, should satisfy the intertwining relation:

$$R(\lambda - \mu)(T(\lambda) \otimes T(\mu)) = (T(\mu) \otimes T(\lambda))R(\lambda - \mu)$$

(9)

where $R(\lambda) \in V_0 \otimes V_0$ is the $R$ matrix satisfying the Yang–Baxter equation. One can define the transfer matrix as $T(\lambda) = \text{Tr}_0 T(\lambda)$, where the trace is taken over the auxiliary space. The transfer matrix now acts as a generating function for a set of mutually commuting conserved charges, including the Hamiltonian. For simplicity we focus in this discussion on $XXZ$-type models (which includes the Lieb–Liniger gas) given by an $R$ matrix of the form

$$R(\lambda) = \begin{pmatrix} f(\lambda) & 0 & 0 & 0 \\ 0 & g(\lambda) & h(\lambda) & 0 \\ 0 & h(\lambda) & g(\lambda) & 0 \\ 0 & 0 & 0 & f(\lambda) \end{pmatrix}.$$  

(10)

For this type of $R$ matrix the monodromy matrix $T(\lambda)$ is a $2 \times 2$ matrix in auxiliary space:

$$T(\lambda) = \begin{pmatrix} A(\lambda) & B(\lambda) \\ C(\lambda) & D(\lambda) \end{pmatrix}.$$  

(11)

The commutation relations of the operators $A(\lambda), B(\lambda), C(\lambda), D(\lambda) \in \mathcal{H}$ follow from (9). Using these operators, eigenstates of the transfer matrix (and thus of the Hamiltonian)
can be constructed as
\[ \langle \Psi \rangle = \langle 0 \rangle \prod_{j=1}^{N} C(\lambda_j) \quad |\Psi\rangle = \prod_{j=1}^{N} B(\lambda_j)||0\rangle \]  
(12)

where the rapidities \( \{\lambda_j\} \) should satisfy the Bethe equations. The pseudovacuum \( |0\rangle \) \((\langle 0 | \equiv |0\rangle^\dagger)\) has the following properties:
\[ \langle 0 | A(\lambda) = a(\lambda)\langle 0 | \quad A(\lambda)||0\rangle = a(\lambda)||0\rangle \]  
(13)
\[ \langle 0 | D(\lambda) = d(\lambda)||0\rangle \quad D(\lambda)||0\rangle = d(\lambda)||0\rangle \]  
(14)
\[ \langle 0 | B(\lambda) = 0 \quad C(\lambda)||0\rangle = 0. \]  
(15)

The form of the vacuum eigenvalues \( a(\lambda) \) and \( d(\lambda) \) depend on the specific representation of the \( R \) matrix.

In order to describe the geometric quench we decompose the Hilbert space into two spatial intervals: one of length \( L_1 \) and one of length \( L_2 - L_1 \) (the part that is added): \( \mathcal{H} = \mathcal{H}_1 \otimes \mathcal{H}_2 \). The operators before the quench act on \( \mathcal{H}_1 \), while the operators after the quench act on \( \mathcal{H}_2 \). To be able to make a connection between the two we consider the generalized two-site model introduced in [35], namely the monodromy matrix \( T(\lambda) \) of any algebraic Bethe ansatz solvable model can be written as a matrix product of two factors:
\[ T(\lambda) = T_2(\lambda)T_1(\lambda) \]  
(16)

with \( T_1(\lambda) \in V_0 \otimes \mathcal{H}_i \). From the decomposition of the monodromy matrix it follows that
\[ B(\lambda) = A_2(\lambda)B_1(\lambda) + B_2(\lambda)D_1(\lambda) \]  
(17)

and similar expressions for the \( A(\lambda), C(\lambda) \) and \( D(\lambda) \) operators. We can write the initial \( N \)-particle state (at \( t = 0^+ \)) as
\[ \langle \Psi^{(1)}(\{\lambda\})| = \left(1\langle 0 | \prod_{j=1}^{N} C(\lambda_j)\right) \otimes 2\langle 0 |, \]  
(18)
while eigenstates in \( \mathcal{H} \) can be expressed as
\[ |\Psi^{(2)}(\{\mu\})\rangle = \left(\prod_{j=1}^{N} B_1(\mu_j)||0\rangle_1\right) \otimes \left(\prod_{j=1}^{N} A_2(\mu_j)||0\rangle_2\right) + \text{terms without overlap}. \]  
(19)

The terms without overlap are terms where not all \( B_1(\mu) \) act on \( |0\rangle_1 \) and will therefore not contribute to the decomposition of the initial state. The overlaps then become
\[ \langle \Psi^{(1)}(\{\lambda\})|\Psi^{(2)}(\{\mu\})\rangle = \prod_{j=1}^{N} d_1(\mu_j) \prod_{k=1}^{N} C_1(\lambda_k) \prod_{l=1}^{N} B_1(\mu_l)||0\rangle_1 \]  
\[ = \prod_{j=1}^{N} d_1(\mu_j)\langle \Psi^{(1)}(\{\lambda\})|\Psi^{(1)}(\{\mu\})\rangle. \]  
(20)
efficiently as a determinant [36, 37]. To obtain the normalized quench overlap $F_1$ as given in (7) one should divide (20) by the norms of the states [38]–[40] before and after the quench. The quench overlap is now defined up to a momentum-dependent phase, which is related to the representation of the $R$ matrix.

So far we considered periodic boundary conditions: however, we can easily generalize this by considering twisted boundary conditions. In this case the scalar product is given in [41]. Since the twist of the state after the quench does not appear explicitly, one has the freedom to choose the twists before and after the quench independently.

2.2. Geometric quench overlap: open boundary conditions

The geometric quench set-up has a natural generalization to the perhaps more physical case of open boundary conditions.

For an integrable system with open boundary conditions one should define the boundary conditions in terms of matrices $K_-(\lambda)$ and $K_+(\lambda)$. For $XXZ$-like models the diagonal solution of the boundary Yang–Baxter equation [42] is given by

$$K_\pm(u) = \begin{pmatrix} \varphi(u \pm \eta \pm \xi_{\pm}) & 0 \\ 0 & \varphi(-u \pm \eta \pm \xi_{\pm}) \end{pmatrix}$$

with $K_-$ and $K_+$ describing the left and right boundaries, respectively. Each is parameterized by $\xi_-, \xi_+$. Following [43] we introduce ‘double-row’ monodromy matrices $U_-$ and $U_+$:

$$U_-(\lambda) = T(\lambda)K_-(\lambda)\hat{T}(\lambda) = \begin{pmatrix} A_-^{(\lambda)} & B_-^{(\lambda)} \\ C_-^{(\lambda)} & D_-^{(\lambda)} \end{pmatrix}$$

$$U_+^{(\lambda)} = T(\lambda)^{t_0}K_+^{\alpha}(\lambda)\hat{T}(\lambda)^{t_0} = \begin{pmatrix} A_+^{(\lambda)} & B_+^{(\lambda)} \\ C_+^{(\lambda)} & D_+^{(\lambda)} \end{pmatrix}$$

where

$$\hat{T}(\lambda) = (-1)^L\sigma^y_0T^{t_0}(\lambda)\sigma^y_0$$

and $t_0$ denotes matrix transposition in the auxiliary space. The operators $A_\pm^{(\lambda)}, B_\pm^{(\lambda)}, C_\pm^{(\lambda)}$ and $D_\pm^{(\lambda)}$ are called the boundary operators in contrast to $A^{(\lambda)}, B^{(\lambda)}, C^{(\lambda)}$ and $D^{(\lambda)}$, which are called the bulk operators. Eigenstates can be constructed using boundary operators

$$\langle \Psi_\pm(\{\xi\}) | = \langle 0 | \prod_{k=1}^N C^{(\lambda)}_{\pm}(\lambda_j), \quad | \Psi_\pm(\{\xi\}) \rangle = \prod_{k=1}^N B^{(\lambda)}_{\pm}(\lambda_j) | 0 \rangle.$$  

The action of boundary operators on the vacuum is similar to that of the bulk operators, except for different vacuum eigenvalues.

We now consider a geometric quench where we keep the left boundary fixed and move the right boundary from $L_1$ to $L_2$. This allows us to write everything in terms of $B_-(\lambda)$ and $C_-^{(\lambda)}$ operators. Equivalently we could fix the right boundary and write everything in terms of $B_+^{(\lambda)}$ and $C_+^{(\lambda)}$. Similar to the case of periodic boundary conditions we factorize the monodromy matrix as

$$U_-(\lambda) = T_2(\lambda)T_1(\lambda)K_-(\lambda)\hat{T}_1(\lambda)\hat{T}_2(\lambda) = T_2(\lambda)U_{-1}\hat{T}_2(\lambda)$$

doi:10.1088/1742-5468/2010/09/L09001
where $U_{-1}$ is the double-row monodromy of the smaller system with the same left boundary. We can now decompose the $B_-(\lambda)$ operator as a combination of bulk and boundary operators:

$$B_-(\lambda) = (A_2(\lambda)B_{-1}(\lambda) + B_2(\lambda)D_{-1}(\lambda))A_2(-\lambda) - (A_2(\lambda)A_{-1}(\lambda) + B_2(\lambda)C_{-1}(\lambda))B_2(\lambda).$$  

(27)

We write the initial state as

$$\left(1 \langle 0 | \prod_{k=1}^{N} C_{-1}(\lambda_k) \right) \otimes 2 \langle 0 |,$$

(28)

and we write the final state as

$$\left(\prod_{k=1}^{N} B_{-1}(\mu_k)\langle 0_1 | \right) \otimes \left(\prod_{k=1}^{N} A_2(\mu_k)A_2(-\mu_k)\langle 0_2 |\right) + \text{terms without overlap}.$$  

(29)

The terms without overlap are terms with no $B_{-1}$ operator acting on $|0_1 \rangle$ and will not contribute when taking the scalar product with (28). This results in the geometric quench overlap:

$$\langle \Psi_1^{(1)}(\{\lambda\})|\Psi_2^{(2)}(\{\mu\}) \rangle = \prod_{j=1}^{N} a_2(\mu_j)a_2(-\mu_j)\langle 0_1 | \prod_{k=1}^{N} C_{-1}(\lambda_k) \prod_{l=1}^{N} B_-(\mu_l)\langle 0_1 |$$

$$= \prod_{j=1}^{M} a_2(\mu_j)a_2(-\mu_j)\langle \Psi_1^{(1)}(\{\lambda\})|\Psi_2^{(2)}(\{\mu\}) \rangle.$$  

(30)

For the XXZ spin chain, the determinant representation for the scalar product $\langle \Psi_1^{(1)}(\{\lambda\})|\Psi_2^{(2)}(\{\mu\}) \rangle$ is computed in [44, 45] and is related to the overlap $F_1$ of (7) by a normalization prefactor [44, 45]. Since (30) does not depend on the right boundary condition, we cannot only expand the system but also change the right boundary condition after the quench.

3. Conclusions and perspectives

We have shown how a sudden, global change in the geometrical support of an integrable model could be completely described within the Bethe ansatz, by providing an exact decomposition of the original (arbitrarily chosen) eigenstate into the basis of eigenstates after such a geometric quench. The idea is quite simple, but potentially very powerful: it applies directly to any model for which the Slavnov formula for wavefunction overlaps is explicitly known and allows us, at least in principle, to reconstruct the exact subsequent time evolution of wavefunctions, operator expectation values and time-dependent correlation functions via techniques similar to the ones used in the equilibrium case. On the practical side, since the energy of the states populated by the geometric quench can be obtained nonperturbatively, results can be accurately given for arbitrarily long times after the quench. Moreover, since eigenstates can be parameterized in terms of a set of quantum numbers $\{I_j\}^{N_2}$ via the logarithmic Bethe equations, efficient truncations of the required Hilbert space sums can be implemented. An important observation is

$$\text{doi:10.1088/1742-5468/2010/09/L09001}$$
that the overlap $F_1(\{\mu\}_{\alpha_2}^{N_2}; \{\lambda\}_{\alpha_1}^{N_1})$ as a function of $\{\mu\}_{\alpha_2}^{N_2}$ (without the restriction that they are a solution of the Bethe equations) has a maximum for $\{\mu\}_{\alpha_2}^{N_2} = \{\lambda\}_{\alpha_1}^{N_1}$. This maximum is simply the rescaled norm of the initial state. By plugging the rapidities $\{\lambda\}_{\alpha_1}^{N_1}$ into the logarithmic Bethe equations for the system parameterized by $N_2$ and $\alpha_2$ a set $\{\tilde{I}_j\}_{\alpha_2}^{N_2}$ is obtained. These numbers will, in general, not be proper quantum numbers. However, rounding them off to the closest admissible quantum numbers will generate a pool containing states with the highest overlaps. More states can be included by considering particle–hole excitations onto this pool of states. In forthcoming publications this truncation scheme will be applied to a number of specific cases.
