Maximal aerobic capacity is associated with lifting capacity, but not with self-reported functioning measures in patients with primary chronic low back pain: a cross-sectional study

Daniël J Vermue, Max V Dol, Jone Ansuategui Echeita, Rienk Dekker, Henrica R Schiphorst Preuper, Michiel F Reneman

ABSTRACT

Objective Maximal exercise testing is considered the gold standard to assess $\dot{V}O_2\text{max}$. However, maximal exercise testing was previously deemed unfeasible and unsafe in chronic low back pain (CLBP) patients. Consequently, most previous studies on aerobic capacity and functioning in patients with CLBP were performed with submaximal testing protocols. A recent study demonstrated the safety, feasibility and tolerance of maximal exercise testing in patients with CLBP. Therefore, the relation between aerobic capacity and functioning should be reevaluated. This cross-sectional study aims to determine the relationship between maximal aerobic capacity and four measures of functioning: lifting capacity, work ability, pain-related disability and physical functioning in patients with CLBP.

Methods The maximal aerobic capacity of patients with CLBP was assessed with a maximal cardiopulmonary exercise test. Functioning was measured with a floor-to-ceiling lifting capacity test and three questionnaires: Work Ability Score, Pain Disability Index and Physical Functioning subscale of RAND-36. The associations between maximal aerobic capacity and each of the functioning measures were analysed with multiple linear regression analyses while controlling for potential confounders.

Results Data of n=74 patients with CLBP were analysed. After controlling for potential confounders, maximal aerobic capacity was moderately associated with lifting capacity ($\beta=0.32$, $p=0.006$), but not with any of the other functioning measures ($\beta=-0.08$ to 0.12, $p>0.288$).

Conclusion A higher level of maximal aerobic capacity is moderately associated with a higher lifting capacity, but not with self-reported work ability, pain-related disability and physical functioning.

INTRODUCTION

Primary chronic low back pain (CLBP) has negative psychosocial and physical effects on patients and decreases functioning and disability.¹² In patients with CLBP, a higher level of physical activity is associated with higher physical functioning and lower pain-related disability.³⁻⁷ Patients with CLBP may be deconditioned due to reduced physical activity, resulting in low maximal aerobic capacity ($\dot{V}O_2\text{max}$).⁸⁻⁹ Most research investigating the relationship between maximal aerobic capacity and functioning in patients with CLBP is performed using submaximal cardiopulmonary exercise tests were established in patients with CLBP.

WHAT IS ALREADY KNOWN ON THIS TOPIC

⇒ Chronic low back pain (CLBP) has negative psychosocial and physical effects on patients and decreases functioning and disability.
⇒ Safety, feasibility and tolerability of a maximal cardiopulmonary exercise test were established in patients with CLBP.

WHAT THIS STUDY ADDS

⇒ Our study shows that maximal aerobic capacity is positively associated with objectively measured lifting capacity in patients with primary CLBP, but not with self-reported work ability, pain-related disability and physical functioning.

HOW THIS STUDY MIGHT AFFECT RESEARCH, PRACTICE AND/OR POLICY

⇒ Personalised aerobic capacity training could be considered to improve the lifting capacity of patients with primary CLBP.
Recently, however, feasibility and tolerance of maximal CPET were established in patients with CLBP. It was demonstrated that 69.3%–91.1% of the participating patients with CLBP managed to complete a maximal CPET. One study used maximal CPET and showed the absence of a relation between maximal aerobic capacity and several self-reported measures of functioning and disability. Recently the relationship between maximal aerobic capacity and disability in patients with complaints of arm, neck and/or shoulder was explored. With maximal CPET being in reach for use in patients with CLBP, the current knowledge on the relationship between maximal aerobic capacity and functioning should be re-examined and expanded.

The research question in this study was: what is the relationship between maximal aerobic capacity acquired by maximal CPET and functioning in patients with CLBP? Functioning was operationalised by four measures: lifting capacity, work ability, pain-related disability and physical functioning. It was expected that patients with CLBP with higher maximal aerobic capacity would have higher levels of functioning. Results of this study can be used to reassess current knowledge on this relationship and may result in new insights into treatment options for patients with CLBP.

**METHODS AND MATERIALS**

**Study design**

An observational study with a cross-sectional design was conducted from September 2017 to June 2019 in the Center for Rehabilitation of the University Medical Center Groningen (CvR-UMCG) in the Netherlands. This study is part of an extensive project of which the protocol is described elsewhere. Medical ethical approval was obtained from the Medical Research Ethics Committee of the UMCG (MET: 2016/702), and procedures are in accordance with the declaration of Helsinki.

**Participants**

Patients between the age of 18 and 65 years at the time of recruitment who were primarily referred to the CvR-UMCG due to CLBP, deemed mentally competent and capable of following instructions, were eligible for the study. Exclusion criteria were the following: patients not having primary CLBP, but a specific diagnosis that would specifically or potentially account for their CLBP symptoms (eg, herniated disc, acute trauma, a history of cancer or osteoarthritis) based on their medical file, a neuralgia and/or radicular pain in the legs, a severe psychiatric condition, a contraindication to CPET or the lifting capacity protocols being pregnant or planning to be during the study.

**Procedure**

All data were collected at the baseline assessment of an interdisciplinary pain rehabilitation programme. All participants were informed about the study’s measurements and signed informed consent before the start of the study.

**Measurements**

Maximal aerobic capacity was measured through a CPET. CPET was performed with a cycle ergometer (Ergoselect 200 p or Ergoselect 200 k, Ergoline, Bitz, Germany) following a defined continuous ramp protocol. Patients started with an unloaded warming-up for 3 minutes at 60–70 rotations per minute before the test began. Depending on the estimated patient’s level of fitness based on clinical characteristics including but not limited to age, BMI, and smoking behaviour, an experienced exercise physiologist and a specialised physician or nurse determined the starting workload (25–100 watts) and ramp (5–25 watts). During the test, the workload was progressively increased every 3 minutes in steps of the predetermined ramp. At the same time, the patient was asked to maintain a constant cadence until their maximum performance was reached. Maximum performance was determined by several variables: a temporary loss of strength and energy (=exhaustion), a plateau in peak oxygen uptake in mL/min, a respiratory exchange ratio higher than 1.15 and/or a heart rate higher than 85% of the maximal predicted heart rate. The plateau in peak oxygen uptake was determined by plotting $\dot{V}_{O_2}$ against external workload. As $\dot{V}_{O_2}$ increases with the increasing external workload, one or more of the determinants of $\dot{V}_{O_2}$ approach limitations (eg, stroke volume, heart rate or tissue extraction) and $\dot{V}_{O_2}$ versus work rate may begin to plateau. Achieving a clear plateau in $\dot{V}_{O_2}$, meaning a variation of $\leq 2$ mL/kg/min with respect to the $\dot{V}_{O_2}$ value from the last test charge increment, has traditionally been used as the best evidence of $\dot{V}_{O_2 \max}$. During the test, patients were monitored on their cardiac activity with an ECG, blood pressure with a blood pressure cuff and their ventilatory gases on a breath-by-breath basis with a metabolic cart (JAEGGER Vyntus CPX, Jaeger, Germany, Hoechberg). The peak oxygen uptake in mL/min ($\dot{V}_{O_2 \max}$) was obtained as the mean of $\dot{V}_{O_2}$ over the last 30 seconds of the test.

Lifting capacity was measured with a floor-to-waist lift capacity test based on the Work-Well Functional Capacity Evaluation protocol. The lift test has high test–retest (one-way random intraclass correlation coefficient (ICC)=0.81) and inter-rater reliability (CR-10 ratings ICC=0.76) in patients with CLBP. Assessors trained in the test procedure provided standardised instructions to repetitively lift a crate with weights from a shelf at waist height to the floor and back. The test started with a weight that could easily be lifted, followed by a progressive increase in load. The tests ended when maximum capacity was reached. The endpoint was determined by various parameters, whichever came first: cardiac endpoint (85% of maximum heart rate), biomechanical endpoint (unsafe increasing weight because of lack of load handling control), patient endpoint (patient decides to stop) and criterion endpoint (normal end of
Work ability was measured using the Work Ability Score (WAS), a single-item question comparing patients’ lifetime best work ability with their current work ability. The WAS ranges from 0 (unable to work) to 10 (best working ability). The single-item question is part of the Work Ability Index (WAI). This questionnaire measures work ability and has shown to be test–retest reliable (difference between test and retest=0.53 in construction workers). The WAS is highly correlated to the 28 items of the WAI among women on long-term sick leave (r=0.87) and among active workers (r=0.63).

Pain-related disability was measured with the Pain Disability Index (PDI), a questionnaire containing seven items. It measures the interference of pain in daily functioning and life activities: family/home responsibilities, recreation, social activities, occupation, sexual behaviour, self-care and life support activities. Each item ranges from 0 (no interference) to 10 (maximal interference). The sum score ranges from 0 to 70, where a higher score means more interference in daily life. In this study, the Dutch translation of the PDI was used, which has shown a good internal consistency (Cronbach’s α=0.85) and test–retest reliability (one-way random ICC=0.76) in patients with musculoskeletal pain.

Physical functioning was measured through the physical functioning subscale of the RAND-36 (RAND-36 PF) questionnaire. Patients answered ten questions about the limitations they experience during their daily activities. The sum score ranges from 0 to 100, where a higher score indicates a greater level of self-reported limitations. The Dutch translation was used, which has shown good internal consistency (Cronbach’s α=0.92) and test–retest reliability (r=0.72–0.82) in the general population.

Clinical information was collected by means of questionnaires, all of which are explained in more detail elsewhere: pain intensity (Visual Analogue Scale–pain, 0–10), catastrophising (Pain Catastrophising Scale, 0–52), perceived injustice (Injustice Experience Questionnaire, 0–48) and psychological traits (Brief Symptom Inventory Global Severity Index T-score, 0–100). In all these questionnaires, higher scores represent worse states. For each patient, age, sex, height, weight, pain symptoms characteristics (diagnosis area and duration), educational level and employment details (physical work demands per Dictionary of Occupational Titles) were collected with a custom-made form.

Statistical analysis
The sample size was estimated at 63 participants as calculated with GPower (G*Power for Windows, V.3.1.9.7) with an alfa error of 0.05 and a power of 0.85. Before any analysis was done, data were prepared as described in the protocol published elsewhere. The data analysis was performed with SPSS software V.25.0 (IBM).

Data distribution was assessed by using the Kolmogorov-Smirnov test and skewness and kurtosis. Data not normally distributed were analysed with non-parametric tests. Differences in maximal aerobic capacity and lifting capacity between males and females were evaluated using two-tailed independent samples t-tests. Correlation coefficients were generated using bivariate correlation analyses to explore relationships between main measures.

| Table 1 Description of participating patients |
|-----------------------------------------------|
| **N** | **Mean** | **SD/×** |
| Age (years) | 74 | 40.4 | ±12.4 |
| Sex | 74 | | |

| Work ability (WAS; 0–10) | 73 | 4.6 | ±2.4 |
| Pain-related disability (PDI; 0–70) | 72 | 36.7 | ±11.9 |
| Physical functioning (RAND-36 PF; 0–100) | 73 | 51.5 | ±19.5 |

BMI, body mass index; BSI, Brief Symptom Inventory; GSIT, Global Severity Index Total Score; IEQ, Injustice Experience Questionnaire; PCS, Pain Catastrophising Scale; PDI, Pain Disability Index; PF, physical functioning; VAS, Visual Analogue Scale; VO₂max, maximal aerobic capacity; WAS, Work Ability Score.
potential confounders (demographic and clinical characteristics). Bivariate correlations were explored using Pearson correlation for continuous normally distributed data, Spearman’s r for continuous not normally distributed and categorical data, and Pearson’s Point-Biserial for dichotomous data. Associations with a significance level of $p<0.05$ were considered potential confounders and were added to the regression analyses. If a bivariate correlation was significant in males or females, the potential confounder was added to the regression analysis. Correlation coefficient values $>0.70$ were considered strong, values between $0.30$ and $0.70$ moderate, and values $<0.30$ weak.

Four multiple linear regression analyses were performed. Lifting capacity, work ability, pain-related disability and physical functioning were the dependent variables, whereas maximal aerobic capacity and potential confounders were the independent variables. Dummy variables were created for categorical data and used as a group in the analyses. A backward selection method was applied, and the least significant variables were manually excluded. The criterion for removal was $F_{\text{change}} >0.05$. For the final regression analyses, the enter method was used. Multicollinearity was checked with the variance inflation factors. Statistical significance was assumed when $p<0.05$.

**Patient and public involvement**

Patients and/or the public were not involved in the design, or conduct, or reporting, or dissemination plans of this research.

**RESULTS**

A total of 97 patients with CLBP enrolled in the study. Five patients declined participation, and fifteen patients were not assessed due to not proceeding to rehabilitation programme treatment. Additionally, one patient was retrospectively excluded because of an existing condition interfering with measurements, and two patients did not perform maximal CPET assessment. Eventually, 74 patients were included in our analyses. No adverse events occurred.

All missing data were accounted for, and missing values were not imputed. Kolmogorov-Smirnov and skewness and kurtosis revealed normal distribution for all variables, except for ‘Pain duration (in years)’ (median: 2.1, IQR: 1.3–4.2). All other demographic and clinical characteristics are presented in table 1. T-tests revealed higher maximal aerobic capacity and lifting capacity in males than in females ($p<0.01$). In all other variables, differences between sexes were non-significant ($p>0.05$).

Results of the correlation analyses between maximal aerobic capacity, lifting capacity, work ability, pain-related disability and physical functioning on the one hand, and demographic and clinical characteristics, on the other hand, are presented in table 2. When correlations were significant, their strengths were weak to moderate.

Results of the regression analyses with lifting capacity, work ability, pain-related disability and physical functioning as dependent variables, respectively, are presented in table 3. The final model for lifting capacity explained 35% of the variance. Both maximal aerobic capacity and sex were significant contributors to the model. The final

BMI, body mass index; BSI, Brief Symptom Inventory; GSIT, Global Severity Index Total Score; VAS, Visual Analogue Scale; VO₂ max, maximal aerobic capacity.

Model for work ability explained 38% of the variance. Maximal aerobic capacity did not significantly contribute to the model, while the diagnosis area (back and legs, and multiple sites), educational level and distress did. The final model for pain-related disability explained 18% of the variance. Maximal aerobic capacity did not significantly contribute to the model, while the diagnosis area (back and legs, and multiple sites), educational level and distress did. The final model for physical functioning explained 23% of the variance. Maximal aerobic capacity did not significantly contribute to the model, while body mass index and pain intensity did.

**DISCUSSION**

Results show that maximal aerobic capacity is positively associated with lifting capacity in patients with CLBP, but not with work ability, pain-related disability and physical functioning. Because this study is one of the first to use maximal CPET to measure maximal aerobic capacity, comparison with results from other studies is hindered. Indirect comparisons can be made with studies using submaximal exercise tests, different study populations or other measures of functioning. The absence of a relation between maximal aerobic capacity and self-reported measures of functioning is consistent with other studies using both submaximal CPET and maximal CPET to determine maximal aerobic capacity. Our study, in which maximal CPET was used, strengthens the overlapping conclusion of the absence of the relation between maximal aerobic capacity and self-reported measures of functioning, drawn in these previous studies using submaximal CPET. Our finding that maximal aerobic capacity is related to lifting capacity is not consistent with the results of the one other study that applied maximal CPET. However, in our study, lifting capacity was objectively measured, whereas in this study, physical functioning was a self-reported measure. Our results are consistent with the findings of one study using submaximal CPET to determine the relation between maximal aerobic capacity and objectively tested functioning.

The absence of a correlation between maximal aerobic capacity and self-reported work ability, pain-related disability and physical functioning might be attributed
to several possible reasons. First of all, these variables of functioning are self-reported and not measured through performance-based testing. Earlier studies revealed that patients consider their functioning to be more limited than it is observed in performance-based testing. Second, despite the low maximal aerobic capacity of patients with CLBP, they may experience no limitations in functioning when their present aerobic capacity is sufficient to perform their usual daily activities.

Research shows that, on average, patients with CLBP tend to reduce their physical activity. This could explain why participants in our study with lower maximal aerobic capacity do not necessarily report lower scores on self-reported functioning. This could be considered a ‘deconditioning paradox’: while present aerobic capacity may be lower than preexisting levels, the present level may still be sufficient for their current desired functioning. Because lifting capacity is a performance-based test and maximal lifting requires a certain amount of aerobic capacity, this might have contributed to the relationship observed in this study.

Strengths
The main strength of this study is that it is one of the first to apply a gold standard method to determine the maximal aerobic capacity in patients with CLBP and uses this direct measure to determine the relationship with functioning. It also replicates the results of a single other study using a similar approach, thereby adding robustness to the results of both studies.

Limitations
The generalisability of the outcomes is limited due to the selection criteria applied in this study. Another limitation is that causal relationships between aerobic capacity and functioning cannot be made due to the cross-sectional study design. Further research is needed to unravel the relationship between maximal aerobic capacity and functioning. Similar studies should expand by means of performing multiple measurements spread across a longer period, preferably during a rehabilitation programme in which regular exercise is implemented. Additionally, a study with a prospective design would make it possible to estimate causal relationships. Because this study revealed no relations between maximal aerobic capacity and self-reported functioning, it does not justify aerobic capacity training during the rehabilitation programme as a standard treatment option for patients with CLBP. On the other hand, if (heavy) lifting is required, for example, for work, training to increase aerobic capacity, (temporarily) decreasing workload, or a combination of both may be considered as a treatment modality.

Future research should investigate whether patients who might benefit from increased maximal aerobic capacity have specific characteristics, such as high physical work demands or high-level leisure demands, enabling better personalised rehabilitation.

An unexpected ‘side effect’ of this study was that patients’ informal responses after CPET were very positive, which we interpret as a sense of accomplishment, self-efficacy, and ‘proof’ of doing more than they had anticipated. However, this is non-systematically gathered data (anecdotal), for which future research is needed.

CONCLUSION
In conclusion, maximal aerobic capacity was significantly associated with lifting capacity but not with self-reported functioning. The absence of a relationship between maximal aerobic capacity and the self-reported functioning variables at group level should not be interpreted as that relationships do not exist at the level of the individual patient. Clinically, the aerobic capacity of the majority of patients will be sufficient to defy the functional demands of everyday functioning. However, individual patients’ capacity may be lower than functionally required, and these patients’ aerobic capacity will be a limiting factor to function normally. In these cases, aerobic capacity training and/or adaptations to match their functional demands should be considered to improve functioning.
