ABSTRACT

The astrophysical stochastic gravitational wave background (SGWB) is mostly produced from unresolved stellar binary mergers, and the number of events at any moment of time is expected to be Poisson-distributed. The event rate is governed by several astrophysical processes. The Poisson nature leads to variation in the number of sources and this causes temporal variations in the SGWB. The intrinsic temporal fluctuations of the SGWB are a rich source of astrophysical information that can be explored via ongoing and future gravitational wave experiments to classify the sources of the SGWB signal. Along with several other methods to estimate the GW event rates from individual sources, the study of the temporal variations of the SGWB signal provides an independent method for estimating the event rates of the GW sources that contribute to the SGWB. Along with direct estimates of event rates, this approach can also distinguish between different sources contributing to the SGWB signal and will be a useful probe of its evolution over a vast cosmic volume. On averaging over observation times, the SGWB will be statistically invariant under time translation. Statistical time translation symmetry of the SGWB is expected due to the negligible evolution of the relevant cosmological and astrophysical phenomena over the observation time-scales over which the data is collected.

Key words: gravitational waves, large-scale structure of Universe, galaxies: star formation

1 INTRODUCTION

Gravitational wave (GW) (Einstein 1918) are a new multi-frequency observational probe of the Universe which will explore a vast range of cosmological redshifts. The GW signal can be produced from astrophysical sources such as black holes (BHs), neutron stars (NSs), white dwarfs (WDs), supernovae (Visheshwara 1970; Press 1971; Chandrasekhar & Detweiler 1975; Blanchet et al. 1995; Buonanno & Damour 1999; Damour et al. 2001; Blanchet et al. 2004; Baker et al. 2006; Pretorius 2005; Campanelli et al. 2006; Buonanno et al. 2005; Marassi et al. 2011; Zhu et al. 2010; Cusin et al. 2018). Along with the astrophysical origins of GWs, it can also be generated in different cosmological scenarios such as during the period of inflation (Starobinsky 1979; Turner 1979; Martin et al. 2014), cosmic strings (Kibble 1976; Damour & Vilenkin 2005), phase transitions (Kosowsky et al. 1992; Kamionkowski et al. 1994) etc. The observed GW signal can be classified as point source or stochastic in nature. The GW signal can be resolved individually in the former case, and will be an unresolved continuous/discontinuous diffused background for the latter case.

The stochastic gravitational wave background (SGWB) (Allen 1996; Maggiore 2000; Wu et al. 2012; Regimbau & Chauvineau 2007; Romano & Cornish 2017; Rosado 2011; Zhu et al. 2011) spans a wide frequency range and is expected to have contributions from both astrophysical binary astrophysical sources (BHs, NSs, WDs, BH-NS, NS-WD) as well as from the cosmological origins. One of the potential candidates of the cosmological SGWB is the primordial GW background produced during the epoch of inflation. This is can be explored at the low frequency ($f \sim 10^{-18}$ Hz) using the large angular scale E-mode polarization of the cosmic microwave background (CMB) which is accessible from CMB experiments such as BICEP-KECK (Ade et al. 2018), Simons Observatory (Aguirre et al. 2019), and LiteBIRD (Suzuki et al. 2018). The high-frequency primordial
inflationary GW signal can in principle be directly probed if the astrophysical SGWB can be successfully distinguished from the inflationary GW signal.

In this work, we focus on the astrophysical SGWB which is produced from a large number of binary mergers of compact objects (Rosoondo 2011; Regimbau & Mandic 2008; Regimbau & Chauvineau 2007; Wu et al. 2012). Such sources will contribute to the total GW energy background $\rho_{GW}$, which can be written in terms of the dimensionless quantity

$$\Omega_{GW}(f) = \frac{1}{\rho_c c^5} \frac{d\rho_{GW}(f)}{d\ln f},$$

where $c$ is the speed of light and $\rho_c = 3H_0^2/8\pi G$ is the critical density of the Universe, which depends on the present value of the Hubble constant $H_0$. The astrophysical SGWB is expected to be anisotropic and several previous methods (Mitra et al. 2008; Thrane et al. 2009; Talukder et al. 2011; Mingarelli et al. 2013; Romano & Cornish 2017) were developed to measure the signal from the GW data. The currently ongoing ground-based GW experiments (such as advanced Laser Interferometer Gravitational-Wave Observatory (LIGO) (Hanford and Livingston) (Aasi et al. 2015), advanced VIRGO detectors (Acernese et al. 2015) and the upcoming ground-based GW experiments such as KAGRA (Akutsu et al. 2019) and LIGO-India (Unnikrishnan 2013) are going to be operational in the coming decade to measure the GW signal in the frequency range $f \approx 30 - 3000$ Hz with a strain noise $\sim 10^{-23} Hz^{-1/2}$. The data from the advanced-LIGO’s first observational run have imposed upper bounds on both spatially varying and non-varying contributions to $\Omega_{GW}(f)$ (Abbott et al. 2017b,c). Another window to the GW signal is through the Pulsar Timing Array (PTA) (Hobbs et al. 2010), which are looking for GW signals in the frequency band $10^{-9} - 10^{-6}$ Hz and have imposed constraints on the strain of SGWB signal as $1.45 \times 10^{-15}$ at $f = 1 \text{yr}^{-1}$ (Arzoumanian et al. 2018). In the future, space-based GW observatory Laser Interferometer Space Antenna (LISA) (Amaro-Seoane et al. 2017) will probe the frequency band $f \sim 10^{-5} - 10^{-1}$ Hz of GW signals. In even longer timescale, the third generation GW experiments (Abbott et al. 2017a) such as Einstein Telescope and Cosmic Explorer are going to measure GW signal for frequencies above $10$ Hz with sensitivity better than $10^{-24} Hz^{-1/2}$ (Abbott et al. 2017a). The third generation detectors will be able to measure the GW sources up to a redshift $z \sim 20$ with an snr $\sim 10$ (Abbott et al. 2017a).

In this paper, we discuss the origin of temporal dependence in the astrophysical SGWB signal and show how this can be used to distinguish between the SGWB signal originating from astrophysical and cosmological sources. The temporal dependence is useful for probing the astrophysical event rates of the SGWB sources, the variations with frequency of GW emission, and the spatial positions of the sources. The study of temporal fluctuations along with spatial anisotropies bring a new dimension for exploring the SGWB background and its statistical properties. We show that this avenue is going be useful for observationally distinguishing between the cosmological and astrophysical SGWB. In Sec. 2, we discuss the origin of the temporal dependence of the SGWB signal. In Sec. 3 and Sec. 4, we discuss the formalism and the corresponding estimator for studying the frequency and temporal fluctuations of the SGWB signal. The measurability of the time variability for a network of detectors such as advanced-LIGO (Hanford and Livingston), Virgo detectors and Cosmic Explorer are shown in Sec. 5. The conclusion and future scope of this work are discussed in Sec. 6.

## 2 ORIGIN OF THE TEMPORAL DEPENDENCE IN SGWB

Along the cosmic light-cone in a particular sky direction and over a particular observational time window $\Delta t$, the SGWB signal has contributions from all of the events coalescing along the line of sight. The number of coalescing events taking place at different times is governed by Poisson statistics as each of the events happens independently $^1$. The corresponding probability mass function of occurrence of $N$ mergers of binaries of mass $M$ in a time interval $\Delta t$ can be written as

$$P(N, M) = e^{-\Lambda(M, \hat{\rho}, z)\Delta t}(\Lambda(M, \hat{\rho}, z)\Delta t)^N \frac{N!}{N},$$

where $\Lambda(M, \hat{\rho}, z)$ is the average event rate (Kalogera et al. 2007; O’Shaughnessy et al. 2008; Bulik et al. 2011; Mandel & O’Shaughnessy 2010; Dvorkin et al. 2018) and is still poorly known from astrophysical observations and is expected to depend on several parameters such as the mass of the binary compact objects $M$, star formation history $\hat{\rho}$, the source redshift $z$. In the above equation the time in the observer’s frame $\Delta t$ is related to the time in the source rest frame $\Delta t_r$ at redshift $z$ by the relation $\Delta t = \Delta t_r (1 + z)$.

The Poisson nature of the GW events results in a variation in the number of GW sources at different time intervals $\Delta t$ with the standard deviation proportional to $(\Lambda(M, \hat{\rho}, z)\Delta t)^{1/2}$. As a result, the SGWB, which is an integrated effect of all of the events, will exhibit a temporal variation at a fixed direction in the sky. The average value of the event rate is expected to be constant as it is governed by the astrophysical and cosmological phenomena, and as a result, we can expect negligible evolution of the event rate $\Lambda(M, \hat{\rho}, z)$ over the observation time. This implies that the SGWB will be time-dependent, but will exhibit statistical time translation symmetry on averaging over large observation time. For large event rates, the Poisson distribution will tend towards a Gaussian distribution (central limit theorem), as the skewness and kurtosis decreases as $(\Lambda(M, \hat{\rho}, z)\Delta t)^{-1/2}$ and $(\Lambda(M, \hat{\rho}, z)\Delta t)^{-1}$ respectively. However, the variance of the signal grows with the event rates indicating the relation $\Lambda(M, \hat{\rho}, z)\Delta t$ that the rms time variability of the SGWB signal will not disappear due to the large event rate.

We can write the observed $\Omega_{GW}(f)$ at a frequency $f$ in terms of the energy emission from each GW source and number of GW events $N(z)$ in a comoving volume between the cosmic time $t(z)$ and $t(z + \Delta z)$ as (Phinney 2001)

$$\Omega_{GW}(f) = \frac{1}{\rho_c c^5} \int dz N(z) \frac{dE_{GW}}{(1+z) d\ln f_r} |_{f_r = (1+z)f},$$

$^1$ It is a reasonable assumption to consider that one coalescing binary system is not triggering other binary events.
where, $\rho_c = 3H_0^2/8\pi G$ and $c$ is the speed of light. The variation in the amplitude of the SGWB signal within the time interval $\Delta t$ will be reflected due to the change in the number of GW events $\Delta N(z, \Delta t)/N(z, t) = N(z, t + \Delta t)/N(z, t) - 1$ in the time interval $\Delta t$. Due to Poisson nature of the GW events, if the variation in the number of sources $\Delta N(z, \Delta t)$ (within a time interval $\Delta t$) is comparable to the total number of GW sources ($N(z, t)$) contributing to the SGWB signal at frequency $f$ and time $t$, then the relative fluctuations in the SGWB signal around the mean value of $\bar{\Omega}_{GW}(f)$ are of the order $\Delta N(z, \Delta t)/N(z, t)$, which implies for the scenario $\Delta N(z) \sim N(z)$ will be satisfied.

The time variability of the SGWB signal depends primarily on three time-scales, (i) the duration $\tau_d$ which a GW source spends at a particular frequency $f$, (ii) the duration between the consecutive events ($\Delta t_{\text{event}} \propto 1/\lambda$), and (iii) the time-scale $\Delta t$ over which we estimate the variation of the sky signal. For the first two time-scales $\tau_d$ and $\Delta t_{\text{event}}$, we can define the duty cycle of the GW signal as the ratio of the duration of the signal emitted between frequency $f$ and $f + \Delta f$, and the time difference between two GW events (Wu et al. 2012; Rosado 2011)

$$\frac{dD}{df} = \int dz n(z) \frac{d\tau_d}{df},$$

where $n(z)$ is the event rate as a function of the cosmological redshift and the duration of the signal $d\tau_d$ at frequency $f$ can be written in terms of the GW chirp mass according to the relation

$$\frac{d\tau_d}{df} = \frac{5c^5}{96\pi^{1/3}G^{5/3}M_{chirp}^{11/3}f^{11/3}}.$$  

A large duty-cycle implies that the duration of the GW signal at frequency $f$ is long compared with the time difference between the events. So, if $\Delta t < \Delta t_{\text{event}}$, the sources of the GW signal are not changing within the time $\Delta t$, resulting in a SGWB signal with no temporal fluctuations. Also, when $\Delta t < \tau_d$, the variations of the GW signal at a frequency $f$ is also negligible within the time scale $\Delta t$. This implies for the scenario $\tau_d \gg \Delta t_{\text{event}} \gg \Delta t$, the number of GW sources produced in the time $\Delta t$ is much smaller than the total number of GW sources contributing to the SGWB signal and also the intrinsic time variability of the signal in the time scale $\Delta t$ is negligible. As a result, the fractional change in the SGWB signal with respect to the average background is tiny for this case.

On the other hand, if the three time-scales satisfies the condition ($\Delta t \geq \Delta t_{\text{event}} \geq \tau_d$), then the SGWB signal shows time variability comparable to the mean average signal in the time scale $\Delta t$. The GW sources satisfying this criterion are expected to contribute maximally to the time variability of the SGWB signal. For this kind of source, the duty cycle is of the order unity or less, i.e $\tau_d \lesssim \Delta t_{\text{event}}$. The condition for the time variability of the SGWB signal can also be written in terms of the overlap function as defined by Rosado (2011). The contribution from the non-overlapping GW sources will cause dominant contribution to time variability in the SGWB signal. Whereas the overlapping sources for which $\Delta N(z) < c N(z)$, is going to produce negligible time variability in the SGWB.

In Fig. 1, we plot the duty-cycle as a function of the GW frequency for binary neutron stars (BNS), black hole neutron star (BH-NS) and binary black holes (BBH). For this plot, we have taken the event rate of GW sources as $1 \text{ Mpc}^{-3} \text{Myr}^{-1}$, $0.03 \text{ Mpc}^{-3} \text{Myr}^{-1}$ and $0.005 \text{ Mpc}^{-3} \text{Myr}^{-1}$ for BNS, BH-NS and BBH respectively. From Fig. 1, it is evident that BNS, followed by BH-NS systems, are going to have overlapping sources resulting in less temporal fluctuations in the SGWB signal as opposed to the BBH systems. As a result, this avenue helps in distinguishing between the SGWB originating from the BNS, BH-NS and BBHs systems.

To show the time variability of the SGWB for BNS, BH-NS and BBH, we estimate the rms temporal fluctuations of the SGWB

$$\Delta \bar{\Omega}_{GW}(f) = \sqrt{\left\langle \left( \frac{\bar{\Omega}_{GW}(t,f) - \bar{\Omega}_{GW}(f)}{\bar{\Omega}_{GW}(f)} \right)^2 \right\rangle}_T}$$

from 100 realizations of $\bar{\Omega}_{GW}(t)$ drawn from a Poisson distribution with the fixed event rates $1 \text{ Mpc}^{-3} \text{Myr}^{-1}$, $0.03 \text{ Mpc}^{-3} \text{Myr}^{-1}$ and $0.005 \text{ Mpc}^{-3} \text{Myr}^{-1}$ for BNS, BH-NS and BBH respectively. The corresponding rms variations in the SGWB signal are shown in Fig. 2 for the frequency range which are relevant for the terrestrial GW observatories such as advanced-LIGO, VIRGO and KAGRA, LIGO-India. The maximum relative temporal fluctuations of the SGWB signal are expected from BBHs as the number of overlapping events is fewer, resulting from a smaller value of the duty cycle. On the other hand, BNS will exhibit less relative time variability due to their larger duty cycles. This behavior of the SGWB over these frequency ranges will allow us to distinguish between the different types of GW sources which are contributing to the signal. The amplitude of the time variability of the SGWB signal depends strongly on the event rate, probability distribution of the compact object mass and their redshift distribution. We show the changes in the rms fluctuation for the BBH case with the variation in the event rates and probability distributions of the black hole masses in Fig. 3. Fig. 2 and Fig. 3 indicates that characterizing the time variability of the SGWB signal is a useful probe to understand different populations of binary GW source and their event rates respectively.

\[2\] Here the notation $\langle \cdot \rangle_T$ implies average in the time domain for different realizations of SGWB.
We show the rms fluctuations in the SGWB signal expected due to the Poisson nature of the GW binary sources. The rms fluctuations for three species of binaries namely binary black holes (BBH), binary neutron stars (BNS) and black holes-neutron star (BH-NS).

The time variability of the SGWB signal is an independent avenue along with other existing methods to detect the GW event rates from the individual GW sources and SGWB signal (Messenger & Veitch 2013; Farr et al. 2015; Smith & Thrane 2018). These frameworks (Messenger & Veitch 2013; Farr et al. 2015; Smith & Thrane 2018) are able to measure the rates from the GW data and can successfully distinguish between the background and individual signal. The detection of the individual GW events are going to be more powerful in detecting the local GW event rates from the "loudest individual events". However, the study of the temporal variation of the SGWB signal will be powerful in mainly distinguishing the population of different SGWB sources and understanding their distribution over the cosmic volume. The event rates that can be inferred from the SGWB signal is capable to probe the signal up to a high redshift which cannot be inferred from the individual loud sources. The temporal dependence of the SGWB signal can also be a useful avenue for distinguishing between astrophysical SGWB signals and the cosmological SGWB signals, since the latter are generally not expected to show sporadic behavior in the temporal domain.

The temporal fluctuations of \( \Omega_{GW}(f, \hat{n}, t) \) can be written as

\[
\Omega_{GW}(f, \hat{n}, t) = \frac{1}{4\pi cT} \int dz \frac{dM_R(z, \hat{n}, t)}{dz} \int dV \frac{dE_{GW}}{df} \cdot (1 + z)
\]

where we can express the emission of the GW signal during the inspiral phase from an individual source in terms of the redshifted chirp mass \( M_\chi = M(1 + z) \) and redshifted frequency \( f_r = (1 + z)f \) by the relation

\[
\frac{dE_{GW}}{df_r} = \left( \frac{G\pi}{3f_r^3} \right)^{2/3} M_\chi^{5/3}
\]

The number of coalescing binaries \( R_M(z, \hat{n}, t) \) per unit earth time, per unit comoving volume, per unit mass-bin for the binaries of redshifted chirp mass \( M_\chi \) can be written as

\[
R_M(z, \hat{n}, t) = \frac{n_{gal}(\hat{n}, z) E_M(z, \hat{n}, t_r)}{(1 + z)}
\]

where, \( n_{gal}(\hat{n}, z) \) is the number density of galaxies and \( E_M(z, \hat{n}, t_r) \) is the number of GW binaries coalescing per galaxy, per unit cosmic time, per unit chirp mass. \( dV/dz \) denotes the comoving volume element which can be written as \( 4\pi c d^2/L^2 ((1 + z)^2 H(z)) \). The merger and the ring-down phase of the individual GW signal can also be included to model the SGWB signal. As the GW events are expected to be a statistical process (Poisson distributed), at any moment of time, \( E_M(z, \hat{n}, t) \) is going to be time-dependent.

The average of \( \Omega_{GW}(f) \) over a large observation time will exhibit statistical time translation symmetry which can be written as

\[
\bar{\Omega}_{GW}(f) = \frac{1}{T} \int dt \frac{1}{\rho_c} \frac{dp_{GW}(f, \hat{n}, t)}{d\ln f}
\]

### 3 ASPECTS OF SGWB IN FREQUENCY AND TEMPORAL DOMAINS

We propose to study three aspects of the astrophysical SGWB: (i) Spectral derivative of the SGWB signal, (ii) Time derivative of the SGWB signal and, (iii) Tomographic redshift estimation of the SGWB signal.

#### 3.1 Spectral derivative of the GW signal at a fixed observation time

The spectrum of the GW signal is an indicator of the mass of the coalescing binaries, as the mergers of the binaries with heavier masses happen at a lower frequency. We can then
construct the spectral derivative of the SGWB signal as

\[
F(t, f_s, f_b, \hat{n}) = \Omega(t, f_s, \hat{n}) - \left( \frac{f_b}{f_s} \right)^2 \Omega(t, f_s, \hat{n})
\]

\[
= \left( G \pi \right)^{2/3} f_{\text{in}}^{2/3} \int dz dM \frac{n_{\text{gal}}(\hat{n}, z)}{1+z} \left[ \left( E_M(z, \hat{n}, t) M_r^{4/3}(t, \hat{n}) \right)_{f_b} - \left( E_M(z, \hat{n}, t) M_r^{4/3}(t, \hat{n}) \right)_{f_s} \right],
\]

where \( f_{\text{in}} = f_b + \Delta f \) and we have used the fact that the GW strains from the individual binaries are not correlated with other coalescing binaries. \( E(z) = \sqrt{\Omega_m(1+z)^3 + \Omega_{\Lambda}} \) is the expansion history of the Universe. The maximum frequency \( f_{\text{max}} \) up to which the GW signal is emitted depends on the last stable orbit of the BBH, BH-NS, and BNS. This depends on the total mass \( M \) of the coalescing binaries as \( f_{\text{max}} = \frac{\sqrt{3}}{8\pi G M} \). So the GW signal emitted from sources with the mass of the coalescing binaries between \( M^a \propto \frac{1}{f^3} \) and \( M^b \propto \frac{1}{f^3} \) will contribute to the differential signal \( F(t, f_s, f_b, \hat{n}) \)

\[
F(t, f_s, f_b, \hat{n}) = \left( G \pi \right)^{2/3} f_{\text{in}}^{2/3} \int dz dM \frac{n_{\text{gal}}(\hat{n}, z)}{1+z} \left[ \left( E_M(z, \hat{n}, t) M_r^{4/3}(t, \hat{n}) \right)_{f_b} - \left( E_M(z, \hat{n}, t) M_r^{4/3}(t, \hat{n}) \right)_{f_s} \right],
\]

where \( H(x) \) is the Heaviside function which is non-zero only for positive values of the argument \( x \). For the same observation time and sky direction, the number of GW sources emitting in individual mass bins is fixed. As a result, the spectral derivative of the SGWB captures the sky luminosity in the redshift-averaged mass-bins corresponding to \( \Delta f \). This will also exhibit temporal fluctuations due to the variation in the number of events with cosmological redshift \( \Delta \). The spatial and time average of the spectral derivative signal in individual mass-bins can be expressed as

\[
F(f_s, f_b) = \frac{1}{4\pi T_{\text{obs}}} \int d^2 \hat{n} \int_{T_{\text{obs}}} dt F(t, f_s, f_b, \hat{n}).
\]

The spatial and time average of the spectral derivative signal in individual mass-bins can be expressed as

\[
\mathcal{T}(t, f_s, f_b, \hat{n}) = \Omega(t, f_s, \hat{n}) - \Omega(t', f_s, \hat{n})
\]

\[
= \left( G \pi \right)^{2/3} f_{\text{in}}^{2/3} \int dz dM \frac{n_{\text{gal}}(\hat{n}, z)}{1+z} \left[ \left( E_M(z, \hat{n}, t) M_r^{4/3}(t, \hat{n}) \right) - \left( E_M(z, \hat{n}, t') M_r^{4/3}(t, \hat{n}) \right) \right].
\]

This is the line-of-sight integrated quantity of the variation of the number of events in any sky direction. The spectrum of this quantity is a direct probe of the variation of the event rate across the GW source population.

### 3.3 Tomographic redshift estimation of the spatial distribution of the GW sources

The three-dimensional spatial distribution of the GW sources depend upon the background cosmology, the redshift of the sources and the spatial distribution of the host galaxy. Cosmological information (such as the redshift distribution of the host galaxies of the GW sources) which is embedded in the SGWB signal is not time-dependent. The contribution of the SGWB signal from individual cosmological redshifts can be obtained by cross-correlating with redshift-known cosmic probes of the density field. From a galaxy survey, we obtain the spatial position of galaxy along with its photometric or spectroscopic redshift. We can construct the tomographic density field at different cosmological redshifts as

\[
\delta_b(\hat{n}, z) = \frac{n_{\text{gal}}(\hat{n}, z)}{n_{\text{gal}}(z)} - 1,
\]

where \( n_{\text{gal}}(\hat{n}, z) \) is the number of galaxies in the redshift bin \( z \) and in the direction \( \hat{n} \) and \( n_{\text{gal}}(z) \) is the average number of galaxies. The two-point correlation function of galaxies \( W_{gg} \) is a probe to the underlying dark matter correlation function \( \xi_{DM}(\chi, \theta) \) given by the relation

\[
W_{gg}(\theta, z) \equiv \langle \delta(\hat{n}, z)\delta(\hat{n}+\theta, z) \rangle = \int d^2 \hat{n} D^2(z) \delta_b^2(\hat{n}) \xi_{DM}(\chi(z), \chi(z), \theta),
\]

where the angular bracket \( \langle \cdot \rangle \) denotes the all-sky average, \( D(z) \) is the growth function, \( b_g(z) = \delta_b/\delta_{DM} \) is the galaxy bias with respect to the dark matter density field \( \delta_{DM} \) and the correction function \( \xi_{DM}(\chi(z), \chi(z), \theta) \) is related to the power spectrum of the dark matter distribution \( P_{DM}(k) \) by

\[
\xi_{DM}(\chi(z), \chi(z), \theta) = \frac{1}{2\pi^2} \int d^2 k P_{DM}(k) j_0(k \chi(z)),
\]

where \( j_0(k \chi(z)) \) is the spherical Bessel function and \( \chi = \sqrt{\chi(z)^2 + \chi(z)^2 - 2\chi(z)^2 \cos \theta} \).

The cross-correlation of the SGWB with the tomographic redshift bins of the large-scale structure encodes the cosmological spatial distribution of the GW sources. The time-dependent \( F(t, f, f', \hat{n}) \) and \( \mathcal{T}(t, f', f, \hat{n}) \) signal intrinsically depends on the redshift distribution of the GW sources. So, the angular cross-correlation of \( F(t, f, f', \hat{n}) \) with the to-
mographic density field $\delta_p(\hat{n}, z)$ can be expressed as

$$W_{\xi_g}(t, f, z, \theta) \equiv \langle F(t, f, \hat{n}) \delta(\hat{n} + \theta, z) \rangle = \int d^2 \hat{n} \int dz' D(z') D(z) b_{\xi_g}(z) b_{\xi_g}(z') \hat{\Omega}(z', z, \theta),$$

where $b_{\xi_g}(t, f, z', \hat{n})$ is the time-dependent GW bias for the spectral derivative which we can express in terms of the GW source properties by the relation

$$b_T(t, f, z, \hat{n}) = \int d^2 \hat{n} \int dz' D(z') D(z) b_{\xi_g}(z) \times \delta_{\xi_g}(\chi(z'), \chi(z), \theta), \quad (17)$$

Similarly, the cross-correlation of $T(t', f, \hat{n})$ with the galaxy distribution will be able to capture the time evolution of the binary events with redshift, which can be written as

$$W_{\xi_g}(t, f, z, \theta) \equiv \langle T(t', f, \hat{n}) \delta(\hat{n} + \theta, z) \rangle = \int d^2 \hat{n} \int dz' D(z') D(z) \times b_T(t, t', f, z', \hat{n}) \hat{\Omega}(z', z, \theta), \quad (18)$$

where, we have defined $b_T(t, t', f, z, \hat{n})$ as

$$b_T(t, t', f, z, \hat{n}) = \frac{(G\pi)^{2/3} \rho_{c}^{2/3}}{3p_{c}c^{2}2} \int dM \left( \frac{E_{\xi_g}(z, \hat{n}, t) M_{l}^{2/3}(\delta_{l})}{(1+z)^{4/3}} \right) \times \left[ H(M_{l}^{c} - M_{s}) - H(M_{s}^{b} - M_{s}) \right]. \quad (19)$$

The two-point cross-correlation $W_{R_g}(t, t', f, z, \theta)$ and $W_{R_\xi}(t, f, z, \theta)$ are all-sky integrated quantities. For a statistically isotropic Universe, the all-sky-averaged of the cross-correlation signal will translate into a temporal average over different realizations of the events. As a result, we can expect the two-point correlation function to have statistically time translation symmetry. It will be related to the mean merger rate of GW sources per unit redshift per unit time which is denoted by $E_{\xi_g}(z)$.

The two-point cross-correlation function, defined in real space, can also be obtained in the spherical harmonic basis of the field $(X_{l_m} = \int d^2 \hat{n} Y_{l_m}^*(\hat{n}) X(\hat{n}))$ using the addition theorem of spherical harmonics

$$W_{XY}(\theta) = \sum_{l} \left( \frac{2l+1}{4\pi} \right) P_l(\cos(\theta)) C_{lX}^{XY}, \quad (21)$$

where $C_{lX}^{XY} = \sum_{m} X_{l_m} X_{l_m}^{*} \delta_{lX} \delta_{mY}$ and $P_l(\cos(\theta))$ are the Legendre Polynomials.

In summary, the time dependence of the SGWB carries a rich source of information about the astrophysical event rate of the GW sources. We show that a set of observables such as $F, \hat{\Omega}, W_{\xi_g}$, and $W_{R_g}$ are capable of probing the event rate as a function of cosmological redshift and the chirp mass of the binaries from the SGWB signal.

### 4 Estimators for the Astrophysical SGWB

In this section, we devise the formalism which will be useful for extracting the astrophysical time-dependence of the SGWB signal from the GW data. The extraction of the stochastic GW signal can be devised in both pixel-space (real space) and spherical harmonic space. We show the estimators which can be used to study the quantities such as $F, \hat{\Omega}, W_{\xi_g}$, and $W_{R_g}$.

#### 4.1 Overview of the analysis technique

In this section, we briefly explain the standard framework for the analysis of stochastic GW data (Mitra et al. 2008; Thrane et al. 2009; Talukder et al. 2011; Romano & Cornish 2017). The time-series data $d_i(t)$ from the detector $i$ can be written as

$$d_i(t) = h_i(t) + n_i(t), \quad (22)$$

where, $h_i(t)$ and $n_i(t)$ are the signal and noise respectively. The observed signal can be written in terms of the true sky signal $h^s_\tau$ and the detector response $F^i_\tau(\hat{n}, t)$ as (Romano & Cornish 2017; Thrane et al. 2009)

$$h_i(t) = \int_{-\infty}^{\infty} df \int d^2 \hat{n} F^i_\tau(\hat{n}, t)e^{2\pi i f (t - \tau_i - \hat{n}/c)} h^s_\tau(f, \hat{n}). \quad (23)$$

The short-time Fourier transform of the sky signal at a particular time ($t$) can be written as

$$d(t,f) = \int_{-\tau/2}^{\tau/2} d(\tau')e^{-2\pi i f \tau'} dt', \quad (24)$$

where the choice of $\tau$ is made such that the detector response function has not changed significantly in the time window $\tau$. It should also not be smaller than the travel time of the GW signal between a pair of detectors. The expectation value of the cross-correlation of $d_i(t)$ between two different detectors is

$$\langle \Omega_i^d (f, t, t') \rangle \equiv \frac{2}{\tau} \langle d_i(t, f) d_i^\prime(t', f) \rangle = \frac{2}{\tau} h_i(t, f) h_i^\prime(t, f), \quad (25)$$

where the noise terms between the detectors are expected to be uncorrelated $\langle n_i(t) n_i^\prime(t') \rangle = 0$. The corresponding noise covariance matrix of $\Omega_i^d(f, t)$ is

$$N_i^d(f, t, t') = \langle \Omega_i^d (f, t) \Omega_i^d(f, t') \rangle - \langle \Omega_i^d (f, t) \rangle \langle \Omega_i^d(f, t') \rangle = N_i(f) N_i(f) \delta_{m} \delta_{ff}', \quad (26)$$

where $N_i$ is the one-sided noise power spectrum for detector $i$ which is uncorrelated with the noise of the other detectors. In this expression, the contribution of the signal is assumed to be negligible in comparison to the detector noise.

With knowledge of the detector response function $F^i_\tau(\hat{n}, t)$ for both the detectors, we can relate the observed cross-correlation spectrum with the true signal in the sky $\Omega^s(\hat{n}, f)$ as

$$\Omega_i^d (f, t) = \int d^2 \hat{n} \gamma(\hat{n}, f, t) \Omega^s(\hat{n}, f, t), \quad (27)$$

where, $\gamma(\hat{n}, f, t)$ is the geometric factor (Flanagan 1993; Christensen 1992)

$$\gamma(\hat{n}, f, t) = \frac{1}{2} F^i_\tau(\hat{n}, t) F_i^\prime(\hat{n}, t) e^{2\pi i f \hat{n} (\xi_i - \xi_i^\prime)/c}. \quad (28)$$

In Eq. 27, we differ from the previous method in two
ways. Firstly, the SGWB signal has an intrinsic temporal dependence $\Omega^\gamma(\hat{n}, f, t)$. Secondly, we have not separated the frequency and the angular parts, but rather kept them together in $\Omega^\gamma(\hat{n}, f, t)$. In the previous analysis (Thrane et al. 2009), the temporal dependence of the data was considered to be only due to the temporal dependence of the geometric factor $\gamma(\hat{n}, f, t)$ and the sky signal was assumed to depend only on the sky direction.

4.2 Estimators

**Spectral-derivative:** The spectral-derivative of the SGWB signal is the difference of the SGWB signal between two frequency channels and at a fixed detector time. The corresponding estimator in terms of the cross-power spectrum of the GW data can be written as

$$\Delta \Omega_\mathcal{F} \equiv \Omega^\mathcal{F}(f, t) - \Omega^\mathcal{F}(f', t),$$

where the frequency bands need to satisfy $|f - f'| = \Delta f < c/(2\pi D)$, such that the geometric factor does not change significantly in this narrow frequency band and with the precise knowledge of the geometric factor, we can make an estimate of the best-fit value of the differential sky signal $\mathcal{F}$, using the log-likelihood of the form $^3$

$$-2\mathcal{L}_\mathcal{F} \propto \sum_i \sum_j \left(\Delta \Omega_\mathcal{F}(\hat{n}_i, f, t) - \gamma(\hat{n}_i, f, t) \mathcal{F}(\hat{n}_i, f, t)\right)^2,$$

where the sum over indices $i$ and $t$ runs over the number of pixels ($N_{\text{pix}}$) and total number of time-bins $T_{\text{bin}} = T_{\text{obs}}/\Delta t$, $\mathcal{F}(\hat{n}, f, t)$ denotes the model of the spectral-derivative signal given in Eq. 11, and $N_\mathcal{F}$ denotes the covariance matrix given by

$$N_\mathcal{F} = (\mathcal{N}(f)\mathcal{N}(f') + \mathcal{N}(f')\mathcal{N}(f))\delta_{ii'}\delta_{ff'},$$

where we have assumed that the noise is the dominant contribution than the sky signal and have also assumed that the noise is uncorrelated between different frequency channels, different observation time and different pairs of detectors. As expected, the noise covariance matrix for the derivative signal gets contribution from both the frequency channels $f$ and $f'$, and it is going to be more noise dominant in comparison to the measurement of $\Omega^\gamma(f)$.

**Temporal-derivative:** The time-derivative signal of the SGWB can be estimated from the data using the form

$$\Delta \hat{T} \equiv \{\Omega^\mathcal{F}(f, t) - \Omega^\mathcal{F}(f, t + \Delta t)\},$$

where $\Delta t$ is a small time interval, over which the detector response function has not changed significantly. The corresponding likelihood to obtain the best-fit value can be written as

$$-2\mathcal{L}_T \propto \sum_i \sum_j \left(\Delta \hat{T}(\hat{n}_i, f, t) - \gamma(\hat{n}_i, f, t)\mathcal{T}(\hat{n}_i, f, t, t')\right)^2,$$

$$N_T^{-1}\left(\Delta \hat{T}(\hat{n}_i, f, t, t') - \gamma(\hat{n}_i, f, t)\mathcal{T}(\hat{n}_i, f, t, t')\right),$$

where the index $t$ is summed over the number of temporal bins $T_{\text{bins}} = T_{\text{obs}}/\Delta t$, index $i$ runs over number of sky pixels and $N_T$ denotes the covariance matrix

$$N_T = 2N_\mathcal{T}(f)_N_\mathcal{T}(f')\delta_{ii'}\delta_{ff'},$$

where we have assumed again that the noise between two detectors are uncorrelated in time and frequency.

**Tomographic redshift estimate:** In order to separate the cosmological and astrophysical signal as discussed in Sec. 3.3, we work in the spherical harmonics space, and define $\Omega_X(\hat{n}, f, t)$ for $X \in \mathcal{F}$ and cosmic density field $\delta(\hat{n}, z)$ as

$$\Delta \Omega_t(\hat{n}, f, t) = \int d^2\hat{n} \Omega_X(\hat{n}, f, t)Y^*_m(\hat{n}),$$

$$\delta_t(z) = \int d^2\hat{n} \delta(\hat{n}, z)Y^*_m(\hat{n}).$$

The maximum value of $l$ is related to the smallest angular scale which can be resolved from the experiment. For the GW interferometer detectors at a distance $D$ apart from each other, the smallest angular scale is diffraction-limited, and this sets the maximum value of $l$ as $l_{\text{max}} = 2\pi fD/c$ (where $c$ is the speed of light). For a higher signal to noise ratio (S/N), we need to go to high $l$ values, hence large spatial separation between the pair of detectors is required.

Using $\hat{T}(\hat{n}, f, t, \Delta t)$ and $\hat{F}(\hat{n}, f, t)$ in the spherical harmonic basis, we can define the cross-correlation with the cosmic density field as

$$\hat{C}^\gamma_t(\mathbf{f}, \mathbf{z}) = \sum_m \hat{T}(\mathbf{f}, \mathbf{z}) \delta_m^\zeta(\mathbf{z}),$$

$$\hat{C}^\gamma_f(\mathbf{f}, \Delta t, \mathbf{z}) = \sum_m \hat{T}(\mathbf{f}, \Delta t) \delta_m^\zeta(\mathbf{z}).$$

Using the cross-correlation power spectrum of the SGWB data with the galaxy surveys, we can estimate the best-fit astrophysical event-rate by using the likelihood

$$-2\mathcal{L} \propto \sum_i \sum_j \left(\hat{C}^\gamma_t(\mathbf{f}, \mathbf{z}) - \hat{C}^\gamma_t(\mathbf{f}, \mathbf{z})\right)^2 N_{\mathcal{T}^{\zeta}}^{-1} \left(\hat{C}^\gamma_f(\mathbf{f}, \Delta t, \mathbf{z}) - \hat{C}^\gamma_f(\mathbf{f}, \Delta t, \mathbf{z})\right),$$

where, $N_{\mathcal{T}^{\zeta}}$ is the covariance matrix which can be calculated from the GW detector noise, network of the GW detectors (which affect the value of $l_{\text{max}}$), shot noise of the galaxy surveys, and the sky fraction of the galaxy surveys. $C^\gamma_t$ denotes the model of the cross-correlation power spectrum given in Eq. 17 and in Eq. 19, where the time-dependence arises only from the bias terms $b_\gamma f$ and $b_\gamma T$. However, the power spectrum of the dark matter distribution $PDM(k)$ remains constant in time. As a result, a best-fit value of the bias parameters $b_\gamma f$ and $b_\gamma T$ and their time dependence can
be inferred by minimizing Eq. 37. Though this remains an interesting avenue to better understand the redshift dependence of the bias, its applicability will depend on the angular resolution $\Delta \theta$, the overlap reduction function $\gamma(n, f, t)$, and the detector noise for different configurations of the future GW detectors network. With the currently available network of detectors LIGO Hanford (H), LIGO Livingston (L), and Virgo (V), we are not going to achieve the required sensitivity to measure the redshift dependent bias of the GW sources from the data.

5 ERROR ESTIMATION FOR MEASURING TEMPORAL FLUCTUATIONS IN SGWB

We make a Fisher analysis to estimate the error-bar using the Cramer-Rao bound ($\sigma_{\Delta \Omega} \geq \sqrt{\mathbf{F}^{-1}}$) of the time-variability and frequency-variability of the SGWB signal which can be measured using network of GW detectors such as advanced-LIGO Hanford (H), advanced-LIGO Livingston (L), advanced Virgo (V) and Cosmic Explorer (CE). The rms fluctuation in the SGWB can be expressed as the modification in the amplitude given by $\Delta \Omega(f) = \sqrt{\left(\frac{\partial GW(f, t)}{\partial n(f)}\right)^2}$. The corresponding Fisher estimate for a network of detectors (I,J) can be written as

$$F_{\alpha \beta} = \int_0^T dt \sum_{J=1}^{N} \sum_{J=1}^{N} \left( \frac{3H_0^2}{2\pi^2} \right)^2 \int_0^\infty df \frac{\gamma^2(j) \partial_n \Omega_{GW}(f) \partial_n \Omega_{GW}(f)}{f^6 N_I(j) N_J(f)},$$

where, $\gamma(f)$ is the overlap reduction function which depends upon the location and orientation of LIGO-H, LIGO-L and Virgo. $\gamma(f)$ is the overlap reduction function as between LIGO-H and LIGO-L, followed by LIGO-L and Virgo and then for LIGO-H and LIGO-L pair of detectors. Only for the frequency range of the GW signal less than $f \leq f_{\text{char}}$, we can make a coincidence detections of the GW signal between a pair of detectors. As a result, most of the statistical power for the measurement of the SGWB signal comes from the range of frequency $f \leq f_{\text{char}}$. This implies, the most statistical power comes from LIGO-H and LIGO-L pair of detectors, followed by LIGO-L and Virgo and then LIGO-H and Virgo.

Using the instrument noise for advanced-LIGO and VIRGO, we obtain the 5-$\sigma$ error-bar on $\Delta \Omega$ in Fig. 5 as a function of the observation time. For the network of three detectors such as LIGO-H, LIGO-L and Virgo, most of the statistical power in the measurement of the signal comes from LIGO-H and LIGO-L for the frequency of GW SGWB signal $f \geq 30$ Hz. For a network of three HL-like detectors, we have assumed the same noise curves and the overlap function $\gamma(f)$ as LIGO-H and LIGO-L, and show the amount of

Figure 4. The overlap reduction function $\gamma(f)$ as a function of frequency $f$ for the case with or without including Virgo are due to two reasons, (i) the fact that the $f_{\text{char}}$ is small than for the case with LIGO-H and LIGO-L, and (ii) the detector noise for Virgo interferometer is higher than CE.

6 CONCLUSION

The SGWB is a rich source of cosmological and astrophysical informations. The astrophysical SGWB arises from a large number of coalescing binary systems of compact objects such as black hole, neutron star and white dwarf. Such events are expected to occur randomly following a Poisson distributed in time with a constant event rate which depends upon the astrophysical parameters such as the mass of the compact objects, star formation history, redshift of the source, etc. Due to the Poissonian nature of the GW events, the SGWB is expected to exhibit a temporal fluctuations due to the variation of the number of events and is expected to attain the time translation symmetry on averaging over a long observation time. We point out the temporal dependence of the SGWB in this paper and discuss the implications of measuring it from the ongoing and future GW experiments. We show that the time-dependence of the SGWB and its rms fluctuations can be a useful probe to learn about several aspects such as the event rate of the GW sources for different chirp masses of the coalescing binaries, the duty cycle of GW signals, and the redshift distribution of the event rate.
Figure 5. The 5-σ error-bar on the fluctuations in the amplitude of the GW signal for different configurations of the GW detectors LIGO-Hanford (H), LIGO-Livingston (L) and Virgo (V). For the case of a three HL-like detector network, we have assumed a configuration with the same detector noise and overlap reduction function as LIGO-H and LIGO-L. For the next generation GW detectors such as Cosmic Explorer (CE) we have considered the instrument noise according to Abbott et al. (2017a) and with the overlap function same as for the LIGO-H and LIGO-L detector pair.

The temporal fluctuations of the SGWB can be studied in frequency domain, temporal domain and in the spatial domain as discussed in Sec. 3. By constructing quantities such as the spectral-derivative of the SGWB denoted by \( \mathcal{F} \) we can estimate the redshift integrated total GW energy density arising from different mass windows of the compact objects. The time-derivative of the SGWB denoted by \( \mathcal{T} \) captures the temporal fluctuation in the SGWB signal which is related to the event rate of the GW signal contributing at a particular frequency of the SGWB. The spatial distribution of the astrophysical GW sources are expected to follow the spatial distribution of the galaxies and can be estimated by cross-correlating with the galaxy distribution available from the upcoming cosmological surveys (such as DESI (Aghamousa et al. 2016), EUCLID (Refregier et al. 2010), LSST (LSST Science Collaboration et al. 2009), SPHEREx (Dore et al. 2018a), WFIRST (Dore et al. 2018b)). The cross-correlation of the SGWB with the galaxy field can probe the time-dependent bias of the SGWB signal for different cosmological redshifts as we have discussed in Sec. 4. The statistical significance of the cross-correlation between the SGWB map with the galaxy distribution is going to be limited by the angular resolution of the SGWB map. For the interferometer-based GW detectors, the smallest angular scale \( \Delta \theta \) that can be resolved in SGWB sky is set by the diffraction limit, which can be written in terms of the frequency of the GW signal and the distance between two detectors \( D \) as \( \Delta \theta = c/2fD \). This implies that the interferometer detectors, which are farthest away are the best for making high-resolution maps of the SGWB signal. However, for the interferometer detectors which are farther away are going to have an overlap reduction function with smaller value of \( f_{\text{char}} = c/2fD \), which can result into a higher instrument noise for frequencies greater than \( f_{\text{char}} \).

We propose that data analysis performed for ongoing GW experiments should search for temporal fluctuations along with the algorithms which search for spatial fluctuations. This procedure will be potentially useful for identifying the event rates for different binary species such as BNS, BBHs and BH-NS systems. The procedure outlined here will help establish the time-translation symmetry of the SGWB and inform us about the astrophysics related to the formation of these binary sources. This avenue of research will provide a useful tool for distinguishing between the astrophysical and cosmological SGWB signals. By exploring the time-dependence aspect of the SGWB signal, we can remove contamination from the astrophysical SGWB signal and peer into the higher frequency \( f \in 10 - 1000 \) Hz cosmological SGWB signals originating at different epochs of the Universe (Starobinsky 1979; Turner 1997; Martin et al. 2014; Kibble 1976; Damour & Vilenkin 2005; Kosowsky et al. 1992; Kamionkowski et al. 1994).

ACKNOWLEDGEMENT

The results of this analysis are obtained using the Horizon cluster hosted by Institut d’Astrophysique de Paris. We thank Stephane Rouberol for smoothly running the Horizon cluster.
