A Robust Method for Estimating Individualized Treatment Effect

Haomiao Meng and Xingye Qiao*

Abstract

We consider an additive model with a main effect and effects from multiple treatments. Our goal is to estimate the heterogeneous treatment effects among patients. Traditionally, one can fit standard regressions in which models for the main effect and the treatment effects are specified. However, mis-specification of either the main or the treatment effects could severely undermine the estimation. A set of recent proposals directly estimate the treatment effect, avoiding the potential mis-specification issue for the main effect. However, performance of these methods rely on either a known or accurate estimator of the propensity score. In this paper, we propose a doubly robust direct learning method (RD-Learning) to estimate the treatment effect. The double robustness comes from the fact that it is robust to the two issues of (1) main effect mis-specification and (2) inaccurate propensity score estimates. As long as these two do not occur at the same time, our estimate is consistent and has a smaller variance than competing methods. It can be used in both the binary and the multi-arm settings. As a by-product, we develop a competitive statistical inference tool for the treatment effect, assuming the propensity score is known. We provide theoretical insights to the proposed method using risk bounds under both linear and non-linear settings. Our method is further demonstrated by simulation studies and a real data example.

Keywords: individualized treatment effect; doubly robust estimator; multi-arm treatments; angle-based approach; precision medicine; statistical learning theory.

1 Introduction

Identifying heterogeneity in treatment effects is an important topic in precision medicine. For example, drug developers tag useful chemical compounds with high treatment effects; health care providers prescribe the best treatment to each individual patient. In this paper, we aim to estimate the difference between the conditional mean outcome given the covariate information for an individual subject and any of two treatments. This problem is typically known as estimation of Individualized Treatment Effect (ITE) or Conditional Average Treatment Effect (CATE).

There is a vast literature on ITE estimation. Two major types of approaches have been widely used. The first type is model-free local-based prototype methods, such as nearest-neighbor matching (Crump et al., 2008), and causal forests (Wager and Athey, 2018). The second type is model-based analytical methods. For example, in Q-Learning (Watkins and Dayan, 1992; Murphy, 2005; Qian and Murphy, 2011; Moodie et al., 2014), a conditional mean outcome is first estimated for each treatment, then ITE is constructed by taking their differences. However, these estimation are subject to model mis-specification, which often includes both the model for the main effect and the model for the treatment effect. A-Learning (Murphy, 2003; Robins, 2004) and D-Learning (Tian et al., 2014; Qi et al., 2018) address this issue by estimating the treatment effect directly imposing no model on the main effect, hence avoiding mis-specifying the latter. However, the success of both A-learning and D-learning rely on an accurate (or known) propensity score. Otherwise, the estimated ITE may be inconsistent. There are also procedures for estimating ITE based on Bayesian framework, for example, Bayesian Additive Regression Trees (Chipman et al., 2007, 2010; Hill, 2011).

Augmented Inverse Propensity Weighted Estimator (AIPWE), a robust estimator, was proposed (Robins et al., 1994; Rotnitzky et al., 1998; Scharfstein et al., 1999) to estimate the (unconditional) Average Treatment Effect (ATE) over the population. AIPWE has a nice “double robustness” property in the sense that as long as the model for either the conditional outcomes or the propensity score is correctly specified, the estimator is consistent. Note that AIPWE is not conditional on individual subjects. There are several recent proposals in personalized medicine with double robustness. For example, Zhang et al. (2012) proposed a framework to estimate the optimal treatment regime by using AIPWE as the objective function. Zhao et al. (2019) constructed the Individualized Treatment Rule (ITR) by treating AIPWE as the weight to solve a
weighted classification problem. For other related work, refer to Bang and Robins (2005); Kang et al. (2007); Cao et al. (2009); Zhang et al. (2013); Zhao et al. (2014); Zhang et al. (2015); Fan et al. (2016); Huang et al. (2019). Most of these procedures are designed for two-arm studies. Doubly robust methods for the multi-arm setting, such as Zhang et al. (2015) and Huang et al. (2019), mainly focus on estimating ITR rather than ITE. Secondly, among the doubly robust estimators for ITE, most of them are based on AIPWE, which requires estimation of the conditional mean outcome for each arm before estimating ITE. See, for example, Funk et al. (2011) and Lee et al. (2017).

In this paper, we propose Robust Direct Learning (RD-Learning) to estimate ITE. This is an improvement based on the D-Learning framework. The method differs from all the aforementioned doubly robust procedures in that it is not based on AIPWE. Specifically, instead of having to estimate the conditional mean outcome for each treatment arm before ITE estimation, we only need to estimate the main effect model. The consistency for ITE is guaranteed if either the main effect model or the propensity score model is correctly specified. Secondly, we generalize the method to the multi-arm case by making use of the angle-based multi-category classification method. Moreover, we consider a special setting with known propensity scores, in which case, we propose an efficient estimator for the main effect and an unbiased estimator for the treatment effect, and derive the asymptotic normality which affords statistical inference.

The rest of the paper is organized as follows. In Section 2, we introduce some notations and background. We present the proposed RD-Learning method in Section 3. Statistical inference in the known propensity score setting can be found in Section 4. In Section 5, we design simulation studies to validate the proposed method, followed by a real data example on AIDS clinical trial in Section 6. Section 7 concludes the paper. All technical proofs are provided in the supplementary material.

2 Notations and Background

First consider a two-arm randomized trial. A patient, with pre-treatment covariate $X \in \mathcal{X} \subseteq \mathbb{R}^p$, is randomly assigned to treatment $A \in \mathcal{A} = \{1, -1\}$. Let $Y^*(j) \in \mathbb{R}$ be the potential outcome the patient would receive by receiving treatment $j \in \mathcal{A}$. The observed clinical outcome is denoted by $Y = Y^*(A)$. Let $p_j(x) = \mathbb{P}(A = j \mid X = x)$. Assumption 1 is a typical regularity assumption.
Assumption 1. For any $j \in A$, $Y^*(j) \perp A \mid X$ and $p_j(x) \geq c$ for some $c \in (0, 1)$.

Let $P$ be the distribution of the triplet $(X, A, Y)$. The goal is to estimate the Individualized Treatment Effect (Chen et al., 2017, ITE), defined as

$$\mathbb{E}(Y^*(1) - Y^*(-1) \mid X = x),$$

denote the conditional mean outcome as $\mu$ based on a training sample $\{(x_i, a_i, y_i)\}_{i=1}^n$ randomly drawn from $P$.

It is typical to consider the following model,

$$Y = m(X) + A\delta(X) + \epsilon, \quad \text{where } \mathbb{E}(\epsilon) = 0, \ Var(\epsilon) = \sigma^2 < \infty. \tag{1}$$

Denote the conditional mean outcome as $\mu_j(x) \triangleq \mathbb{E}(Y^*(j) \mid X = x) = \mathbb{E}(Y \mid X = x, A = j)$. It can be easily verified that the main effect $m(x) = (\mu_1(x) + \mu_{-1}(x))/2$, and the treatment effect $\delta(x) = (\mu_1(x) - \mu_{-1}(x))/2$. Thus, to estimate ITE is equivalent to to estimate $\delta(x)$. In this article, we refer to $\delta(x)$ as the treatment effect.

One way to estimate $\delta(x)$ is to conduct regression modeling for $\mu_j(x)$, $j \in \{1, -1\}$. This approach is known as Q-Learning (Murphy, 2005; Qian and Murphy, 2011), where $\mu_j(x)$ is referred to as the “Q function”. For example, one may consider linear regression models for $\mu(x)$ and $\delta(x)$, such as $m(x) = x^T\alpha$ and $\delta(x) = x^T\beta$ with $x = (1, x^T)^T \in \mathbb{R}^{p+1}$. The coefficients are estimated by solving the following optimization problem,

$$\min_{\alpha, \beta \in \mathbb{R}^{p+1}} \frac{1}{n} \sum_{i=1}^n (y_i - x_i^T\alpha - a_i x_i^T\beta)^2.$$

This approach may be vulnerable to model mis-specification of $m(x)$ and $\delta(x)$. A partial solution is to consider a broader model space (e.g. non-parametric models) to avoid model mis-specification.

Tian et al. (2014) proposed a new method to estimate $\delta(x)$ without specifying the model for $m(x)$ under the completely randomized trail setting, i.e., $p_1(x) = 1/2$. By observing that $\mathbb{E}(AY \mid X = x) = \delta(x)$, we may use a linear function $x^T\beta$ to model $\mathbb{E}(AY \mid X = x)$ directly. Chen et al. (2017) considered a more general framework to accommodate other proportion $p_1(x)$ than 1/2, as well as observational studies. Specifically, for linear modeling, the treatment effect $\delta(x)$ is estimated by $x\hat{\beta}$ where

$$\hat{\beta} = \arg\min_{\beta \in \mathbb{R}^{p+1}} \frac{1}{n} \sum_{i=1}^n \frac{1}{p_{a_i}(x_i)} (a_i y_i - x_i^T\beta)^2 = \arg\min_{\beta \in \mathbb{R}^{p+1}} \frac{1}{n} \sum_{i=1}^n \frac{1}{p_{a_i}(x_i)} (y_i - a_i x_i^T\beta)^2. \tag{2}$$

This estimator has been proved to be consistent under Assumption 1. Unlike Q-Learning, in which
the estimator to $\delta(x)$ is based on the estimators for $\mu_j(x)$'s, this approach directly estimates the treatment effect $\delta(x)$. Hence, it is named Direct Learning or D-Learning (Qi et al., 2018). Non-linear or sparse modeling is also possible in this framework.

One advantage of D-Learning over Q-learning is that it avoids mis-specification of the main effect $m(x)$. However, existing consistency results for D-Learning assume that the propensity score $p_j(x)$ is known or at least correctly specified, which may not be satisfied in observational studies. Moreover, as will be shown later, the D-Learning estimator also suffers a larger variance compared to other methods.

3 RD-Learning

We first introduce our proposed Robust Direct Learning (RD-Learning) approach for the binary case, then generalize it to the multi-arm case. This is followed by the theoretical study of the proposed method.

3.1 RD-Learning in the Binary Case

Given a training sample $\{x_i, a_i, y_i\}_{i=1}^n$, the RD-Learning method is based on an estimator for the propensity score $p_1(x)$, denoted by $\hat{p}_1(x)$, and an estimator for the main effect $m(x)$, denoted by $\hat{m}(x)$. They can be any existing estimators commonly used in the literature. If we consider linear modeling for the treatment effect, i.e., $\delta(x) = x\beta$, then RD-Learning estimator for $\beta$ is obtained by solving

$$\hat{\beta} = \arg\min_{\beta \in \mathbb{R}^{p+1}} \frac{1}{n} \sum_{i=1}^{n} \frac{1}{\hat{p}_{a_i}(x_i)} (y_i - \hat{m}(x_i) - a_i x_i^T \beta)^2,$$

(3)

where $x_i = (1, x_i^T)^T$, and the treatment effect is estimated by $\hat{\delta}(x) = x^T \hat{\beta}$.

A major difference between (3) and (2) is that RD-Learning replaces $y_i$ in D-Learning by a residual $y_i - \hat{m}(x)$. In the literature, similar procedures have been proposed in many other methods. For example, Shi et al. (2016) and Nie and Wager (2017) proposed Robust Learning to estimate $\delta(x)$ by replacing $y_i$ in A-Learning (Murphy, 2003; Robins, 2004) with $y_i - \hat{\Phi}(x_i)$, where $\hat{\Phi}(x)$ is an estimator for $E(Y \mid X = x)$. In the literature of Individualized Treatment Rule (ITR), similar efforts have been made to improve Outcome Weighted Learning (Zhao et al., 2012, OWL).
using Residual Weighted Learning (Zhou et al., 2017, RWL), where the latter one replaces the outcome $y_i$ in OWL by $y_i - \hat{m}(x_i)$. In general, such procedures can reduce the variance of the estimators. Even when $\Phi(x)$ or $m(x)$ is mis-specified, the estimators are still consistent as long as the propensity score $\hat{p}_1(x)$ can be consistently estimated. That is to say, these estimators are robust against model mis-specification with respect to $\Phi(x)$ or $m(x)$. The RD-Learning method that we propose here to estimate ITE also enjoys this robustness property. Beyond that, it has an additional “double robustness” property, which is described in the following theorem.

**Theorem 1.** Suppose model (1) holds. Let $\tilde{p}_1(x)$ be a working model for the propensity score $p_1(x)$ with $0 < \tilde{p}_1(x) < 1$ and $\tilde{m}(x)$ be a working model for the main effect $m(x)$. Assume that Assumption 1 holds. Then we have

$$\delta \in \arg\min_{f \in \{X \to \mathbb{R}\}} \mathbb{E} \left[ \frac{1}{\tilde{p}_1(X)} (Y - \tilde{m}(X) - Af(X))^2 \right]$$

if either $\tilde{p}_1(x) = p_1(x)$ or $\tilde{m}(x) = m(x)$ for $x \in \mathcal{X}$ almost surely.

Theorem 1 also holds when, the functions $\tilde{p}_1(x)$ and $\tilde{m}(x)$ are replaced by the limiting functions of estimators $\hat{p}_1(x)$ and $\hat{m}(x)$. This suggests that the empirical version of the minimizer above $\hat{\delta}(x)$ (whose definitions are given in (3) and in Section 3.2) will be consistent with $\delta(x)$ if either $\hat{p}_1(x)$ or $\hat{m}(x)$ is consistent. Compared to the aforementioned robustness procedures, this estimator is robust against two types of model mis-specification, with respect to both $p_1(x)$ and $m(x)$. We call this property “double robustness”.

To compare RD-Learning and D-Learning, we compute the bias and the variance of the estimators from these two methods. Denote $X = (x_1, \ldots, x_n)^T$, $y = (y_1, \ldots, y_n)^T$, and $m(X) = (m(x_1), \ldots, m(x_n))^T$. Let $A = \text{diag}(a_i)$, and $P_a = \text{diag}(\hat{p}_a(x_i))$, from (3) we derive

$$\hat{\beta} = (X^T P_a^{-1} X)^{-1} X^T A P_a^{-1} (y - \hat{m}(X)).$$

(4)

Let $r(X) = m(X) - \hat{m}(X)$ be the difference between the true main effect and its estimator. It can be shown that

$$\mathbb{E}(\hat{\beta} | X, A) = \beta + (X^T P_a^{-1} X)^{-1} X^T A P_a^{-1} r(X),$$

(5)

$$\text{Var}(\hat{\beta} | X, A) = \sigma^2 (X^T P_a^{-1} X)^{-1} X^T P_a^{-2} X (X^T P_a^{-1} X)^{-1}, \quad \text{and}$$

$$\text{Var}(\hat{\beta} | X) = \text{Var} \left( (X^T P_a^{-1} X)^{-1} X^T A P_a^{-1} r(X) | X \right) + \mathbb{E} \left( \text{Var}(\hat{\beta} | X, A) | X \right).$$

(6)
Note that D-Learning can be viewed as a special case of RD-Learning, where \( \hat{m}(x_i) = 0 \) for all \( i \), in which case \( r(x_i) = m(x_i) \). Firstly, from (5) we observe that the estimator by RD-Learning has a smaller bias if \(|r(x_i)| < |m(x_i)|\) holds. In the extreme that \( \hat{m}(x) = m(x) \) which means that \( r(x) = 0 \), the RD-Learning estimator \( \hat{\beta} \) is an unbiased estimator. Secondly, from (6) we notice that RD-Learning also has a smaller variance. This is because in general the variability of the residual term \( r(X) \) is smaller than that of \( m(X) \), which results in a smaller value in the first term of (6). The smallest variance is achieved when \( r(x) = 0 \) (perfect estimation of \( m(x) \)).

For high dimensional data, RD-Learning can be generalized by using a sparsity penalty. For example, we may solve a LASSO problem,

\[
\min_{\beta \in \mathbb{R}^p, \beta_0 \in \mathbb{R}} \frac{1}{n} \sum_{i=1}^{n} \frac{1}{\hat{p}_{a_i}(x_i)} \left( y_i - \hat{m}(x_i) - a_i(x_i^T \beta + \beta_0) \right)^2 + \lambda \| \beta \|_1
\]  

(7)

with the tuning parameter \( \lambda > 0 \). To adopt a richer model space, we could also consider a non-linear function form for \( \delta(x) \). For example, we may solve a kernel ridge regression problem as follows.

\[
\min_{\beta \in \mathbb{R}^n, \beta_0 \in \mathbb{R}} \frac{1}{n} \sum_{i=1}^{n} \frac{1}{\hat{p}_{a_i}(x_i)} \left( y_i - \hat{m}(x_i) - a_i(K_i^T \beta + \beta_0) \right)^2 + \lambda \beta^T K \beta,
\]

where \( K_i \) is the \( i \)th column of the gram matrix \( K = (K(x_i, x_j))_{n \times n} \), with \( K(\cdot, \cdot) \) a kernel function. Other non-linear regression models such as generalized additive model and gradient boosting can be applied in the RD-Learning framework.

Figure 1 compares Q-Learning, D-Learning, and RD-Learning using two toy examples. In each example, the Subpopulation Treatment Effect Pattern Plots (STEPP), a typical visualization method for exploring the heterogeneity of treatment effects (Bonetti and Gelber, 2000, 2004), shows the relationship between the estimated ITEs and predictor \( x_1 \). Case I has a non-linear main effect and a linear treatment effect, where \( \mu_j(x) = 2 \cos(x_1 + \pi/4) + (3 - j)x_1/2 - \tanh(x_1) \) for \( j \in \{1, -1\} \) and \( p_1(x) = 0.2 + 0.61[x_1 < 0] \). For Q-Learning, we use kernel ridge regression to estimate \( \mu_j(\cdot) \); for D-Learning, we use LASSO as in Qi et al. (2018) to estimate the treatment effect \( \delta(\cdot) \); in RD-Learning, we use kernel ridge regression to estimate \( m(\cdot) \) and the LASSO estimator (7) to estimate \( \delta(\cdot) \). Both the main effect and the treatment effect in Case II have a linear form, with \( \mu_j(x) = (3 - j)x_1/2 + x_2 \) for \( j \in \{1, -1\} \) and \( p_1(x) = 1/2 \). We use LASSO to estimate \( \mu_j(\cdot) \), \( m(\cdot) \), and \( \delta(\cdot) \) in all three methods. Note that the true ITE is \( \mu_1(x) - \mu_{-1}(x) = -x_1 \) in both cases. From Figure 1, it is clear that RD-Learning is a robust method. In particular, compared
to Q-Learning, RD-Learning reduces bias in estimating ITE when the main effect tends to be mis-specified (Case I). Compared to D-Learning, RD-Learning reduces variance in both examples.

Figure 1: Subpopulation Treatment Effect Pattern Plots (STEPP) by different methods on two simulated data with $X \subseteq \mathbb{R}^{20}$. Blue regions are 95% confidence region based on 200 replications, and the black line is the true ITE. In both cases RD-Learning has a good performance.

3.2 RD-Learning in Multi-arm Case

In this section, we generalize RD-Learning to the case when there are more than two treatment arms. Let $A \in \mathcal{A} = \{1, \ldots, k\}$ be the treatment assignment. We assume the model to be

$$Y = m(X) + \delta_A(X) + \epsilon, \quad \text{where} \sum_{j=1}^{k} \delta_j(x) = 0, \ E(\epsilon) = 0, \ \text{Var}(\epsilon|X) = \sigma^2(X) < \infty. \quad (8)$$

As in the binary case, $m(\cdot)$ is the main effect. $\{\delta_j(\cdot)\}_{j=1}^{k}$ are the treatment effects, where each of them measures the difference between the expected outcome of treatment $j$ and the main effect, i.e., $\delta_j(x) = \mu_j(x) - m(x)$. The sum-to-zero constraint guarantees the model is identifiable.
We also allow heteroskedasticity in the white noise term $\epsilon$ to make the model more general. To estimate the treatment effect $\delta_j(x)$, we consider the following angle-based approach.

Angle-based approach (Zhang and Liu, 2014) is a method used in multicategory classification problem and recently it has been introduced to solve a multicategory ITR problem (Zhang et al., 2018; Qi et al., 2019). In the angle-based framework, we represent $k$ arms by $k$ vertices of a $(k-1)$-dimensional simplex, denoted by $W_1, \ldots, W_k$:

$$W_j = \begin{cases} (k-1)^{-1/2}1_{k-1} & j = 1 \\ -(1+k^{1/2})(k-1)^{-3/2}1_{k-1} + \left[k/(k-1)\right]^{1/2}e_{j-1}, & 2 \leq j \leq k, \end{cases}$$

where $1_{k-1}$ is a $(k-1)$-dimensional vector with all elements equal to 1 and $e_{j-1} \in \mathbb{R}^{k-1}$ is a vector with the $(j-1)$th element 1 and 0 elsewhere. It is easy to check that $\|W_j\| = 1$ and the angle $\angle(W_i, W_j)$ is the same for all $i \neq j$. The angle-based approach uses a $(k-1)$-dimensional vector-valued function $f(x) = (f_1(x), \ldots, f_{k-1}(x))^T$ as the decision function. In an ITR problem, by computing the angles between $f(x)$ and these vertices $W_j$s, the optimal treatment for patient with covariates $x$ is chosen to be argmin$_{j \in A} \angle(W_j, f(x))$.

Note that for any $f(x) \in \mathbb{R}^{k-1}$, the sum-to-zero constraint is satisfied for the inner products implicitly, $\sum_{j=1}^k \langle W_j, f(x) \rangle = 0$. On the other hand, for treatment effects $\{\delta_j(x)\}_{j=1}^k$ with $\sum_{j=1}^k \delta_j(x) = 0$, there is a unique $f(x) \in \mathbb{R}^{k-1}$ such that $\langle W_j, f(x) \rangle = \delta_j(x)$ for $j \in A$. This motivates us to estimate the treatment effect $\delta_j(x)$ by $\langle W_j, f(x) \rangle$ in the angle-based framework.

**Theorem 2.** Suppose model (8) holds. Let $\tilde{p}_j(x) > 0$ be a working model for $p_j(x)$ and $\hat{m}(x)$ be a working model for $m(x)$. Define

$$f^* \in \arg\min_{f \in \{X \to \mathbb{R}^{k-1}\}} \mathbb{E} \left[ \frac{1}{\hat{p}_A(X)} (Y - \hat{m}(X) - \langle W_A, f(X) \rangle)^2 \right].$$

Under Assumption 1, if either $\tilde{p}_j(x) = p_j(x)$ or $\hat{m}(x) = m(x)$ holds for $x \in X$ almost surely and all $j \in A$, then $\delta_j(x) = \langle W_j, f^*(x) \rangle$ except on a set of measure zero.

By Theorem 2, we propose the angle-based RD-Learning $^1$ by solving

$$\min_{f \in F} \frac{1}{n} \sum_{i=1}^n \frac{1}{\hat{p}_{a_i}(x_i)} (y_i - \hat{m}(x_i) - \langle W_{a_i}, f(x_i) \rangle)^2,$$  \hspace{1cm} (9)

where $F$ is a function space. For example, we may let $F$ to be the linear space, i.e. $F = \{f = \ldots$  

---

$^1$Angle-based D-Learning has been studied in Qi et al. (2019) with a different formulation.
(f_1, \ldots, f_{k-1})^T; f_j(x) = x^T \beta_j, j = 1, \ldots, k-1); or, we may consider \( \mathcal{F} \) in a Reproducing Kernel Hilbert Space (RKHS) with kernel function \( K(\cdot, \cdot) \), i.e. \( \mathcal{F} = \{ f = (f_1, \ldots, f_{k-1})^T; f_j(x) = \sum_{i=1}^n K(x_i, x) \beta_{ij} + \beta_{0j}, j = 1, \ldots, k-1 \} \). An \( L_1 \) or \( L_2 \) norm constraint can be also added to \( f \) to prevent overfitting. Denote the solution of (9) by \( \hat{f} \). Then the estimator for \( j \)th treatment effect is given by

\[
\hat{\delta}_j(x) = \langle W_j, \hat{f}(x) \rangle.
\]  

Note that the binary RD-Learning introduced in Section 3.1 is a special case of the angle-based RD-Learning. Note that when \( k = 2 \), we have \( W_1 = 1 \) and \( W_2 = -1 \). So \( \langle W_a, f(x) \rangle = f(x) \) for \( a = 1 \) and \( \langle W_a, f(x) \rangle = -f(x) \) for \( a = 2 \) thus (9) reduces to (3) for the linear function space.

### 3.3 Theoretical Analysis of RD-Learning

In this section, we study the theoretical property of \( \hat{\delta}_j(x) \) defined in (10) by solving (9). Note that it suffices to consider angle-based RD-Learning since binary RD-Learning is a special case of angle-based RD-Learning. Denote \( \hat{\delta} = (\hat{\delta}_1, \ldots, \hat{\delta}_k)^T \). The goal of our theoretical study is to obtain the convergence rate for the prediction error (PE) of \( \hat{\delta} \), defined by

\[
\text{PE}(\hat{\delta}) = \mathbb{E} \sum_{j=1}^k \left( \hat{\delta}_j(X) - \delta_j(X) \right)^2,
\]

where the expectation is with respect to \( X \). Note that since \( \hat{\delta} \) depends on the training data, \( \text{PE}(\hat{\delta}) \) is a random quantity. We consider linear models and non-linear models separately.

Before we present the main results, we make two additional assumptions for the two estimators \( \hat{p}_j(x) \) and \( \hat{m}(x) \).

**Assumption 2.** Given estimator \( \hat{p}_j \), we have \( \| \hat{p}_j^{-1}(x) - p_j^{-1}(x) \|_\infty \leq r_p \) with constant \( r_p > 0 \).

**Assumption 3.** Given estimator \( \hat{m} \), we have \( \| \hat{m}(x) - m(x) \|_\infty \leq r_m \) and \( |Y - \hat{m}(X)| \leq C_m \) with \( r_m > 0 \) and \( C_m > 0 \).

Assumptions 2 and 3 state that the estimation error for \( \hat{p}_j^{-1}(x) \) and \( \hat{m}(x) \) are bounded with \( r_p \) and \( r_m \) characterizing the accuracy for both estimators. Recall that \( \hat{p}_j(x) \) and \( \hat{m}(x) \) are the limiting functions of \( \hat{p}_j(x) \) and \( \hat{m}(x) \) in Theorem 2. The case of \( \hat{p}_j(x) = p_j(x) \) corresponds to \( r_p \ll r_m \); the case of \( \hat{m}(x) = m(x) \) corresponds to \( r_m \ll r_p \).
3.3.1 Linear Function Space

We consider a linear function space $\mathcal{F}$ with a bounded $L_1$ norm:

$$
\mathcal{F} = \mathcal{F}(p, s) \triangleq \{ f = (f_1, \ldots, f_{k-1})^T; f_j(x) = \mathbf{x}^T \beta_j + \beta_{0j}, j = 1, \ldots, k-1, \sum_{j=1}^{k-1} \| \beta_j \|_1 \leq s \}.
$$

Without loss of generality, we bound each covariate in $[-1, 1]$ for simplicity. The result still holds if we bound each covariate in $[-B, B]$ for any large number $B > 0$.

Assumption 4. $X \in \mathcal{X} = [-1, 1]^p$.

Theorem 3. Denote $p_n$ as the dimension of the data which may depend on sample size $n$. Let $\mathcal{F} = \mathcal{F}(p_n, s_n)$ and $\tau_n = (n^{-1} \log p_n)^{1/2} \to 0$ as $n \to \infty$. Under Assumptions 1 to 4, we have

$$
\text{PE}(\hat{\delta}) \leq O \left( \max \left\{ (C_m + s_n)^2 \tau_n \log \tau_n^{-1}, \min\{r_1, r_2\}, d_n \right\} \right),
$$

almost surely, given estimators $\hat{p}_j(\cdot)$ and $\hat{m}(\cdot)$, where $r_1 = (C_m + s_n)^2 r_p$, $r_2 = (1 + r_p) r_m^2$, and $d_n = \inf_{f \in \mathcal{F}(p_n, s_n)} \| f - f^* \|_2^2$.

Remark 1. Theorem 3 claims that the order of $\text{PE}(\hat{\delta})$ is determined by three terms. The first term is the estimation error similar to the excess risk in the classification literature. As $n \to \infty$, the term will vanish for fixed $s_n$, while for fixed $n$ and $p_n$, it increases as $s_n \to \infty$ indicating a more complicated function space. The second term is determined by the accuracy of the two preliminary estimators $\hat{p}_j(\cdot)$ and $\hat{m}(\cdot)$. Specifically, $r_1$ describes the error from $\hat{p}_j(\mathbf{x})$ while $r_2$ describes the error from $\hat{m}(\mathbf{x})$. This term is small as long as either $r_p$ or $r_m$ is small, corresponding to the case when $\hat{p}_j(\mathbf{x})$ or $\hat{m}(\mathbf{x})$ is accurate. Hence, this term reflects the “double robustness” property of the proposed estimator. The third term $d_n$ is the approximation error of the function space $\mathcal{F}(p_n, s_n)$, and it will decrease as $s_n$ increases in general. The choice of $s_n$ represents a trade-off between the three terms.

Remark 2. By Theorem 3, RD-Learning improves D-Learning in the following two aspects. Firstly, the second term in the upper bound of $\text{PE}(\hat{\delta})$ offers an additional way to decrease the error. Note that D-Learning is a special case of RD-Learning with $\hat{m} \equiv 0$, which means $r_2$ is a large number. Therefore, for D-Learning to work well, $r_1$ must be small. On the other hand, RD-Learning offers a good ITE as long as either $r_1$ or $r_2$ is small. Secondly, the estimator of RD-Learning has a smaller variance than that of D-Learning. This is because by replacing $y_i$ in
D-Learning with $y_i - \hat{m}(x_i)$, the upper bound $C_m$ for $|Y - \hat{m}(X)|$ in Assumption 3 also becomes smaller in general, which further reduces the first term in $PE(\hat{\delta})$. This explains the narrower confidence bands of RD-Learning in Figure 1.

Theorem 3 is a general statement for the convergence rate of $PE(\hat{\delta})$. It neither makes assumptions on the magnitude of $r_p$ and $r_m$ which have impacts on the second term, nor assumes the true treatment effect falls in a particular function space $\mathcal{F}$ which influences the third term. If we assume one of $r_p$ and $r_m$ is zero, the second term can be ignored. For example, in clinical trial $p_j(x)$ is known so $\hat{p}_j(x) = p_j(x)$ and $r_p = 0$. If we further assume $\delta_j(x)$ to be a linear function that only depends on finite many covariates for each $j$, the third term can be also eliminated. Since in that case, there exists a finite $p^*$ and $s^*$ such that the true population minimizer $f^*$ belongs to the $\mathcal{F}(p_n, s_n)$ as long as the function space we consider is large enough so that $p_n \geq p^*$ and $s_n \geq s^*$. In this case, the third term $d_n = 0$ for sufficient large $n$. The result is given in Corollary 1.

**Corollary 1.** Let $\mathcal{F} = \mathcal{F}(p_n, s_n)$ and $\tau_n = (n^{-1} \log p_n)^{1/2} \to 0$ as $n \to \infty$. Suppose the true treatment effect $\delta_j(\cdot)$ depends on finite many covariates for each $j \in \mathcal{A}$. Under Assumptions 1 to 4, if either $r_p = 0$ or $r_m = 0$ holds, then we have

$$PE(\hat{\delta}) \leq O(\tau_n \log \tau_n^{-1}),$$

almost surely.

From Corollary 1, we first observe that the convergence of $PE(\hat{\delta})$ requires that $p_n$ increases with the order at most $\exp(n)$. Secondly, since $O(\log x) < O(x^t)$ for all $t > 0$, $PE(\hat{\delta}) \leq O(\tau_n^{1-t})$ for any small positive $t$. This implies that the upper bound of $PE(\hat{\delta})$ is almost $O(\tau_n) = O((n^{-1} \log p_n)^{1/2})$. Furthermore, when $p_n$ is a fixed number, i.e., $p_n = O(1)$, the rate is almost $O(n^{-1/2})$. These results are coincident with most of the classical LASSO theory.

### 3.3.2 Reproducing Kernel Hilbert Space

We consider $\mathcal{F}$ to be a Reproducing Kernel Hilbert Space (RKHS) to demonstrate the results for non-linear learning. The “kernel trick” has been successfully used in many other methods like penalized regression and Support Vector Machine (SVM). There is a vast literature on RKHS. One can refer to Scholkopf and Smola (2001), Steinwart et al. (2007), Hofmann et al. (2008), Trevor et al. (2009) for more details.
Let $\mathcal{H}_K$ be a RKHS with kernel function $K(\cdot, \cdot)$. By the Mercer’s theorem, $K$ has an eigen-
expansion $K(x, x') = \sum_{i=1}^{\infty} \gamma_i \phi_i(x) \phi_i(x')$ with $\gamma_i \geq 0$ and $\sum_{i=1}^{\infty} \gamma_i^2 < \infty$. Any function in $\mathcal{H}_K$ can be written as $f(x) = \sum_{i=1}^{\infty} c_i \phi_i(x)$ under the constraint that $\|f\|^2_{\mathcal{H}_K} = \sum_{i=1}^{\infty} c_i^2 / \gamma_i < \infty$. Define the function space $\mathcal{F}$ as
\[
\mathcal{F} = \mathcal{F}(s) \triangleq \{ f = (f_1, \ldots, f_{k-1})^T; f_j = f_j' + b_j, j = 1, \ldots, k - 1, \sum_{j=1}^{k-1} \|f_j'\|^2_{\mathcal{H}_K} \leq s^2 \}.
\]
Note that as in the linear case, the penalty term does not include the intercept term $b_j$. Rewrite
the solution to (9) under such $\mathcal{F}$ as $\hat{f} = \hat{f}' + \hat{b}$ where $\hat{f}' = (\hat{f}_1', \ldots, \hat{f}_k')^T$ with $f_j' \in \mathcal{H}_K$. By the representer theorem (Wahba, 1990), $\hat{f}_j'$ can be represented by
\[
\hat{f}_j'(x) = \sum_{i=1}^{n} K(x_i, x) \hat{\beta}_{ij},
\]
and the penalty term is written as $\|\hat{f}_j'\|^2_{\mathcal{H}_K} = \sum_{i=1}^{n} \sum_{l=1}^{n} K(x_i, x_l) \hat{\beta}_{ij} \hat{\beta}_{lj}$.

When developing RKHS theory, the following assumption is usually made.

**Assumption 5.** The RKHS $\mathcal{H}_K$ is separable and $\sup_x K(x, x) = B < \infty$.

The separability of the RKHS is commonly assumed in many papers concerning RKHS. A bounded kernel ensures that the rate of $\text{PE}(\delta)$ does not explode. It naturally holds for some popular kernels like Gaussian radial basis kernel, where $B = 1$. In general, it requires that $\mathcal{X}$ can be covered by a compact set.

**Theorem 4.** Let $\mathcal{F} = \mathcal{F}(s_n)$. Under Assumptions 1, 2, 3, and 5, we have
\[
\text{PE}(\delta) \leq O \left( \max \left\{ \left( C_m + Bs_n \right)^2 n^{-1/2} \log n, \min\{r_1, r_2\}, d_n \right\} \right),
\]
almost surely, given estimators $\hat{p}_j(\cdot)$ and $\hat{m}(\cdot)$, where $r_1 = (C_m + Bs_n)^2 r_p$, $r_2 = (1 + r_p) r_m^2$, and $d_n = \inf_{f \in \mathcal{F}(s_n)} \| f - f^* \|^2_2$.

**Remark 3.** Similar to Theorem 3, there is a trade-off between the estimation error, the approximation error, and the error from $\hat{p}_j$ and $\hat{m}$ for kernel learning. $s_n$ is the tuning parameter to balance these three terms. The result also shows that compared to D-Learning, RD-Learning still enjoys a better convergence rate through a smaller $r_m$ and $C_m$.

Theorem 4 can be simplified in some special cases. Firstly, the second term can be ignored when $r_p$ or $r_m$ is negligible (for example, in clinical trails). Secondly, by assuming the approximation
error $d_n \leq O(s_n^{-q})$ for some $q > 0$, which is standard in the literature on RKHS (Smale and Zhou, 2003), we have a neat convergence rate by appropriately choosing $s_n$, shown in Corollary 2.

**Corollary 2.** Let $\mathcal{F} = \mathcal{F}(s_n)$. Suppose $d_n = \inf_{f \in \mathcal{F}(s_n)} \| f - f^* \|_2^2 \leq O(s_n^{-q})$ for some $q > 0$. Under Assumption 1, 2, 3, and 5, if either $r_p = 0$ or $r_m = 0$ holds, then by choosing $s_n = O\left((n^{1/2} \log^{-1} n)^{1/2q}\right)$, we have

$$\text{PE}(\hat{\delta}) \leq O\left(n^{-\frac{q}{2q+2}}\right),$$

almost surely.

According to Corollary 2, the convergence rate of $\text{PE}(\hat{\delta})$ approaches to $O\left(n^{-1/2}\right)$ for sufficiently large $q$, corresponding to the case that $f^*$ can be well approximated by a function in $\mathcal{F}(s_n)$. This result is consistent with most of the learning theories under the kernel setting.

### 4 Statistical Inference with Known Propensity Score

In this section, we consider the case when the propensity score $p_j(x)$ is known for each $j \in \mathcal{A}$. A typical example is clinical trials, where the treatments are assigned to patients randomly with a fixed probability given $x$. In this case, we propose a consistent estimator for the main effect $m(x)$, which, according to the theories in Section 3.3, helps to reduce the variance of the treatment effect estimator $\hat{\delta}_j(x)$. A more fundamental contribution we make in this setting is an unbiased estimator for the treatment effect $\delta_j(x)$ which is allowed by the known propensity score. We also derive its asymptotic normality which is useful for constructing confidence intervals.

#### 4.1 A Direct Method in Estimating the Main Effect

The RD-Learning framework we proposed in Section 3 is a two-step procedure. While the discussion so far focuses on the second step, i.e., estimating the treatment effect $\hat{\delta}_j(x)$, we note that the first step, i.e., estimating the main effect $m(x)$, is also important.\(^2\) The theoretical studies in Section 3.3 show that an accurate $\hat{m}(x)$ reduces the variance of $\hat{\delta}_j(x)$. Moreover, the estimation of the main effect has its own value. For example, in biomedical studies, it can help researchers to identify prognostic biomarkers (Kosorok and Laber, 2019).

\(^2\)There is no need to estimate $p_j(x)$ in this case since we assume the propensity score is known.
A common method to estimate the main effect is Q-Learning. One first estimates each $\mu_j(x)$ for $j \in A$ separately, and then estimates $m(x)$ by taking their average. However, this main effect estimator may be inconsistent if $\mu_j(x)$ is mis-specified for some $j$. In addition, since the estimation of each $\mu_j(x)$ depends on only a portion of the data, i.e., $\{(x_i, a_i, y_i); a_i = j\}$, the estimator may suffer a large variance when there are very few observations in some treatment arms.

We propose to estimate the main effect using all the data points at the same time using weighted least square. This estimator is motivated by the important observation that under model (8),

$$\mathbb{E}\left[\frac{1}{p_A(x)}(Y - g(x))^2 \mid X = x\right] = \sum_{j=1}^{k} (Y^*(j) - g(x))^2 = \sum_{j=1}^{k} (\mu_j(x) - g(x))^2 + k\sigma^2(x),$$

and the fact that $m(x) = k^{-1}\sum_{j=1}^{k} \mu_j(x) = \arg\min_{g(x) \in \mathbb{R}} \sum_{j=1}^{k} (\mu_j(x) - g(x))^2$.

Based on these observations, we propose to estimate the main effect using

$$\hat{m} = \arg\min_{g \in \mathcal{G}} \sum_{i=1}^{n} \frac{1}{p(a_i(x_i))} (y_i - g(x_i))^2,$$

(11)

where $\mathcal{G}$ is an appropriate function space. Theorem 5 below implies that this estimator is consistent if $m \in \mathcal{G}$.

**Theorem 5.** Suppose the model (8) holds. Under Assumption 1,

$$m \in \arg\min_{g \in \{X \to \mathbb{R}\}} \mathbb{E}\left[\frac{1}{p_A(X)}(Y - g(X))^2 \right].$$

Compared to the Q-Learning based method, the proposed method uses all the data to fit a single estimator. Besides, this estimated adopts the form of weighted least square, which can be easily generalized to and solved by many existing regression methods, such as LASSO, (kernel) ridge regression, generalized additive model, gradient boosting, and so on.

### 4.2 Unbiased Treatment Effect Estimator

In this section we focus on statistical inference of treatment effects by RD-Learning, under the special case that $\hat{p}_j(x)$ in the RD-Learning estimator is replaced the known propensity score $p_j(x)$ for each $j \in A$.

We start from the binary case under model (1). By assuming $\delta(x) = x^T\beta$, the estimator $\hat{\beta}$ by RD-Learning is given by (4). However, we have to point out that this estimator is biased unless...
\( p_1(x_i) = 1/2 \) or \( \hat{m}(x_i) = m(x_i) \) for each \( i \). In fact, according to (5), the bias term can be explicitly written as

\[
\text{bias}(\hat{\beta}) = E(\hat{\beta}) - \beta = E((X^T P^{-1}_a X)^{-1} X^T A P^{-1}_a r(X)).
\]

**Remark 4.** To see why \( \hat{\beta} \) is biased, consider a simple case where \( n = 3 \), \( X = 1_3 \), and \( p_1(x) = p_1 \triangleq 2/3 \). Suppose we have an estimator \( \hat{m}(x) \) with the residual term \( r(x) = m(x) - \hat{m}(x) = 1 \). It can be checked that \( \text{bias}(\hat{\beta}) = E\left( (\sum_{i=1}^3 p_{A_i}^{-1})^{-1} \sum_{i=1}^3 A_i/p_{A_i} \right) \), where the expectation is taken with respect to \( \{A_i\} \). Note that there are 8 possible assignments for \( \{A_i\} \): \((1,1,1),(1,1,-1),\ldots,(-1,-1,-1)\), with probabilities \((2/3)^3,(2/3)^2(1/3),\ldots,(1/3)^3\). So by computing this expectation explicitly, we have \( \text{bias}(\hat{\beta}) = 17/135 \neq 0 \) in this toy example.

To remove the bias completely, we modify (4) as

\[
\tilde{\beta} = \frac{1}{2} (X^T X)^{-1} X^T A P^{-1}_a (y - \hat{m}(X)). \tag{12}
\]

The original RD-Learning estimator (4) was based the following normal equation of (3),

\[
X^T P^{-1}_a X \beta = X^T A P^{-1}_a (y - \hat{m}(X)). \tag{13}
\]

Since we assume \( p_{a_i}(x_i) \) is known, we can verify that the expectation of the left hand side of (13) with respect to \( A \) for any \( \beta \) is

\[
E\left( X^T P^{-1}_a X \beta \mid X \right) = 2X^T X \beta.
\]

Then by replacing the left hand side of (13) by its expectation, we derive the modified estimator (12). One can check that the bias of the modified estimator is 0.

In the multi-arm case (8), we use the angle-based approach to estimate a \((k-1)\)-dimensional decision function \( f(x) = (x^T \beta_1, \ldots, x^T \beta_{k-1})^T \) first and then use \( \langle W_j, f(x) \rangle \) to estimate \( \delta_j(x) \). Specifically, we solve

\[
\{\hat{\beta}_1, \ldots, \hat{\beta}_{k-1}\} \in \arg\min_{(\beta_j)} \frac{1}{n} \sum_{i=1}^n \frac{1}{p_{a_i}(x_i)} \left( y_i - \hat{m}(x_i) - \langle W_{a_i}, f(x_i) \rangle \right)^2.
\]

Denote \( \hat{\mathbf{B}}_{(p+1)\times(k-1)} \) as \( (\hat{\beta}_1, \ldots, \hat{\beta}_{k-1}) \). By using the similar trick as described above for the binary case, we modify \( \hat{\mathbf{B}} \) to be an unbiased \( \tilde{\mathbf{B}} \). The modified estimator for the treatment effect is then \( \tilde{\delta}_j(x) = \langle W_j, x^T \tilde{\mathbf{B}} \rangle = x^T \tilde{\gamma}_j \) where \( \tilde{\gamma}_j \triangleq \tilde{\mathbf{B}} W_j \). We can verify that

\[
\tilde{\gamma}_j = (X^T X)^{-1} X^T \text{diag} \left( 1[a_i = j] - \frac{1}{k} \right) P^{-1}_a (y - \hat{m}(X)). \tag{14}
\]
Theorem 6. Let \( \{ (x_i, a_i, y_i) \}_{i=1}^{n} \) be a random sample with \( p_j(x_i) > 0 \) for all \( i \) and \( j \). Assume the model (8) holds with the true treatment effect \( \delta_j(x) = x^T \gamma_j \) and columns of \( X \) are linear independent. Given an estimator for the main effect \( \hat{m}(x) < \infty \), denote \( \gamma = (\gamma_1^T, \ldots, \gamma_k^T)^T \) and its estimator \( \hat{\gamma} = (\hat{\gamma}_1^T, \ldots, \hat{\gamma}_k^T)^T \) with \( \hat{\gamma}_j \) defined in (14). Then we have

\[
\mathbb{E}(\hat{\gamma}) = \gamma.
\]

Furthermore, let \( r(x_i) = m(x_i) - \hat{m}(x_i) \). Suppose \( x_i, r(x_i), p_j^{-1}(x_i), \) and \( \sigma^2(x_i) \) are uniformly bounded. Denote \( P_{k \times k}(x) = \text{diag}(p_j(x)), \delta(x) = (\delta_1(x), \ldots, \delta_k(x))^T, \) and \( C(k) = I - k^{-1}J \), where \( J \) is a \( k \times k \) matrix with all elements equal to 1. If

\[
V = \lim_{n \to \infty} n^{-1}X^TX,
\]

\[
M = \lim_{n \to \infty} n^{-1} \sum_{i=1}^{n} (C(k) \text{diag}((r(x_i) + \delta_j(x_i))^2) P^{-1}(x_i) C(k) - \delta(x_i) \delta(x_i)^T) \otimes (x_i x_i^T),
\]

\[
\Sigma = \lim_{n \to \infty} n^{-1} \sum_{i=1}^{n} (C(k) \sigma^2(x_i) P^{-1}(x_i) C(k) ) \otimes (x_i x_i^T)
\]

are finite and positive definite, then

\[
\sqrt{n}(\hat{\gamma} - \gamma) \xrightarrow{D} N \left( 0, (J \otimes V^{-1}) (M + \Sigma) (J \otimes V^{-1}) \right).
\]

Theorem 6 implies \( \hat{\gamma}_j \) is an unbiased estimator of \( \gamma_j \), and it is \( \sqrt{n} \)-consistent. Moreover, its variance is determined by two matrices \( M \) and \( \Sigma \), where \( M \) depends on the estimator \( \hat{m}(\cdot) \), and \( \Sigma \) on the variance of \( \epsilon \). Note that in D-Learning, \( r(x_i) \) in \( M \) becomes \( m(x_i) \), which is larger than \( r(x_i) \) in RD-Learning. This also explains why RD-Learning has a smaller variance than D-Learning.

Remark 5. In the binary case, \( \beta = \gamma_1 = -\gamma_2 \). From Theorem 6, the variance of \( \tilde{\beta} \), defined in (12), can be written as

\[
\text{Var}(\tilde{\beta}) = (X^TX)^{-1}X^T \text{diag} \left( c(x_i) \left( (r(x_i) + \delta_1(x_i))^2 + \sigma^2(x_i) \right) - \delta_1^2(x_i) \right) X(X^TX)^{-1},
\]

where \( c(x) = p_1^{-1}(x)(1 - p_1(x))^{-1}/4 \). Observe that \( c(x) \) is minimized when \( p_1(x) = 1/2 \). This implies that the estimator renders the smallest variance in completely randomized design given other terms the same. In fact, when \( p_1(x_i) = 1/2, \sigma^2(x_i) = \sigma^2 \) for all \( i \), and \( \hat{m}(\cdot) = m(\cdot) \), we have \( \text{Var}(\tilde{\beta}) = \sigma^2(X^TX)^{-1}, \) which is the same variance as in the classical linear regression model.

Theorem 6 can be used for constructing the confidence interval for \( \gamma \) (or the treatment effect \( \delta_j \)).
However, the variance of $\hat{\gamma}$ involves two unknown terms $\delta(x_i)\delta(x_i)^T$ and $(r(x_i) + \delta_j(x_i))^2 + \sigma^2(x_i)$. We may replace them by their consistent estimators, as in the heteroskedasticity literature (White et al., 1980). Specifically, $\delta_j(x)$ in the first term can be estimated by $\hat{\delta}_j(x_i) = x_i^T \hat{\gamma}_j$. For the second term, note that

$$\mathbb{E}[(Y - \hat{m}(x) - \delta_A(x) - \delta_j(x))^2 \mid X = x] = \mathbb{E}[(r(x) + \delta_j(x) + \epsilon)^2 \mid X = x] = (r(x) + \delta_j(x))^2 + \sigma^2(x).$$

This implies that we may estimate $(r(x_i) + \delta_j(x_i))^2 + \sigma^2(x_i)$ by $(y_i - \hat{m}(x_i) - \hat{\delta}_a(x_i) + \hat{\delta}_j(x_i))^2$.

## 5 Simulation Studies

We compare the proposed method with four other popular methods in estimating the treatment effect. They are Q-Learning (Qian and Murphy, 2011), Robust Learning (Shi et al., 2016; Nie and Wager, 2017, R-Learning), causal forests (Wager and Athey, 2018) and D-Learning (Chen et al., 2017; Qi et al., 2018). Note that except Q-Learning and D-Learning, all other methods are two-step procedures, where the first step involves estimating either $m(x)$ or $\mathbb{E}(Y \mid X = x)$. We fix the number of covariates to be 100, where $X_1, X_2$ and $X_3$ are i.i.d. from $N(0, 3)$, and $X_4, \ldots, X_{100}$ are i.i.d. from Uniform(0, 1). For each simulation setting, we let the number of observations to be $n = 50, 100, 200$. The prediction error of $\hat{\delta}_1$ is reported based on a testing set of size 400.

**Case I**: It is a two-arm design, with

$$\mu_1(x) = 2 \cos(x_1 + \pi/4) + x_1 - \tanh(x_2) \quad \text{and} \quad \mu_2(x) = 2 \cos(x_1 + \pi/4) + 2x_1 - \tanh(x_2).$$

The treatment assignment depends on $x$. Specifically, $p_1(x) = 0.2 + 0.61[x_1 < 0]$. Since $\mu_1(\cdot)$, $\mu_2(\cdot)$ and the main effect are non-linear functions of $x$, we consider kernel functions in Q-Learning, and in the first step of causal forests, R-Learning, and RD-Learning. On the other hand, because the treatment effect is linear, we use linear models with an $L_1$ penalty in D-Learning as well as in the second step of R-Learning and RD-Learning.\(^3\)

**Case II**: This is an example to test the robustness of the proposed method against mis-

---

\(^3\)By default, the second step of causal forest uses a non-linear regression tree.
specification of the main effect. In this case, we have

\[ \mu_1(x) = \tanh(x_1) - 4/(1 + \exp(x_2 - x_1)) + 3 \quad \text{and} \]
\[ \mu_2(x) = \tanh(x_1) + 4/(1 + \exp(x_2 - x_1)). \]

It is a randomized design with \( p_1(x) = 1/5 \). Both the main effect and the treatment effect are non-linear. Hence we are supposed to use non-linear function spaces for all the methods. However, to test the robustness of the proposed RD-Learning method, we use linear models with an \( L_1 \) penalty to estimate the main effect in the first step and kernel ridge regression in the second step. For comparison purposes, we adopt the same function spaces (linear and kernel) in all the other two-step procedures, and use kernel ridge regression in the one-step Q-Learning and D-Learning.

**Case III**: This is an example to test the robustness of the proposed method against mis-specification of the propensity score. In this example,

\[ \mu_1(x) = x_1 - x_2 + x_3 \quad \text{and} \quad \mu_2(x) = 2x_1 - x_2. \]

The propensity score is defined as \( p_1(x) = 2/(2 + \exp(x_1)) \). In this case, we use linear models with an \( L_1 \) penalty in all methods and both steps. To test the robustness of RD-Learning, we deliberately use a wrong propensity score \( \hat{p}_1(x) = 1/2 \) instead. For comparison, we let \( \hat{p}_1(x) = 1/2 \) in the other methods.

**Case IV**: This is a three-arm design, with

\[ \mu_1(x) = (x_1^2 + x_2^2 + x_3^2)/3 + x_1 - x_2, \]
\[ \mu_2(x) = (x_1^2 + x_2^2 + x_3^2)/3 + x_2 - x_3, \quad \text{and} \]
\[ \mu_3(x) = (x_1^2 + x_2^2 + x_3^2)/3 + x_3 - x_1. \]

The propensity score depends on \( x \). Specifically,

\[ (p_1(x), p_2(x), p_3(x)) = \begin{cases} 
(1/2, 1/4, 1/4), & \text{for } x_1 \geq x_2 \text{ and } x_1 \geq x_3 \\
(1/4, 1/2, 1/4), & \text{for } x_2 > x_1 \text{ and } x_2 \geq x_3 \\
(1/4, 1/4, 1/2), & \text{for } x_3 > x_2 \text{ and } x_3 > x_1.
\end{cases} \]

This setting is similar to Case I in the sense that it has a non-linear main effect and a linear treatment effect. We use the same function space as in Case I. We do not report the results by causal forests and R-Learning because currently these two methods cannot be applied to the.
Figure 2: The average prediction error of $\hat{\delta}_1$ based on 200 replications with standard error by different methods. In all cases RD-Learning has the best performance.

**Estimation of the treatment effect**

From Figure 2, we first observe that the proposed RD-Learning method has the smallest prediction error in most scenarios. Secondly, Q-Learning and D-Learning typically have a larger standard error than the two-step procedures. This is consistent with the well known intuition (see also Theorem 3 and 4) that by replacing $y_i$ with $y_i - \hat{m}(x_i)$, the variance of estimators can be
reduced. Thirdly, we see that RD-Learning is indeed “doubly robust” against mis-specification of the main effect (in Case II) and the propensity score (in Case III). For the discussion below, we only focus on the three best methods, namely, R-Learning, Q-Learning, and RD-Learning. Recall that Case II is an example where we deliberately use a wrong function space for the main effect. Since R-Learning is robust against this kind of mis-specification, it has a better performance than Q-Learning. However, in Case III where we deliberately use a wrong propensity score, R-Learning has a much worse performance than Q-Learning since it relies on a correctly-specified \( \hat{p}_j(\cdot) \). But RD-Learning is as good as, and in many cases, much better than any of these two in both settings.

Figure 3: Boxplots for the prediction error of \( \hat{m} \) based on 200 replications in Case I (left) and Case IV (right). The proposed method has a smaller error than Q-Learning in estimating the main effect.

**Estimation of the main effect**

In addition to the treatment effect, we also report the estimator for the main effect using the proposed direct method in Section 4.1 and the Q-Learning method that estimates each \( \mu_j \) and takes the average. Figure 3 shows the result based on the same simulation data in Case I and Case IV. We observe that by using all the data at the same time and using propensity score as the weight, the proposed method has a better performance compared to the Q-Learning method.

**Confidence Interval for the Coefficients**

Finally, we compute the unbiased estimator defined by (14) using the data in Case I and
Case IV and construct the confidence interval for the coefficient of an important covariate \( x_1 \). The relation between the nominal confidence level and the empirical coverage rate, defined as the proportion of the confidence intervals that cover the true parameter, is shown in Figure 4. Most of the empirical coverage rates are close to the nominal confidence levels, supporting the asymptotic distribution derived in Theorem 6. In the worse case scenario, for nominal level 95\%, the resulting confidence interval missed it by 1.5\% (in Case IV).

Figure 4: Nominal confidence levels ranging from 90.1\% to 99.9\% and the empirical coverage rate based on 200 replications in Case I (left) and Case IV (right) with sample size \( n = 200 \). The 45° straight line represents the ideal situation.

6 Real Data Analysis

In this section we apply RD-Learning on a real dataset from the AIDS Clinical Trials Group Study 175 (Hammer et al., 1996, ACTG175). The dataset includes 2,139 HIV-1 infected subjects. They were randomly assigned with equal probabilities to one of the four treatments: zidovudine (ZDV) only, ZDV with didanosine (ddI), ZDV with zalcitabine (ddC), and ddI only. The endpoint (outcome) we consider is the change of the CD4 cell count (per cubic millimeter) at 20 ± 5 weeks from the baseline. Note that a decrease in the number of CD4 cell count usually implies a progression to AIDS. In other words, a larger value indicates a better outcome.
To apply the proposed RD-Learning method, we first estimate the main effect using the direct estimator proposed in Section 4.1 based on the 18 variables that were measured prior to the initiation of the study. Specifically, we use the generalized additive model (GAM) to solve the weighted least square problem (11). The best GAM model is selected through stepwise AIC.

For the second step in which the treatment effect is estimated, we follow the analysis of Fan et al. (2017) and Qi et al. (2019) and consider only 12 variables measured at baseline as the covariates for each subject. Five of 12 covariates are continuous: age (years), weight (kilogram), Karnofsky score (on a scale of 0-100), CD4 cell counts (per cubic millimeter), and CD8 cell counts (per cubic millimeter). The rest seven are binary: hemophilia (0=no, 1=yes), homosexual activity (0=no, 1=yes), history of intravenous drug use (0=no, 1=yes), race (0=white, 1=non-white), gender (0=female, 1=male), antiretroviral history (0=naive, 1=experienced), and symptomatic indicator (0=asymptomatic, 1=symptomatic).

We compare the performance of RD-Learning with Q-Learning and D-Learning through 5-fold cross validation. However, since it is a real data set in which the true treatment effect is not observed, the prediction error cannot be calculated. Instead of evaluating the prediction error, we first derive the estimated optimal ITR of each method by $\hat{d}(x_i) = \arg\max_j \hat{\delta}_j(x_i)$. Then we
calculate the empirical expected outcome under the obtained ITR \( \hat{d} \), defined as

\[
V(\hat{d}) = \frac{\sum_{i=1}^{n} y_i I[a_i = \hat{d}(x_i)]/p_{a_i}(x_i)}{\sum_{i=1}^{n} I[a_i = \hat{d}(x_i)]/p_{a_i}(x_i)}
\]

(Murphy et al., 2001; Zhao et al., 2012). Note that in this application \( V(\hat{d}) \) measures the average increase in CD4 cell counts (per cubic millimeter) by taking the recommended treatment. Larger value \( V(\hat{d}) \) is preferred. Finally, we replicate the procedure for 400 times and the boxplot of \( V(\hat{d}) \) is shown in Figure 5.

From Figure 5, we observe that RD-Learning yields the largest value, and \( V(\hat{d}) \) of D-Learning is slightly higher than that of Q-Learning. This implies that patients would benefit more by following the recommended treatment that is based on the treatment effect estimated by RD-Learning.

Table 1: Significant coefficients of each treatment effect for ACTG175 Data. Each column stands for a treatment arm, and each row corresponds to a covariate. Significant coefficients and levels identified by each method are marked.

|        | ZDV        | ZDV+ddI     | ZDV+ddC     | ddI         |
|--------|------------|-------------|-------------|-------------|
| Age    | Q***, D**, RD*** | Q**, D*, RD** |             |             |
| Weight |             |             |             |             |
| Hemophilia |             |             |             |             |
| Homosexual | Q*, D*, RD* |             | Q*, D, RD*  |             |
| Drug use |             | Q           | D, RD       |             |
| Karnofsky | D**, RD    |             | RD          |             |
| Race   | Q*, D*, RD* |             |             |             |
| Gender |             |             |             |             |
| Antiretroviral |         |             |             |             |
| Symptomatic |             |             |             |             |
| CD4 Baseline | Q**, D***, RD* |             | Q**, D*, RD** |             |
| CD8 Baseline |             |             |             |             |

* “Q”, “D”, and “RD” stand for Q-Learning, D-Learning, and RD-Learning, respectively.

* Significant code example: “Q” for p-value < 0.1 using Q-Learning. Similarly, “Q*” for p-value < 0.05, “Q**” for p-value < 0.01, and “Q***” for p-value < 0.001.
To identify important biomarkers, we estimate the coefficients of the 12 covariates by (14) and compute their standard errors. The significant level of each variable using Q-Learning, D-Learning, and RD-Learning is marked in Table 1.\footnote{Q-Learning is a linear regression based method with standard significance score. Since D-Learning can be viewed as a special case of RD-Learning, we derive the significance level using our method in Section 4.2.}

From Table 1, we observe that these three methods give similar results in general. The different patterns of those significant coefficients across different treatment effects suggest that heterogeneity does exist in these four treatment arms. For example, if we project the data on two important biomarkers “age” and “CD4 baseline” and mark each point according to its optimal treatment assignment estimated by RD-Learning, we can visualize how the treatment effects depend on these two biomarkers. In Figure 6, we first notice that the treatment ZDV is inferior to the other three treatments. This result is consistent with previous findings (Hammer et al., 1996; Fan et al., 2017; Qi et al., 2019). Furthermore, for the majority of the patients, ZDV with ddI is the best treatment. ZDV with ddC is most effective on young patients (age < 25), and ddI alone is better than the others for patients who have more CD4 cells (CD4 counts > 500 per cubic millimeter) at baseline.

\begin{figure}[h]
\centering
\includegraphics[width=0.5\textwidth]{figure6.png}
\caption{ACTG175 data projected on “age” and “CD4 baseline”, with the best treatment based on the estimated treatment effect by the RD-Learning marked by different colors and symbols.}
\end{figure}

\footnote{Q-Learning is a linear regression based method with standard significance score. Since D-Learning can be viewed as a special case of RD-Learning, we derive the significance level using our method in Section 4.2.}
7 Conclusion

In this work, we propose a doubly robust method RD-Learning to estimate ITE under two-arm and multi-arm settings. The estimated ITE is consistent if either the model for the main effect or the model for the propensity score is correctly specified. The proposed framework is flexible enough that it can incorporate with existing base procedures such as LASSO, kernel ridge regression, generalized additive model, and so on. We also propose a direct estimation approach for the main effect and provide statistical inference tools for the treatment effects when the propensity scores are known.

There are a few possible future research directions based on this work. Firstly, by modifying the quadratic loss function, the framework can be extended to other types of outcome, such as binary outcome and survival outcome (Chen et al., 2017; Qi et al., 2019). Secondly, one may want to improve our two-step procedure to a one-step method based on (9), i.e., estimating $p_j(x)$, $m(x)$, and $\delta_j(x)$ simultaneously. Such ITE estimator would still enjoy a doubly-robust property while the convergence rate of $\text{PE}(\hat{\delta})$ may be different from the proposed method. Thirdly, the method can applied to dynamic treatment regime (Murphy, 2003; Robins, 2004) by considering a multi-stage optimization problem, so that a sequence of treatment effects and the optimal treatment rules can be estimated robustly in a multi-stage clinical trial. Finally, based on the asymptotic distribution in Theorem 6, one can consider a new framework for the set-valued treatment rule (Laber et al., 2014; Meng et al., 2020). That is, several treatments with similar outcomes are recommended to a patient which allows patients to tailor the best treatment for themselves.
