Keywords: HIV reverse transcriptase; drug resistance; HIV-2; TAMs; AZT

ABSTRACT

Nucleoside reverse transcriptase (RT) inhibitors (NRTIs) are the backbone of current antiretroviral treatments. However, emergence of viral resistance against NRTIs is a major threat to their therapeutic effectiveness. In HIV-1, NRTI resistance-associated mutations either reduce RT-mediated incorporation of NRTI triphosphates (discrimination mechanism) or confer an ATP-mediated nucleotide excision activity that removes the inhibitor from the 3’-terminus of DNA primers, enabling further primer elongation (excision mechanism). In HIV-2, resistance to zidovudine (AZT, 3’-azido-3’-deoxythymidine) and other NRTIs is conferred by mutations affecting nucleotide discrimination. Mutations of the excision pathway such as M41L, D67N, K70R, or S215Y (known as thymidine-analogue resistance mutations [TAMs]) are rare in virus from HIV-2–infected individuals. Here, we demonstrate that mutant M41L/D67N/K70R/S215Y HIV-2 RT lacks ATP-dependent excision activity, and recombinant virus containing this RT remains susceptible to AZT inhibition. Mutant HIV-2 RTs were tested for their ability to unblock and extend DNA primers terminated with AZT or other NRTIs, when complexed with RNA or DNA templates. Our results show that Met73 and, to a lesser extent, Ile75 suppress excision activity when TAMs are present in the HIV-2 RT. Interestingly, recombinant HIV-2 carrying a mutant D67N/K70R/M73K RT showed 10-fold decreased AZT susceptibility, and increased rescue efficiency on AZT- or tenofovir-terminated primers, as compared with the double-mutant D67N/K70R. Molecular dynamics simulations reveal that Met73 influences β3–β4 hairpin loop conformation, while its substitution affects hydrogen bond interactions at position 70, required for NRTI excision. Our work highlights critical HIV-2 RT residues impeding the development of excision-mediated NRTI resistance.

INTRODUCTION

Although the human immunodeficiency virus type 1 (HIV-1) is responsible for most of the global AIDS pandemic, it has been estimated that one to two million people are infected with HIV type 2 (HIV-2) worldwide (1). HIV-2 is endemic in West Africa but it is also found in regions of Western Europe, India, Brazil and South Africa. HIV-2 has a longer asymptomatic phase and shows slower progression to AIDS in comparison with HIV-1 (2). However, fewer treatment options are available for those infected with HIV-2. Nonnucleoside reverse transcriptase (RT) inhibitors, the fusion inhibitor enfuvirtide and several protease inhibitors approved for treatment of HIV-1 infection are ineffective against HIV-2 (3,4). In contrast, HIV-1 and HIV-2 show similar susceptibilities to nucleoside RT inhibitors (NRTIs) (5). Those drugs constitute the backbone of current therapies against infections caused by both types of HIV (6).
HIV RTs are heterodimeric enzymes that convert the single-stranded RNA genome into a double-stranded DNA that can be integrated in the host cell genome (7,8). RTs have two catalytic activities: (i) a DNA polymerase activity that uses RNA or DNA as templates, and (ii) a ribonuclease H (RNase H) activity that degrades RNA from RNA/DNA hybrids. NRTIs are converted to triphosphate derivatives inside the cell and incorporated into the DNA by the polymerase activity of the RT. Further DNA synthesis is then blocked due to the absence of a 3’OH in the ribose moiety of the NRTI (9). Although HIV-1 and HIV-2 share some NRTI resistance mutations, clinical studies have shown that NRTI resistance emergence is faster in HIV-2.

In HIV-1, NRTI resistance can be achieved through a discrimination mechanism (i.e. changes in the RT’s ability to incorporate nucleoside analogues versus natural dNTP substrates) or by an excision mechanism by which NRTI-resistant RTs are able to remove the inhibitor from the 3’-end of the primer, thereby allowing the extension of the unblocked DNA chain (10,11; reviewed in refs. 6,9). The excision reaction requires a pyrophosphate donor which in most cells is ATP. It is most efficient for primers terminated with thymidine analogues (zidovudine (AZT, 3’-azido-3’-deoxythymidine) or stavudine (d4T, 2’,3’-didehydro-2’,3’-dideoxythymidine)) or tenofovir (12-14). Amino acid substitutions conferring resistance to NRTIs through the excision pathway are M41L, D67N, K70R, L210W, T215F or T215Y, and K219E or K219Q (15), which are widely known as TAMs (thymidine analogue resistance mutations). In patients receiving long-term therapy, TAMs appear in two clusters: TAM1 (M41L, T215Y) and TAM2 (D67N, K70R, K219E/Q, and sometimes T215F) (16). M41L/T215Y in TAM1 or D67N/K70R in TAM2 are needed to achieve significant ATP-dependent excision activity (11,17). Amino acid changes in the HIV-1 RT that antagonize the effects of TAMs in excision while increasing NRTI susceptibility have been found at the dNTP binding site (e.g. K65R, L74V, V75I, and M184V), the nonnucleoside RT inhibitor binding site (e.g. L100I or Y181C), or have been related to foscarnet resistance (e.g. W88G, E89K, L92I and S156A) (for a review, see ref. 6).

K65R, Q151M (sometimes accompanied by V111I) and M184V are the major mutations conferring resistance to NRTIs in HIV-2 (18,19). The combination K65R/Q151M/M184V confers class-wide nucleoside analogue resistance (20). Amino acid substitutions in this complex affect residues of the dNTP binding site in the DNA polymerase domain of the RT, and biochemical studies carried out with the HIV-1 enzyme showed that those changes interfered with the incorporation of nucleotide analogues (reviewed in ref. 9). On the other hand, TAMs are difficult to select in cell culture after HIV-2 passage in the presence of AZT (21), and are found with a very low prevalence in HIV-2 obtained from patients treated with AZT and other nucleoside analogues (22,23; reviewed in ref. 24). HIV-1 and HIV-2 RTs have similar levels of DNA polymerase activity but the HIV-2 enzyme incorporates AZT-triphosphate (AZTTP) less efficiently than HIV-1 RT and shows a much lower ability to excise the inhibitor in the presence of ATP (25). Moreover, substituting Tyr for Ser215 in the HIV-2 RT did not increase its ATP-dependent phosphorolytic activity but had a detrimental effect on polymerase activity (26). In those studies, authors speculated with the possibility that selection of TAMs would be detrimental for HIV-2 RT function, and this would justify why the excision mechanism has a negligible influence in HIV-2 resistance to NRTIs. On the other hand, the presence of Ile25 in HIV-2 RT instead of Val as in HIV-1 RT could be responsible in part for the lack of the excision-based resistance mechanism, as suggested by the antagonistic effect of V75I when combined with TAMs in the context of an excision-proficient HIV-1 RT (27). The presence of Ile25 is expected to facilitate the selection of Q151M, since this substitution together with A62V, V75I, F77L and F116Y forms the ‘Q151M complex’ that in HIV-1 confers resistance to all approved NRTIs except tenofovir (28,29).

In this work, we show that HIV-2 ROD RT with the four classical TAMs (M41L/D67N/K70R/S215Y) has negligible ATP-dependent excision activity. Despite the high level of amino acid sequence similarity between HIV-1 and HIV-2 RTs, there are important differences in their primary structures that affect residues in the β3-β4 hairpin loop (i.e. at positions 63-73), and around Tyr215, in addition to residues elsewhere that in HIV-1 have an antagonistic effect on TAMs.
The systematic replacement of HIV-2 RT residues by those found in the HIV-1 RT and the subsequent analysis of the ATP-dependent excision activity of the resulting RTs, using different NRTIs and template/primers, shows that Met\textsuperscript{73} in HIV-2 RT (instead of Lys as found in HIV-1 RT) acts as a molecular barrier that curbs the possibility of developing HIV-2 resistance through the accumulation of TAMs.

**RESULTS**

HIV-1\textsubscript{BH10} and HIV-2\textsubscript{ROD} RTs share 61% amino acid sequence identity. The crystal structures of AZT-resistant HIV-1 RT containing TAMs M41L, D67N, K70R, T215Y and K219Q in its unliganded form, in complex with AZT-terminated DNA/DNA template/primers, and with double-stranded DNA and AZT adenosine dinucleoside tetraphosphate (AZTppppA) (30) showed that TAMs at positions 67, 70 and 219 contribute to the proper orientation of the pyrophosphate moiety during ribonucleotide-dependent nucleotide excision, while Tyr\textsuperscript{215} interacts with the adenine moiety in AZTppppA and defines the ATP binding site. Based on the available crystal structures and previous work with mutant RTs having insertions and deletions in the β3-β4 hairpin loop (31,32), we hypothesized that the major determinants of the excision activity in AZT-resistant RTs locate within residues 60-76 (β3-β4 hairpin loop and adjacent residues of β-strands 3 and 4), and around position 215. The amino acid sequences of HIV-1 and HIV-2 RTs show differences at those regions (Figure 1a). In addition, HIV-1 and HIV-2 RTs differ at specific positions that were previously shown to modulate the excision reaction in the presence of TAMs. Thus, previous studies demonstrated that by themselves V75I, W88G and Y181C decrease the ATP-dependent excision activity of HIV-1 RTs carrying TAMs (reviewed in ref. 6). The wild-type (WT) HIV-2\textsubscript{ROD} RT contains Ile\textsuperscript{75}, Thr\textsuperscript{88} and Ile\textsuperscript{181} instead of Val, Trp and Tyr, as found in the HIV-1 RT. These differences could be also responsible for the suppression of the excision activity in HIV-2 RTs. Based on those observations, we obtained HIV-2\textsubscript{ROD} RT variants whose amino acid sequences are given in Figure 1b. They included enzymes where the sequence of the β3-β4 hairpin loop of the HIV-1\textsubscript{BH10} RT was introduced in the HIV-2\textsubscript{ROD} RT together with TAMs M41L and T215Y (e.g. 5M\textsubscript{STK}), others that contained different substitutions in the 210-215 sequence (e.g. 5M\textsubscript{LRWL}), or combinations of mutations including potential antagonists of TAMs such as I75V, T88W or I181Y. The enzymes were purified and tested for their ability to remove thymidine analogues and tenofovir, in rescue assays carried out with RNA/DNA and DNA/DNA template/primers.

**Identification of suppressors of the ATP-dependent unblocking activity of DNA primers terminated with AZT or tenofovir in the HIV-2 RT** – The ability of HIV-2\textsubscript{ROD} RTs to rescue AZTMP-terminated primers in the presence of ATP (3.2 mM) was first assessed with the RNA/DNA template/primer 31Trna/21P (Figure 2). Reactions were carried out in two steps. First, the RT and the RNA/DNA hybrid were incubated in the presence of inhibitor (AZTTP) to generate a blocked 22-nucleotide primer. Then, the addition of dNTPs and ATP (the pyrophosphate donor) facilitated unblocking and further extension of the primer to obtain a product of 31 nucleotides. In these assays, the HIV-1\textsubscript{BH10} RT that contained TAMs M41L and T215Y (LY_HIV-1) showed relatively high levels of excision activity. In contrast, the WT HIV-2\textsubscript{ROD} RT and the quadruple mutant M41L/D67N/K70R/S215Y (4M RT) showed almost negligible activity in the presence of 3.2 mM ATP.

Although Asp\textsuperscript{67} and Lys\textsuperscript{70} are conserved in HIV-1 and HIV-2 RTs, there are differences at four residues of the β3-β4 hairpin loop region of both polymerases. By introducing the amino acids found at positions 68, 69, 73 and 75 in HIV-1\textsubscript{BH10} RT in the sequence context of the 4M HIV-2 RT we obtained enzymes with high ATP-dependent excision activity (Figure 2). The substitution of Lys for Met\textsuperscript{73} in the HIV-2\textsubscript{ROD} RT had the largest impact on rescue activity among all tested polymerases. Thus, mutants 5M\textsubscript{STK} and 5M\textsubscript{SK} showed efficiencies that were almost two-fold higher than those obtained with the reference HIV-1\textsubscript{BH10} RT mutant M41L/T215Y, and well above the efficiencies of the WT HIV-2\textsubscript{ROD} RT. Other RTs showed lower ATP-dependent excision activities. However, substituting Val\textsuperscript{75} for Ile in the 4M RT produced a modest but significant increase in rescue efficiencies. The subsequent addition of K68S and/or N69T, several combinations of mutations in the vicinity of Tyr\textsuperscript{215}, or substitutions...
with a potential antagonistic effect on TAMs (i.e. T88W and I181Y) had a minor effect on DNA primer rescue catalyzed by the 5M RT mutant enzyme.

Similar assays carried out with a DNA/DNA complex containing an AZTMP-terminated primer also revealed that the substitution of Lys for Met73 in the HIV-2ROD RT had a large impact in the rescue activity of the polymerase (Supplementary Figure S1). Mutant derivatives containing M73K (i.e. 5M_SK and 5M_STK) rescued between 30 and 35% of the AZTMP-terminated primers after incubating the template/primer and the RT for 20 min in the presence of ATP and dNTPs. On the other hand, 5M, 5M_K68S and 5M_ST RTs had lower excision activity (<14%) under the same conditions. Nevertheless, these three enzymes showed a modest increase in rescue activity in comparison with the 4M RT. This could be attributed to the substitution of Val for Ile75 that could facilitate excision by neutralizing the small but significant antagonistic effect of Ile75. As in the case of experiments carried out with the RNA/DNA hybrid, T88W and I181Y had a minor effect on DNA primer rescue when combined with I75V and other TAMs, although we observed a slight increase with the substitution I181Y. In contrast, none of the mutations located in the vicinity of Tyr215 seemed to affect the rescue activity of the 5M mutant, since all tested HIV-2 RT variants showed rescue activities below 14%, after 20 min-incubation in the presence of ATP and dNTPs.

In general, removal of AZTMP and further extension of the unblocked primer was more efficient with the RNA template than with the DNA template for all tested RTs. Analysis of the efficiencies of the rescue reactions with different RTs and the 31Trna/21P complex confirms the suppressor effect of Ile75, since mutant 5M shows higher rescue activity than 4M, although the addition of K68S and N69T produced a slight but non-significant increase in rescue efficiency. In any case, the effects of those substitutions were relative small in comparison with the addition of M73K.

The ATP-dependent rescue activity was also tested with all mutants using tenofovir-terminated primers and the DNA/DNA hybrid D38T/25PGA (Supplementary Figure S2). The observed ranking of rescue efficiencies was similar to those obtained with AZT-terminated primers, supporting the notion that the inhibitor had a minor impact on the relative excision activity of the RTs. The amounts of rescued primer obtained with the WT HIV-2 RT and its mutant derivative 4M were very small. Again, the presence of the additional substitution I75V produced a significant increase in tenofovir excision and further extension of the unblocked primer. This effect was reduced if other β3-β4 hairpin substitutions such as K68S or N69T were added to the mutational complex. However, in those cases, addition of M73K rendered excision-proficient RTs with rescue efficiencies higher than those observed for the well-characterized HIV-1BH10 RT mutant M41L/T215Y (LY_HIV-1).

**ATP-dependent rescue activities of WT and mutant HIV-2 RTs**

- **Assays described above have consistently shown that M73K and in a lesser extent I75V facilitate rescue of NRTI-terminated primers by TAM-containing HIV-2 RTs. However, those assays combine excision with DNA primer extension. In Figure 3 we show that I75V confers some ATP-dependent excision activity on primers terminated with AZT when added to the 4M complex, while the subsequent addition of M73K (in combination with K68S) results in a further enhancement of the excision activity. Interestingly, the effects of I75V were not observed in ATP-dependent excision reactions carried out with primers terminated with d4TMP. Mutants 5M, 5M_K68S and 4M and the WT HIV-2 enzyme showed negligible activity \( k_{\text{obs}} < 1.6 \times 10^{-3} \text{ min}^{-1} \). However, addition of the M73K substitution to the 5M_K68S complex rendered an RT with significant excision activity, and showing a \( k_{\text{obs}} \) of \( 5.8 \times 10^{-3} \text{ min}^{-1} \). Taken together, the enzymatic assays reveal the strong effect of Met73 in the context of HIV-2ROD RTs bearing TAMs, by suppressing NRTI excision.

**M73K restores ATP-dependent rescue activity of HIV-2 RT bearing TAMs D67N and K70R**

- Unlike in HIV-1 (11,32), the double mutant D67N/K70R HIV-2 RT has very low or negligible rescue activity on primers terminated with AZT either in RNA/DNA or in DNA/DNA template/primer complexes (Figure 4a,b). As expected, M73K alone had no effect on the unblocking and
extension reactions and showed a phenotype similar to that obtained with the WT HIV-2 RT. The three RTs showed significant DNA polymerization activity in single-nucleotide incorporation assays, carried out with template/primer D38/25PGA, under steady-state conditions. In those reactions, the turnover rates ($k_{cat}$) for WT HIV-2 RT, and mutants D67N/K70R and D67N/K70R/M73K were 7.19 ± 0.82 min$^{-1}$, 3.87 ± 0.43 min$^{-1}$ and 3.42 ± 0.19 min$^{-1}$, respectively.

The only available crystal structure of HIV-2 RT (Protein Data Bank (PDB) file 1MU2) has an overall folding similar to that of the HIV-1 RT (33) but has no ligands and is incomplete, lacking several key loops. Therefore, for modeling purposes, we used the crystal structure of a ternary complex of HIV-1 RT, double-stranded DNA and dTTP (PDB file 1RTD). Structural models of catalytically competent WT and mutant HIV-1 RTs were obtained after refinement by molecular dynamics. In HIV-1 RT, residue 73 is Lys instead of Met as occurs in the HIV-2 enzyme (Figure 1). The structural models of mutant HIV-1 RTs D67N/K70R and D67N/K70R/K73M were compared with the one previously obtained for the catalytically competent WT HIV-1 RT (34).

As shown in the Supplementary Figure S3A, root-mean-square deviations (rmsd) corresponding to the backbone $C_\alpha$ atoms of the modeled ternary complexes remained below 2.4 Å. Superimpositions of the simulated structures were consistent with the results of the rmsd analysis, although significant differences were observed between the conformation of the $\beta_3$-$\beta_4$ hairpin loop of D67N/K70R/K73M and the equivalent structures of the WT HIV-1 RT and mutant D67N/K70R (Supplementary Figure S4A). Mutations did not affect critical interactions required to maintain the catalytic attack distance between the $3^{'}-OH$ of the primer and the $\alpha$ phosphorous (Supplementary Figure S3B). At the end of the simulation, interactions in the catalytic site of the ternary complex containing two Mg$^{2+}$ ions were similar for the three studied RTs (Supplementary Figure S4).

Molecular dynamics simulations showed that the position of Arg$^{30}$ was largely affected by substitutions at the $\beta_3$-$\beta_4$ hairpin loop. Interestingly, in the double mutant D67N/K70R, distances between the $\zeta$ carbon of Arg$^{30}$ and the $\gamma$ phosphorous of the dNTP remained stable and below 4.5 Å, and were compatible with the establishment of hydrogen-bonding interactions between the amido groups of Arg$^{30}$ and the hydroxyl substituents of the dNTP $\gamma$ phosphate (32). These interactions were not predicted for RTs devoid of excision activity, such as the WT enzyme or a mutant RT having a single amino-acid deletion at position 69 (32). Interestingly, in the D67N/K70R/K73M HIV-1 RT model, the side chain of Arg$^{30}$ moved away from the dNTP binding site (Figure 5) leading to the loss of the hydrogen bonding network involved in the excision reaction. The side chain of Lys$^{73}$ points towards the incoming nucleotide in the structure of the double-mutant. However, its substitution by Met$^{73}$ produces an internal rearrangement in the fingers subdomain of the RT that results from the establishment of hydrophobic interactions between the side-chains of Val$^{69}$ and Met$^{73}$. These interactions affect the positioning of $\beta_3$ and $\beta_4$ strands, and influence folding at the tip of the hairpin loop.

Further support of the role of Lys$^{73}$ in nucleotide excision was obtained by comparing the rescue efficiencies of HIV-1 RT mutants D67N/K70R and D67N/K70R/K73M. As shown in Figure 6, the triple-mutant had almost negligible activity, while D67N/K70R rescued about 16% of the AZTMP-terminated primers after incubating the blocked D38/25PGA complex for 20 min in the presence of 3.2 mM ATP. These rescue efficiencies were observed for the mutant RT D67N/K70R, at ATP concentrations as low as 1 mM.

**Antiretroviral drug susceptibility of recombinant HIV-2** – Susceptibility to AZT was determined in MT-4 cells for selected HIV-2 mutants in order to test whether the results obtained in rescue and excision assays correlated with phenotypic drug susceptibility of recombinant HIV-2. As shown in Table 1, the presence of the four classical TAMs (M41L/D67N/K70R/S215Y) in HIV-2 did not produce an AZT-resistant virus (i.e. compare 4M vs. WT HIV-2ROD). However, substituting Val$^{75}$ for Ile (5M mutant) decreased AZT susceptibility almost 4 times. Other substitutions in the $\beta_3$-$\beta_4$ hairpin loop had no significant effect on thymidine analogue resistance, although we were unable to show the effects of M73K when multiple amino acid substitutions were introduced in the HIV-2 RT. Recombinant HIV-2 with RTs 5M_SK and
5M_STK were not viable and unable to replicate in MT-4 cells. Nevertheless, a 10-fold increase in the IC\textsubscript{50} for AZT was observed for the triple mutant D67N/K70R/M73K HIV-2 RT when compared with the double mutant D67N/K70R. These data are consistent with the biochemical assays showing that amino acid substitutions M73K and in a lesser extent I75V confer resistance through increased primer-unblocking activity on AZT-terminated primers.

**DISCUSSION**

In HIV-1, high-level AZT resistance develops through the accumulation of TAMs in the viral RT. These amino acid substitutions confer an excision activity that enables the polymerase to unblock DNA primers terminated with AZT and other NRTIs, and resume DNA synthesis. The excision reaction takes place in the presence of a pyrophosphate donor (usually ATP). However, in HIV-2 this pathway is suppressed, and TAMs are rarely observed in treated individuals (23,35-39). In HIV-2 RT, AZT resistance is usually conferred by Q151M despite the fact that S215F/Y, a key mutation in the excision mechanism requires only one nucleotide change, in contrast to HIV-1, where two mutations are needed to generate the equivalent substitution (i.e. T215F/Y). Q151M occurs at the nucleotide binding site and affects the enzyme’s ability to discriminate between NRTI-triphosphates and dNTPs (40).

Our results demonstrate that the major determinants that suppress resistance through the excision pathway in HIV-2 are located adjacent to the β3-β4 hairpin loop, at positions 73 and 75 of the RT. HIV-2 RT bearing the four major TAMs (M41L/D67N/K70R/S215Y) lacks ATP-dependent excision activity and fails to unblock and extend primers terminated with AZT or tenofovir. However, when the HIV-1 RT sequence NSTRWRKLV (residues 67-75) was introduced at the equivalent positions of the HIV-2 RT in combination with TAMs M41L and S215Y, the enzyme was turned into an excision-proficient RT. Interestingly, our mutagenesis analysis shows that major contributors to this phenotype are Lys\textsuperscript{73} and in a lesser extent Val\textsuperscript{75}. The presence of Ile\textsuperscript{75} in HIV-2 may favor the acquisition of resistance through the discrimination pathway since V75I is part of the multi-NRTI resistance Q151M complex of HIV-1 RT (28), and V75I antagonizes the effect of TAMs in HIV-1 RT (27). As in HIV-1, development of Q151M in HIV-2 requires at least two nucleotide changes with potential viable intermediates bearing amino acid substitutions Q151I or Q151L (38,41,42). Residues in the vicinity of Tyr\textsuperscript{215}, or amino acid substitutions with a potential antagonistic effect on TAMs do not seem to have a major impact on HIV-2 NRTI resistance through the excision mechanism. These results are in agreement with previous findings showing that HIV-2 RT mutants S215Y and F214L/S215Y had negligible excision activity on NRTI-terminated DNA primers (26).

Met\textsuperscript{73} in HIV-2 RT plays a critical role in the suppression of the excision pathway. All HIV-2 RT mutants having the substitution M73K were excision-proficient in biochemical assays. However, HIV-2 variants carrying this substitution in the RT showed impaired viral replication, rendering non-viable virus in those cases where HIV-2 contained mutant RTs 5M_SK and 5M_STK. Although HIV-2 RT variants with the substitution M73K were active in biochemical assays, we found that those mutated enzymes were prone to degradation, and therefore additional purification steps had to be introduced to obtain enzymes of highest purity. In HIV-1 RT, random mutagenesis studies have shown that Lys\textsuperscript{73} can be replaced by many different amino acids (even non-conservative substitutions) while maintaining catalytic activity, although Met was not identified among the recovered active mutants (43). On the other hand, Lys\textsuperscript{73} is absolutely conserved in all groups and subtypes of HIV-1, while Met\textsuperscript{73} is conserved in all HIV-2 groups as well as in major SIV species (e.g. mac, mne, smm) (44).

Our results showing that M73K could confer HIV-2 RT significant ATP-dependent rescue activity in enzymatic assays in the presence of D67N/K70R, and decreased AZT susceptibility to the corresponding recombinant virus raise the question of how Lys\textsuperscript{73} could affect the conformation of the β3-β4 hairpin loop and the interactions needed for NRTI removal. Previous molecular dynamics studies with insertion- and deletion-containing HIV-1 RTs had revealed that changes at positions 67 and 70 affected critical hydrogen bond interactions between amido groups of Arg\textsuperscript{76} and the hydroxyl substituents of the dNTP γ phosphate (32). These interactions that could be
established in the mutant D67N/K70R RT, were consistent with the formation of equivalent hydrogen bonds in the crystal structure of the excision-proficient HIV-1 RT M41L/D67N/K70R/T215Y/K219Q, complexed with AZT-terminated DNA/DNA template/primers, and AZTppppA (30).

In contrast, when we replaced Met for Lys73 in the HIV-1 RT D67N/K70R model and performed molecular dynamics simulations, there were remarkable conformational changes that eventually led to the loss of the potential hydrogen bond between Arg70 and the incoming dNTP. This proposal is consistent with the results of rescue assays carried out with AZTMP-terminated primers that showed that unlike the double-mutant D67N/K70R, the HIV-1BH10 RT D67N/K70R/K73M had negligible ATP-dependent phosphorolytic activity (Figure 6).

According to the molecular models, the hydrophobic side-chain of Met73 moves away from the dNTP binding site into the hydrophobic core of the RT, to interact with Val60. Interestingly, Val or Ile are found at this position in all HIV-1 strains, while Thr60 is highly conserved in all HIV-2 and SIV variants. The interaction between Met73 and Thr60 is likely to be stabilized through hydrogen bonding and/or hydrophobic interaction of their side chains. Therefore, the presence of Thr60 in the HIV-2 RT would be an additional restriction to the development of NRTI resistance through the excision pathway, if wild-type Met73 is replaced by Lys.

Apart from their influence on nucleoside analogue resistance, differences in the conformation of the β3-β4 hairpin loop may also affect other properties of the HIV-2 RT DNA polymerase activity. Recently, we showed that the tenofovir resistance-associated mutation K65R that confers increased fidelity of DNA synthesis in HIV-1 group M and group O RTs, had no effect on the accuracy of the enzyme when introduced in the HIV-2 RT (45). This result was consistent with a previous report showing relative minor differences in the mutation rates determined for WT and K65R RT-containing SIVmac239 infecting pigtailed macaques (46). Interestingly, the amino acid sequence of the β3-β4 hairpin loop region is identical in HIV-2 and SIVmac239 RTs.

Despite having similar NRTI susceptibilities, our work underlines the important differences between HIV-1 and HIV-2 RTs, including the development of resistance through different pathways. However, these differences can be mapped to a couple of residues and suggest that genotypic monitoring for the emergence of mutations affecting the β3-β4 hairpin loop will be needed in the long run to prevent the eventual emergence of HIV-2 NRTI resistance through the excision pathway. In any case, continuing efforts in the development of anti-HIV-2 drugs are needed to overcome limitations imposed by the reduced armamentarium of antiretroviral drugs available to combat HIV-2 infection.

**EXPERIMENTAL PROCEDURES**

Expression and purification of RTs – WT heterodimeric (p66/p51) HIV-1BH10 RT and mutants M41L/T215Y, D67N/K70R and D67N/K70R/K73M were purified as previously described (47-49). Histidine-tagged WT and mutant HIV-2ROD RTs were obtained as p68/p54 heterodimers after co-expression of the p68-coding region of the HIV-2ROD RT together with the HIV-2 protease, using constructs derived of plasmid pT5m (50). HIV-2 RT heterodimers were purified by immobilized metal affinity chromatography on Ni2+-nitriloacetic acid-agarose, followed by ionic exchange chromatography (45). Before dialysis and concentration, the purity of the enzyme was tested by SDS-polyacrylamide gel electrophoresis. Before biochemical studies, RT concentrations were determined by active site titration (51,52). Steady-state kinetics of nucleotide incorporation were determined with 32P-labeled D38/25PGA complexes, under conditions previously described (53).
the large subunit of the HIV-2ROD RT was used as template (50) to obtain the HIV-2 RT mutants. Complementary mutagenic primers (Supplementary Table S1) were used to amplify the entire pT5m(RODRT) plasmid in a thermocycling reaction carried out with high-fidelity Pfu DNA polymerase. Mutant RTs were constructed in an orderly manner. First, we obtained the double-mutant D67N/K70R that was used as template to generate the M41L/D67N/K70R/S215Y mutant. The I75V substitution was introduced in this construct to obtain M41L/D67N/K70R/I75V/S215Y, a quintuple-mutant that was then used to generate derivatives containing one additional mutation, such as K68S, T88W, I181Y, N210L or N210W. The complex M41L/D67N/K68S/K70R/I75V/S215Y was used as template to introduce additional mutations such as N69T, M73K or N69T/M73K. The combination G211R/L212W was introduced in the context of M41L/D67N/K70R/I75V/N210L/S215Y, and the obtained plasmid was used as template to generate the mutant M41L/D67N/K70R/I75V/N210L/G211R/L212W/F214L/S215Y. HIV-1BH10 mutants D67N/K70R and D67N/K70R/K73M were obtained by following the same protocol, but using plasmid p66RTB as template (48,49) and the corresponding mutagenic primers listed the Supplementary Table S1. All constructs were verified by DNA sequencing.

Nucleotides and template/primers – Stock solutions (100 mM) of dNTPs and rNTPs were obtained from GE Healthcare. AZTTP was purchased from Trilink Biotechnologies (San Diego, CA). Tenofovir diphosphate (tenofovir-DP) and stavudine triphosphate (d4TTP) were obtained from Toronto Research Chemicals (Toronto, Canada) and Sierra Bioresearch (Tucson, AZ), respectively. Before use, nucleoside triphosphates were treated with inorganic pyrophosphatase (Roche) to remove traces of pyrophosphate, as described (13). DNA oligonucleotides 21P (5’-ATACTTTAACATATGTACCC-3’), 25PGA (5’-TGTTAGGGCTATACATTCTTGCAGG-3’), D38 (5’-GGGTCCCTTCTACCTGCAAGAATGTATA GCCCTACCA-3’), and the RNA oligonucleotide 31Trna (5’-UUUUUUUUAGGAUCAAUUGGUAAAG UAU-3’) were obtained from Life Technologies and Sigma. Primer oligonucleotides were labeled at their 5’ termini with 1-2 µCi of [γ-32P]ATP (10 mCi/ml; 3000 Ci/mmol, Perkin Elmer) and 5 units of T4 polynucleotide kinase (New England Biolabs) in 70 mM Tris-HCl pH 7.6 buffer, containing 10 mM MgCl2 and 5 mM DTT. Template/primer solutions were prepared at 300 nM in 500 mM Hepes pH 7.0 buffer, containing 150 mM magnesium acetate and 150 mM NaCl.

Chain terminator excision assays – RT-catalyzed DNA rescue reactions were carried out as previously described with template/primers D38/25PGA, D38T/25PGA, and 31Trna/21P (54,55). Reactions were carried out in 70 mM Hepes pH 7.0 buffer containing 20 mM magnesium acetate, 20 mM NaCl, 130 mM potassium acetate, 1 mM DTT and 5% (w/v) polyethylene glycol 6000. First, labeled template/primers (75 nM) were preincubated with the corresponding RT (60 nM active enzyme concentration) at 37ºC for 10 min. Primers were then blocked by adding an equal amount of buffer containing AZTTP or tenofovir-DP, at a final concentration of 25 µM, and incubated at 37ºC for 30 min. Rescue reactions were initiated by adding a mixture of all dNTPs in the presence of 3.2 mM ATP. In rescue assays carried out with DNA/DNA template/primers, dNTPs were supplied at 100 µM (final concentration), except dATP (with D38/25PGA) or dTTP (with D38T/25PGA) whose concentration was kept at 1 µM in order to minimize the inhibitory effect of the next complementary dNTP, caused by the formation of “dead-end” complexes (9,56). Inhibitor and dNTP concentrations were two-fold higher in assays carried with the RNA/DNA template/primer 31Trna/21P. After addition of dNTPs and the pyrophosphate donor, reactions were incubated for up to 20 min at 37ºC to facilitate nucleotide excision and primer elongation. Aliquots were removed at appropriate times and reactions were stopped by adding an equal amount of sample loading buffer (10 mM EDTA in 90% formamide containing 3 mg/ml of xylene cyanol FF and 3 mg/ml of bromphenol blue). Products were resolved on denaturing 20% (w/v) polyacrylamide/8M urea gels, and primer rescue was quantified by phosphorimaging with a BAS 1500 scanner (Fuji), using the program Tina.
version 2.09 (Raytest Isotopenmessgerate GmbH, Staubenhardt, Germany).

Kinetics of the ATP-dependent excision reaction – The kinetics of the excision reaction were monitored with template/primers D38/25PGAd4TMP and D38/25PGAd4TMP, obtained after blocking the primer with nucleotide analogues with terminal deoxynucleotidyltransferase (Roche) or WT HIV-1BH10 RT, respectively (13,53). AZTMP and d4TMP excision was determined by using template/primers D38/25PGAAZTMP and D38/25PGAd4TMP, respectively. To ensure single turnover conditions we used an excess of enzyme over template/primer. Thus, RTs (80 nM) and blocked template/primers (60 nM) were preincubated at 37°C for 10 min, in 0.11 M Hepes pH 7.0 buffer, containing 30 mM NaCl, 30 mM magnesium acetate, 130 mM potassium acetate, 1 mM DTT and 5% (w/v) polyethylene glycol 6000. Reactions were initiated by adding one volume of a solution containing 6.4 mM ATP in 130 mM potassium acetate, 1 mM DTT and 5% (w/v) polyethylene glycol 6000. Excision reactions were carried out for 0 to 80 min at 37°C and aliquots were removed at appropriate times, stopped with sample loading buffer and analyzed by denaturing polyacrylamide gel electrophoresis as described above. The amount of hydrolyzed product generated over time was fitted to a single exponential decay equation: 
\[
[P] = A \times e^{-k_{obs} x t},
\]
where \(k_{obs}\) is apparent kinetic constant of the excision reaction.

HIV drug susceptibility assays – AZT and darunavir susceptibility assays were carried out with infectious HIV-2 clones generated in this study, and with previously described recombinant HIV-1 carrying either the WT BH10 RT or a double-mutant M41L/T215Y RT (49). To generate infectious HIV-2 carrying the different RT variants, we prepared three DNA fragments by PCR covering the full-length HIV-2 proviral DNA. These three PCR DNA fragments overlap 31-35 base pairs and after transfection of susceptible MT-4 cells they were able to generate infectious HIV-2 particles (57). Template for fragments I and III (HIV-2ROD strain nucleotides 1-2421 and 4019-9671, respectively) was proviral DNA obtained from MT-4 cells infected with HIV-2ROD (Centre for AIDS Reagents, NIBSC, ID: 0121) (58). Fragment II, corresponding to HIV-2 RT (HIV-2ROD nucleotides 2381-4049), was obtained by PCR from the RT expression plasmids described above. PCR oligonucleotides for fragments I, II and III were 1HIV-2RODF (5'-GGTGCCTTGGAGGAGGCT-3', HIV-2ROD nts 1-20) and 2HIV-2RODR (5'-GGCTTTAGCATTATTTTTAGTGCTACTTTGCGC-3', HIV-2ROD nts 2384-2421), 2HIV-2RODF (5'-GCCAAAGTAGCCCAATAAAATATGCTAAGCC-3', HIV-2ROD nts 2384-2421) and 3HIV-2RODF (5'-GTCTGATACCTGAGCTCAGTCTAAATGTCTAAGG-3', HIV-2ROD nts 9645-9671), respectively. Proviral DNA was purified using the QuickExtract DNA extraction protocol (Epicentre Biotechnologies). Cycling parameters were 1 cycle of denaturation at 94°C for 2 min, followed by 40 cycles of 45 s at 95°C, 45 s at 55°C, and 2-6 min at 68°C, with a final extension step of 68°C for 7 min. High fidelity Platinum Taq DNA Polymerase (Thermofisher) was used for PCR amplifications. After PCR purification (QIAquick PCR Purification Kit, Qiagen), 100 ng of each of the three PCR fragments were co-transfected into MT-4 cells as we previously described (32). Cell culture supernatants were harvested on days 3, 5, and 7 after transfection when the concentration of HIV-1 p24 antigen (Innotest HIV Antigen mAB, Fujirebio) surpassed 500 ng/ml. If p24 antigen was not detected after 7 days of culture, three blind passages, feeding the cultures with fresh medium and new MT-4 cells, were performed to recover viable virus. The nucleotide sequence of the RT-coding region of the progeny virus was checked for possible reversions or undesired mutations. After three blind passages without p24 antigen detection in the cultured supernatant, the construct was considered nonviable in MT-4 cell culture. Susceptibility to AZT and darunavir was determined in MT-4 cells as previously described (49), using a multiplicity of infection of 0.003. Viable cells at different drug concentrations were quantified with a tetrazolium-based colorimetric method (59). AZT and darunavir were obtained from the NIH AIDS Research and Reference Reagent Program. HIV-2 shows natural resistance to nonnucleoside RT inhibitors and
several protease inhibitors. We used darunavir as a control due to its potent in vitro activity against both types of HIV (reviewed in ref. 4).

Homology modeling and molecular dynamics – A structural model of HIV-1 RT bearing the amino acid substitutions D67N/K70R/K73M bound to double-stranded DNA and dTTP was constructed by standard homology modeling techniques (60), using as reference the one previously obtained for the double-mutant D67N/K70R (32). Molecular dynamics simulations, based on the models, were performed as previously described for the WT HIV-1 RT (34). This model for the catalytically-competent WT RT was based on the X-ray structure determined by Huang et al. (61) (PDB file 1RTD) corresponding to a ternary complex of HIV-1 RT, a dideoxyguanosine-terminated primer-template and dTTP, and containing two Mg²⁺ ions at the DNA polymerase active site. Atomic charges for dTTP were obtained with the RESP program (62) to fit potentials calculated at 6-31G* level using the Gaussian-03 package (63). Van der Waals parameters for Mg²⁺ were taken from Allnér et al. (64). The total simulation length was around 10 ns, and the analysis of trajectories was performed as previously reported (34). The SHAKE algorithm was applied allowing for an integration time step of 2 fs (34).

Acknowledgements: This work was supported in part by the Spanish Ministry of Economy and Competitiveness through grants BIO2013-48788-C2-1-R and BIO2016-76716-R (AEI/FEDER, UE) to L.M.-A. and SAF2016-75277-R to M.A.M. M.N. was supported by the ISCIII through the Spanish AIDS network (RD16-0025/0041). An institutional grant of the Fundación Ramón Areces to the CBMSO is also acknowledged.

Conflict of interest: Authors declare that they have no conflict of interest with the contents of this article.

Author contributions: M.A.M. and L.M.-A. designed research; M.A. prepared RT mutants and carried out their biochemical characterization including rescue assays with different NRTI-terminated primers; M.N. obtained the recombinant HIV-2 variants and performed drug susceptibility assays with the virus; J.M. carried out molecular dynamic studies with modelled RTs; M.A., M.N., J.M., M.A.M. and L.M.-A. analyzed data; M.A., M.A.M. and L.M.-A. wrote the paper.

| D67N/K70R      |      | 14.4 ± 3.7 (1.1) | 3.6 ± 1.9 (1.0) |
| D67N/K70R/M73K |      | 135.7 ± 63.9 (10.5)* | 17.1 ± 10.9 (4.9) |
| HIV-1BH10      |      |              |          |          |
| WT             |      | 7.9 ± 0.9 (0.6) | 1.2 ± 0.3 (0.3) |
| LY_HIV-1 (M41L/T215Y) | 26.0 ± 4.0 (2.0)* | 1.3 ± 0.2 (0.4) |

a The IC50 values shown are averages ± standard deviations of at least three tests, with each one performed six times. The fold increase in IC50 relative to wild-type HIV-2ROD control is shown between parentheses. The significance of the differences of HIV-2ROD and HIV-1BH10 mutants with their corresponding WT strains were determined by using a Student t test (*, P<0.05).

b Amino acid substitutions in the RT relative to the corresponding WT strain are indicated between parentheses.

c nd, not determined (recombinant viruses were not viable).
FIGURE LEGENDS

Figure 1. Amino acid sequence differences within residues 1-250 of HIV-1BH10 and HIV-2ROD RTs and mutant HIV-2ROD RTs analyzed in this study. (A) Sequence alignments showing differences between HIV-1 and HIV-2 RTs at positions associated with the excision pathway of resistance to thymidine analogues. Differences between both RTs are highlighted in red. Amino acids shown in blue were introduced in one or more HIV-2ROD mutant RTs generated in this study. (B) HIV-2ROD RTs analyzed in this study and their abbreviated designations.

Figure 2. ATP-mediated excision of AZTMP from RNA/DNA template/primers by WT and mutant RTs. Assays were carried out with 31/21-mer RNA/DNA complexes (sequences shown below the upper panel). The inhibitor was first incorporated at position +1 (indicated with an asterisk) of the 21-nucleotide primer (lane P) to generate a 22-nucleotide product (lane B). Excision of the inhibitor and further primer extension in the presence of 3.2 mM ATP and a mixture of dNTPs led to the formation of a fully extended 31-nucleotide product. Aliquots were removed 2, 4, 6, 8, 10, 12, 15 and 20 min after the addition of ATP. Time courses of the excision reactions are shown in three panels, each one containing data from different sets of related RTs. Time courses obtained with WT HIV-2 RT and mutant 5M are included in all panels for comparison. All dNTPs in the assays were supplied at 200 µM, except for dATP whose concentration was 2 µM. Template/primer and active RT concentrations in these assays were 30 nM and 24 nM, respectively. Represented values (means ± standard deviations [error bars]) were obtained from at least three independent experiments.

Figure 3. Kinetics of the ATP-dependent excision of AZTMP and d4TMP from DNA/DNA template/primer (D38/25PGA). Time courses of the excision reactions of AZTMP- and d4TMP-terminated primers (26mers) annealed to their corresponding 38-nucleotide DNA templates (30 nM) were determined in the presence of 3.2 mM ATP (A and B, respectively). The excision reactions were catalyzed by WT and mutant RTs (40 nM active site concentration). Aliquots were removed 2, 5, 10, 15, 20, 30, 45, 60 and 80 min after the addition of ATP. Represented values were obtained from at least three independent experiments.

Figure 4. ATP-mediated excision of nucleoside analogues from RNA/DNA and DNA/DNA template/primers by WT HIV-2 RT and mutants M73K, D67N/K70R and D67N/K70R/M73K. Assays were carried out with 31/21-mer RNA/DNA complexes (A) or 38/25-mer DNA/DNA complexes (B, C) (sequences shown above excision reaction time courses). The inhibitors (AZT in panels A and B, and tenofovir in panel C) were first incorporated at position +1 to generate 22- or 26-nucleotide products. Excision of the inhibitor and further primer extension in the presence of 3.2 mM ATP and a mixture of dNTPs led to the formation of a fully extended primers of 31 or 38 nucleotides. Aliquots were removed at appropriate times after ATP addition. Time courses of the excision reactions are shown below. The dNTPs in the assays carried out with RNA/DNA complexes were supplied at 200 µM, except for dATP whose concentration was 2 µM. In assays using DNA/DNA complexes, the dNTP concentration was kept at 100 µM, except for dATP (AZT-terminated primers) or dTTP (tenofovir-terminated primers) which were supplied at 1 µM. Template/primer and active RT concentrations in these assays were 30 nM and 24 nM, respectively. Represented values (means ± standard deviations [error bars]) were obtained from at least three independent experiments.

Figure 5. Comparison of the structural models of WT and mutant HIV-1 RTs D67N/K70R/K73M and D67N/K70R, complexed with double-stranded DNA and an incoming dNTP. (A) Ribbon representation of the polypeptide backbone around the nucleotide binding site of the RT. The side chains of Val60, Arg70 and Met73/Lys73 and the incoming dNTP are shown with stick and sphere representations. In the double-mutant, molecular dynamics simulations predict the formation of a hydrogen bond between amido and hydroxyl groups of the RT (Arg70) and the incoming dNTP, respectively (dotted line). The distance between relevant atoms (shown in red) is 2.4 Å in this structure, while in the D67N/K70R/K73M RT model, this value increases up to 6.2 Å. (B) View of the β3-β4 hairpin loop, the incoming dNTP and the two Mg²⁺ ions, based on the structural alignment of the three modeled RTs. The catalytically competent WT HIV-1 RT is shown in orange, the D67N/K70R RT in green, and the D67N/K70R/K73M RT in red. Side chains at
positions 60 (Val in all cases), 70 (Lys/Arg) and 73 (Met/Lys) are represented with sticks. Spheres are used to indicate the location of Val$^{60}$ and Met$^{73}$ in the structure of the triple mutant. The hydrogen bond between Arg$^{70}$ and the incoming dNTP, predicted for the D67N/K70R RT is shown with a dotted line.

**Figure 6.** ATP-mediated excision of AZTMP from DNA/DNA template/primers by HIV-1 RT mutants D67N/K70R and D67N/K70R/K73M. Assays were carried out with 38/25-mer DNA/DNA complexes (sequences shown below the upper panel). The inhibitor was first incorporated at position +1 (indicated with an asterisk) of the 25-nucleotide primer (lane P) to generate a 26-nucleotide product (lane B). Excision of the inhibitor and further primer extension in the presence of 3.2 mM ATP and a mixture of dNTPs led to the formation of a fully extended 38-nucleotide product. Aliquots were removed 2, 4, 6, 8, 10, 12, 15 and 20 min after the addition of ATP. Time courses of the excision reactions are shown below. All dNTPs in the assays were supplied at 100 µM, except for dATP whose concentration was 1 µM. Template/primer and active RT concentrations in these assays were 30 nM and 24 nM, respectively. Represented values (means ± standard deviations [error bars]) were obtained from at least three independent experiments.
