Abstract. This study aimed to investigate the beneficial effects of elevated CO\textsubscript{2} levels and nitrogen fertilization on the nitrogen distribution in a cotton–soil system in China, using CO\textsubscript{2} obtained as an industrial byproduct. A semi-open-top artificial climate chamber was used to investigate the effects of ambient CO\textsubscript{2} concentration (360 \textmu mol·mol\textsuperscript{-1}, Xinjiang) and elevated CO\textsubscript{2} concentrations (540 and 720 \textmu mol·mol\textsuperscript{-1}) and application of nitrogen (N) fertilizer (0, 150, 300, and 450 kg·hm\textsuperscript{-2}) on cotton growth and available N distribution in the cotton–soil system. The results showed that the cotton biomass was positively influenced by the increase in CO\textsubscript{2} concentration and N application. The total N content in the cotton significantly increased with N application, and this increase was more significant with CO\textsubscript{2} treatment compared with CO\textsubscript{2} treatment. The N accumulation in buds and bolls was the highest, followed by leaves and then stems; it was the lowest in the roots. When the CO\textsubscript{2} concentration was elevated to 540 \textmu mol·mol\textsuperscript{-1}, the soil NO\textsubscript{3}–N content decreased significantly. The soil NH\textsubscript{4}+–N content slightly increased with 0 and 150 kg·hm\textsuperscript{-2} N application. When the CO\textsubscript{2} concentration was elevated to 720 \textmu mol·mol\textsuperscript{-1}, the soil NO\textsubscript{3}–N content still decreased and the soil NH\textsubscript{4}+–N content increased. Overall, when the CO\textsubscript{2} concentration was elevated, the application of 300 kg·hm\textsuperscript{-2} N fertilizer significantly increased the cotton biomass and the total N content. It also promoted the absorption of soil N, especially that of NO\textsubscript{3}–N. The findings provided practical guides for N application in the context of elevated CO\textsubscript{2} concentration in cotton fields.

Keywords: elevated CO\textsubscript{2} concentration, nitrogen fertilizer application, cotton growth, biomass, plant total N content, soil NO\textsubscript{3}–N, soil NH\textsubscript{4}+–N

Introduction

The massive emission of industrial CO\textsubscript{2} has become promoting global warming (Guo et al., 2013). It is expected that the atmospheric CO\textsubscript{2} concentration will approach 1100 \textmu mol·mol\textsuperscript{-1} (ppm) by the end of the 21st century (IPCC, 2014). Doubling of the concentration of CO\textsubscript{2} in the atmosphere affects not only climate, but also the agroecological environment (Ainsworth et al., 2005; Kimbal et al., 2016). Current climate projections indicate that the atmosphere on the earth’s surface fluctuating more
frequently, and extreme weather such as hyperthermia, drought and extreme cold will appear more frequently (NOAA-ESRL, 2018). The industrial emission CO\(_2\) storage technology is becoming more and more mature, but the rational reuse method and the related utilization quantity are still in the bottle-neck period. The reuse of industrial emission CO\(_2\) has been the focus of climate and environment research groups (Liu et al., 2018).

CO\(_2\) is an important raw material for plant photosynthesis. It has been proven that a certain amount of CO\(_2\) supplied could increase the biomass and economic yield of C\(_3\) and C\(_4\) plants (Morgan et al., 2001; Leakey et al., 2009). N is an important component of plant proteins and chlorophyll. Thus, the N addition has both direct and indirect effects on photosynthesis, respiration, and other metabolism pathways, affecting the distribution of N nutrients in plant-soil system. Studies have found that the photosynthetic capacity and plant biomass significantly increase under elevated CO\(_2\) and N additions (Fang et al., 2000; Xu et al., 2003; Leakey et al., 2011; José et al., 2016); this in turn promotes the absorption and metabolism of N in plants (Bloom et al., 2002; Mitchell et al., 2018). Research by Pitelka (1994) showed that an elevated CO\(_2\) concentration was conducive to the accumulation of carbohydrates in plant tissues, thus reducing the N content of plants. Recently Other studies (Talbot et al., 2000; Kimball et al., 2001; Dong et al., 2002; Lyu et al., 2015; Cai et al., 2016; Broughton et al., 2017a) have showed that C/N values in cotton, wheat, corn, and rice increased to different degrees under doubled CO\(_2\) concentration, with a decrease in N content in the roots of leguminous plants, but an increase in the N content of the aboveground parts (Yang, 2002; Fitzgerald et al., 2005). It might be that legumes utilized rhizobia to fix N from the air to supplement their N needs to support their rapid growth under high CO\(_2\) concentration. Xu et al. (2004) reported that CO\(_2\) doubling reduced the N content of Caragana korshinskii and Hedysarum laeve leaves by 10.4% and 5.06%, respectively. However, in different ecosystems, the distribution and absorption of N in different parts of the plant under high CO\(_2\) concentration is related to the photosynthetic pathways of the plant itself, the supply of exogenous N nutrients, the nutrient status of the soil itself, and the amount of N absorbed (Oberbauer et al., 1986; Grunzweig et al., 2001; Charles et al., 2019). Therefore, following increases in CO\(_2\) concentration, exogenous N nutrition could compensate for increased plant growth and metabolism (Stitt et al., 1999; Johnson, 2000; Yang, 2002; Zhang, 2002). It is known that a shortage of N limits the production of CO\(_2\) (Larigauderie et al., 1998; Joel et al., 2001). Under low N conditions, the photosynthetic rates under high CO\(_2\) concentration is lower than under normal CO\(_2\) concentration. Further research revealed that increasing the availability and simultaneous supply of N source can prevent this photosynthetic adaptation (Guo et al., 2006; Mitchell, 2018).

There has been a significant focus of research on the response and adaptation of plants in different ecosystems under elevated CO\(_2\) concentration and different N application and the research objects mainly focus on horticultural plants, rice, wheat and forest. Cotton is a typical C\(_3\) plant, and empirical and modeling studies (Morgan et al., 2007; Zhang et al., 2017; Broughton et al., 2017b; Li et al., 2020) have shown that possible increase in sensitivity of the physiology and plant productivity to enhancing atmospheric CO\(_2\) concentration. These researches focused on the effect of CO\(_2\) enrichment on cotton growth while the interaction mechanism of CO\(_2\) and N coupling on cotton ecosystem is not clear. Xinjiang is a major agricultural province and is the biggest commercial cotton production base in China. Cotton plays an irreplaceable role...
in agricultural production and economy in China and Xinjiang. The latest statistical data (data source: National Climatic Data Center in China) and the current studies (Gao et al., 2015; Cui et al., 2019) have shown that the ambient CO$_2$ concentration in background air was generally about ~330-372 ppm, which is far from meeting the photosynthetic demand of cotton, and elevated CO$_2$ concentration can improve the light saturation point of cotton.

The objective of this study focused on the impact of elevated CO$_2$ and N fertilizer application in the Xinjiang cotton field ecosystem. The project used a semi-open top artificial climate chamber to investigate the response of cotton plants to increases in CO$_2$ at different levels of N fertilizer application. The total N content of cotton plant and the distribution of NO$_3^-$-N and NH$_4^+$-N in rhizosphere soil were determined to reveal the response mechanisms of cotton and the soil to the CO$_2$ and N interaction. Given that the response mechanism of cotton is used to determine the optimal N application level under elevated CO$_2$ concentrations in cotton canopy, our results would be beneficial to guide the optimal application of N fertilizers in cotton fields under the high CO$_2$ concentration. Meanwhile, the findings of this study provided a technical scheme for the rational utilization of industrial CO$_2$ emission. It also provided a scientific basis for accurately predicting the terrestrial ecosystem response and crops yield potential model in the context of elevated CO$_2$ concentration, and simultaneously it will be of great significance to the healthy and sustainable development of China’s cotton industry.

Materials and experimental methods

Research area

The experiment was carried out in 2016-2018 in a semi-open-top artificial climate chamber at the Xinjiang Academy of Agricultural Sciences in China (N44°18’.288, E85°59.961’). Our previous studies (Yin et al., 2011; Gao et al., 2015; Yin et al., 2016) have found that the CO$_2$ concentration at surface boundary layer in cotton field was generally about ~330-360 ppm from 10 a.m. to 6 p.m. Xinjiang is a typical continental arid climate, the annual precipitation in this area is ~125.0-207.7 mm, the annual evaporation is 1946 mm, the annual average temperature is ~7.5-8.2 °C, the annual sunshine hours are 2526-2874 h, with the sunshine hours in the growing season being ~1900-2000 h, and the total radiation of light per year is next to that of Qinghai-Tibet Plateau. The frost-free period is about ~160 days, and the accumulated temperature of ≥10 °C is ~3570-3729 °C. The basic physical and chemical properties of the soil used in the study are shown in Table 1. Cotton was planted on April 15 and harvested on September 30.

**Test materials**

The test crop was cotton and the variety was Xinluzao 33, the density was 22.5 million plant per ha; the fertilizer used was urea (CO(NH₂)₂), with a measured N content of 46%; CO₂ was sourced from a gas cylinder supplied by the Shihezi Tiangang acetylene plant.

**Test device**

The experimental set up a semi-closed open top artificial climate chamber, surrounded by a light-transmissive plastic film (blue film in a greenhouse), with a film height of 1.5 m (Fig. 1A). The outside of the gas chamber was connected to a CO₂ gas cylinder and CO₂ was administered via drip irrigation belt that ran inside the chamber (Fig. 1B). When the cotton entered the flowering period, which was the most vigorous stage of cotton growing, CO₂ was released from 12:00 to 15:00 (the illumination is strongest in Xinjiang) daily via the drip irrigation belt. The gas input was controlled by a CO₂ decompression flow valve, and the internal concentration was measured in real time through a portable infrared CO₂ concentration detector (AT-B-CO₂, Beijing Antai Jihua Technology Co., Ltd.) with S-type distribution.

![Figure 1. (A) Semi-closed open top artificial climate chamber. (B) CO₂ gas cylinder and pressure reducing valve](image)

**Experimental design**

The test was carried out in a split zone design. Three CO₂ concentration levels were used: 360 μmol·mol⁻¹ (CK, Xinjiang background level), 540 μmol·mol⁻¹ (1.5 times higher than the background level) and 720 μmol·mol⁻¹ (two times higher than the background level) (referred to as CO₂ 360, CO₂ 540 and CO₂ 720, respectively). Four levels of application N (0, 150, 300, and 450 kg·hm⁻²; referred to as N₀, N₁₅₀, N₃₀₀, and N₄₅₀, respectively) were used for each CO₂ concentration based on the results of previous studies and local fertilization levels. The moderate water and fertilizer conditions in the northern cotton area of Xinjiang required 300 kg of pure nitrogen to determine the N concentration gradient for this study (Yin et al., 2010,
2011). The CO₂ concentration was the main treatment, and the N fertilizer was the secondary treatment. There were 12 treatments, each repeated three times, over a total of 36 plots. Each the plot area was 42 m² (2.8 m × 15 m). The main treatment plots were separated by median intervals and whereas the secondary treatment plots were next to each other.

N fertilizer was applied in the form of analytical grade urea, and the phosphorus and potassium fertilizers were applied as KH₂PO₄ (K₂O ≥33.9%, P₂O₅ ≥51.5%). The fertilization measures were based on the local field requirements: thus, 30% N fertilizer was applied initially, followed by 40% at the first time of watering and 30% at the second time of watering.

The phosphate fertilizer (P₂O₅) dosage was 125 kg·hm⁻², potassium fertilizer (K₂O) dosage was 54 kg·hm⁻², and both were used as base fertilizers. The N fertilizer was applied according to the proportion of base application 30%, application 40% for the first irrigation and application 30% at the second water drip, respectively. The times of irrigation was nine in the whole growth period. Treatments with increased CO₂ concentrations began at the start of the cotton flowering period (July 18), under the conditions of optimal light intensity (from ~12:00 h to 15:00 h). The drip irrigation capillary system was used to inject CO₂ gas into the chamber until the desired CO₂ concentration was reached. N fertilizer was applied simultaneously with the water droplets to achieve the simultaneous application of carbon and N. The other field management measures (e.g., verticillium wilt control, topping and so on) were the same as used generally in cotton fields.

**Test indicators and analysis methods**

On 18 August (after 30 days of CO₂ gas addition), three points were selected from each treatment plot according to Z pattern and the size of each point was 2.8 m × 2 m. Ten healthy cotton plants were selected from each point and divided into their aboveground and belowground tissues, which were then heated in an over at 105 °C for 30 min and then dried at 80 °C for 24 h. The dry weight was then determined. After smashing and sieving, 10 mg of the plant sample was measured by using the standard Kjeldahl method. In each cotton plant sampling point, it was used that tubular auger (the length of auger is 1 m, bit depth is 20 cm and diameter is 3 cm) to collect fresh soil at the depth of ~0–20 cm and ~20–40 cm soil layer; 1 mol·L⁻¹ KCl 50 mL was added to 10 g of the fresh soil sample and then shaken for 30 min. The suspension was then filtered through filter paper, and the nitrate nitrogen (NO₃⁻–N) and ammonium nitrogen (NH₄⁺–N) in the soil were using a Continuous Flow Analytical System (CFA). Soil moisture was determined by the drying method.

SPSS 19.0 was used to analyze the data using ANOVA and P value test significance tests. The functional relationship between CO₂ concentration and N application level was constructed by using Sigmaplot 12.5 and Excel 2007 to analyze the gradient changes in total N and soil NH₄⁺–N and NO₃⁻–N content. The datas in chart were the anverage of 2016–2018 year.

**Results and analysis**

**Effects of elevated CO₂ concentration and N fertilizer application on cotton biomass**

In this study, dry matter weight was adopted to analyse the changes in cotton biomass. ANOVA showed that the biomass of cotton organs and the whole plant was significantly affected by CO₂ concentration, N application and the interaction of CO₂ and N (Table 2). In general, the biomass of buds and bolls, stems, and the whole plant was increased significantly
with CO₂ concentration elevation, whereas the biomass of leaves and roots in CO₂ 540 concentration was higher than that in CO₂ 720 concentration.

Gao and Guo (2003) reported that elevated CO₂ concentrations could also promote the biomass increase in desert plant, and the roots, stems, and leaves responded differently to elevated CO₂ concentrations. Some studies indicated that the initially promotion effect high concentration CO₂ on plant would gradually disappear as time going by (Chen, 2005). At the same CO₂ concentration, the biomass of different cotton organs increased with N fertilizer application increasing, with more significant increases occurring at the higher N application levels, which was consistent with the results of some researchers (Zhang et al., 1999; Stitt et al., 1999). Overall, at the flowering and boll-forming stages, the biomass of buds and bolls was the highest, followed by leaves, and lowest in stems and roots, indicating the transport of nutrients from the roots to reproductive organs.

The results also showed that the effect of elevated CO₂ concentrations on cotton biomass was closely related to the supply of mineral nutrients. When atmospheric CO₂ concentrations elevated from 350 μmol·mol⁻¹ to 700 μmol·mol⁻¹, the crop yield and biomass could increase by 24–25% (Kimball, 2016), but this response would be lower in the case of water and nutrients deficiency (Oechel, 1994). Therefore, when considering the growth–promoting effects of elevated CO₂ concentrations on plant growth, it is necessary to ensure the appropriate timing of fertilizer application (Roser et al., 1999; Yang et al., 2007; Coskun et al., 2016; Zhang et al., 2017).

**Table 2. Changes in the biomass of cotton in response to elevated atmospheric CO₂ and N application (g)**

Effects of elevated CO2 concentration and N fertilizer application on the total N content in different organs of cotton

The changes in total N content of leaves are shown in Figure 2A. Leaves are important photosynthetic organs for photosynthesis and the major source for carbohydrates. Elevated CO2 concentrations are hypothesized to be beneficial to photosynthesis and respiration in leaves (Oerbauer et al., 1986; Wang et al., 2011; Zhang et al., 2016), which is also likely to affect nutrient absorption by the leaves. Analysis of variance showed that elevated CO2 concentration, N fertilizer application and the interaction of CO2 concentration and N fertilizer could significantly increase the total N content in leaves ($P = 0.005, 0.000$ and $0.002$, respectively). In the same CO2 concentration treatment, the total N content in leaves increased significantly with increasing N fertilizer application ($P = 0.012$). At the same N level, the total N content in leaves in the CO2 720 treatment group was higher than that in the CO2 540 treatment group, but there was no significant difference. Under high CO2 concentrations, C3 plants were able to adapt their photosynthesis under low N conditions (Zhou et al., 2006; Xia et al., 2019). These results indicated that when the CO2 concentration was elevated to between 540 and 720 $\mu$mol·mol$^{-1}$, it promoted the N absorption and utilization by leaves. The effect of elevating CO2 concentration on the N demand resulting from increased growth was compensated by increasing N fertilizer application. Previous researches also showed that N nutrition delays the senescence of mature leaves and improves the adaptability of plant to adverse conditions (Zhang et al., 2002).

Changes in total N content in buds and bolls are shown in Figure 2B. This result showed that elevated CO2 concentration and N fertilizer application had significant effects on the total N content in buds and bolls ($F = 19.13$ and $29.10$, respectively), and this was also significant in terms of the interaction between CO2 concentration and N fertilizer ($F = 2.89$). Under ambient CO2 conditions, the total N content in buds and bolls showed a significant positive correlation with N fertilizer application dosages. When the CO2 concentration was elevated by 0.5 and 1.0 times, the total N content in buds and bolls significantly increased, and this was more significant in the CO2 540 treatment group. Compared with CO2 360 treatment, when the CO2 concentration was elevated to 540 $\mu$mol·mol$^{-1}$, the total N content in buds and bolls at N0, N150, N300, and N450 level increased by 12.57%, 13.41%, 28.42% and 17.50% respectively; when the CO2 concentration was elevated to 720 $\mu$mol·mol$^{-1}$, the total N content in buds and bolls showed no significant changes at N0 and N150 level, but increased by 14.75% and 12.50% at N300 and N450 level, respectively. In general, of the different CO2-N combination treatments, the total N content in buds and bolls was the highest in CO2 540-N300 treatment group.

Changes in total N content in stems are shown in Figure 2C. The total N content in stems increased with the increasing of N fertilizer application in each CO2 concentration treatment. Compared with ambient CO2 concentration treatment group, the total N content in stems increased significantly when CO2 concentration was elevated to 540 $\mu$mol·mol$^{-1}$ ($P = 0.703$), although there was no significant change when CO2 concentration was elevated to 720 $\mu$mol·mol$^{-1}$ ($P = 0.53$). This suggested that when the atmospheric CO2 concentration was elevated to 540 $\mu$mol·mol$^{-1}$, N fertilizer application was more beneficial to promote the N nutrition increasing in stems.

Changes in total N content in roots are shown in Figure 2D. There were no significant differences in total N content in roots among the different CO2 concentration
treatments \((P = 0.051)\). In ambient \(\text{CO}_2\) concentration treatment, the total N content in roots increased with increasing N fertilizer application dosages \((P = 0.016)\). When the \(\text{CO}_2\) concentration was elevated to 540 \(\mu\text{mol} \cdot \text{mol}^{-1}\) and 720 \(\mu\text{mol} \cdot \text{mol}^{-1}\), the interaction of \(\text{CO}_2\) concentration and N fertilizer application had significant effect on N content in roots and the total N content at \(N_{300}\) was lower than that at \(N_{150}\) level.

In general, different combinations of \(\text{CO}_2\) concentration and N fertilizer had significant effects on N absorption and utilization of different cotton organs. The total N content in buds and bolls was the highest, followed by leaves, then was in stems, being lowest was in roots. This was probably because the combination of elevated \(\text{CO}_2\) concentrations and N fertilizer applications promoted the photosynthesis and growth metabolism of the aboveground tissues of cotton, which then needed to absorb nutrition from belowground tissues to support increase. Thus, N nutrients were transported to the buds, bolls and other vegetative organs of cotton via the roots and stems to meet the nutritional needs of reproductive growth \((\text{Hu et al., 2006; Wang et al., 2010; Yin et al., 2011})\).

The effects of elevated \(\text{CO}_2\) concentration and N fertilizer application on total N in the whole cotton plant are shown in Table 3. When the \(\text{CO}_2\) concentration was elevated by 0.5 times and 1.0 times, the total N content in whole cotton plant increased...
significantly compared with the ambient CO₂ concentration, this increasing effect was more significant in CO₂ 540 treatment. That indicated the CO₂ concentration was elevated to 720 μmol·mol⁻¹ and above would restrict N nutrient utilization by the cotton. Under the same CO₂ concentration treatment, the total N content in the whole plant increased with the N fertilizer application dosages, which was consistent with the general fertilization effect. Meantime, the interaction of elevated CO₂ concentration and N fertilizer application did have a significant effect on the total N content in the whole cotton plant (P = 0.008).

This suggests that when the atmospheric CO₂ concentration is elevated to ~540-720 μmol·mol⁻¹, which promotes the N nutrient absorption and accumulation in cotton plant, it would be necessary to increase the application of external N fertilizer to compensate for the nutrient absorption by the plants caused by the increasing CO₂ concentration.

### Table 3. The total N content in the whole cotton plant under different CO₂ and N treatments (%)

| Treatments | N₀      | N₁₅₀   | N₃₀₀   | N₄₅₀   |
|------------|---------|---------|---------|---------|
| CO₂ 360    | 4.11±0.20 dB | 4.63±0.12 cC | 4.82±0.04 bB | 5.08±0.21 aC |
| CO₂ 450    | 4.83±0.17 dA  | 5.08±0.12 cA  | 5.35±0.40 bA  | 5.65±0.17 aA  |
| CO₂ 720    | 4.56±0.11 dB  | 4.97±0.25 cAB | 5.28±0.06 abA | 5.45±0.23 aAB |

The different lowercase letters in the same row indicated significant differences among different N treatments at P < 0.05. The same capital letters in the same column indicate no significant differences among different CO₂ treatments at P < 0.05

### Effects of elevated CO₂ concentration and N fertilizer application on root soil NO₃⁻–N content in cotton fields

The response of NO₃⁻–N content to different CO₂ and N fertilizer treatments varied in the ~0–20 cm and ~20–40 cm soil layers, as shown in Figure 3A and B, respectively. Soil NO₃⁻–N content decreased significantly with increasing CO₂ concentrations and this decrease was more significant at the CO₂ 540 level than that at the CO₂ 720 level. The interaction of elevated CO₂ concentration and N fertilizer application had a significant effect on the NO₃⁻–N content in the ~0–20 cm soil layer and ~20–40 cm soil layer (P = 0.032 and 0.000, respectively).

In ambient CO₂ concentration, the NO₃⁻–N content in ~0–20 cm soil layer significantly increased with increasing N fertilizer application (P = 0.001). When the CO₂ concentration was elevated to 540 μmol·mol⁻¹, the soil NO₃⁻–N content showed no significant difference between different N application dosages (P = 0.420), although it was lowest at the N₃₀₀ level. When the CO₂ concentration was elevated to 720 μmol·mol⁻¹, the soil NO₃⁻–N content increased with the increase in N fertilizer application (P = 0.040).

At the same N fertilizer application level, the soil NO₃⁻–N content in root layer decreased significantly in proportion to the elevated CO₂ concentrations. Compared with the ambient CO₂ concentration, in the CO₂ 540 concentration treatment group, the soil NO₃⁻–N content decreased by 25.90%, 25.05%, 47.77% and 37.38% at N₀, N₁₅₀, N₃₀₀, and N₄₅₀ level, respectively; in the CO₂ 720 concentration treatment group, the soil NO₃⁻–N content decreased by 6.94%, 4.52%, 18.31% and 19.30% at N₀, N₁₅₀, N₃₀₀ and N₄₅₀ level, respectively. The NO₃⁻–N content at the N₃₀₀ and N₄₅₀ levels was
significantly lower than at N\textsubscript{0} and N\textsubscript{150} level under elevated CO\textsubscript{2} concentrations. In a general, in the interaction treatment groups of CO\textsubscript{2} concentration and N fertilizer, the soil NO\textsubscript{3}–N content was lowest in CO\textsubscript{2} 540–N\textsubscript{150} treatment group. Other studies reported that, at high N application levels, the soil NO\textsubscript{3}–N content decreased significantly under elevated CO\textsubscript{2} concentrations and N fertilizer application, mainly due to N application significantly promoted the growth and metabolism of the plants (Mauney et al., 1994; Ma et al., 2004; Liu et al., 2018), increasing NO\textsubscript{3}–N absorption by plants from soil, thus affecting the soil N nutrients conditions. In addition, an anaerobic environment was formed by the drip irrigation system, inhibiting soil-nitrifying microbial activity and reducing the soil NO\textsubscript{3}–N content. The reduction in the soil NO\textsubscript{3}–N content in the CO\textsubscript{2} 540 concentration treatment was greater than that in the CO\textsubscript{2} 720 concentration treatment; this suggests that the level of CO\textsubscript{2} enrichment was too high. If this negatively impacted the ability of cotton to adapt to higher levels of CO\textsubscript{2} then this would inhibit the absorption of soil nutrients by the plants.

The soil NO\textsubscript{3}–N content decreased with the soil depth increasing. In the ~0–20 cm soil layer, the changes in NO\textsubscript{3}–N content were the same as in the ~0–20 cm soil layer among different CO\textsubscript{2} concentrations and N fertilizer treatments; however, the increasing trends in NO\textsubscript{3}–N content were more significant in the ~0–20 cm soil layer, given the interaction effects between the increasing CO\textsubscript{2} concentration and N fertilizer application.

**Effects of elevated CO\textsubscript{2} concentration and N fertilizer application on root soil NH\textsubscript{4}+–N content in cotton fields**

The soil NH\textsubscript{4}+–N content varied significantly under different CO\textsubscript{2} concentration and N fertilizer treatments as shown in Figure 3C and D. ANOVA analysis showed that elevated CO\textsubscript{2} concentration, N fertilizer application and the interaction of CO\textsubscript{2} and N all had significant effects on NH\textsubscript{4}+–N content in the ~0–20 cm soil layer (F = 176.7, 98.06, and 9.925, respectively) and in the ~20–40 cm soil layer (F = 191.784, 65.150, and 6.270, respectively).

In the ~0–20 cm soil layer, in the ambient CO\textsubscript{2} concentration, the NH\textsubscript{4}+–N content significantly increased with increasing N fertilizer addition (P = 0.000), and this was more significant at the N\textsubscript{300} and N\textsubscript{450} levels. Compared with the ambient CO\textsubscript{2} concentration, the NH\textsubscript{4}+–N content showed a slightly increase at the N\textsubscript{0} and N\textsubscript{150} levels when the CO\textsubscript{2} concentration was elevated to 540 μmol·mol\textsuperscript{-1}, but a decrease at the N\textsubscript{300} and N\textsubscript{450} levels (reduced by 16.40% and 17.94%, respectively). This suggests that the interaction of CO\textsubscript{2} concentration and the high N fertilizer application could significant promote the NH\textsubscript{4}+–N nutrition absorption by cotton plants. This was consistent with the trends also recorded in the total N content in cotton plants (Table 3). When the CO\textsubscript{2} concentration was elevated to 720 μmol·mol\textsuperscript{-1}, the soil NH\textsubscript{4}+–N content was significantly increased with increasing N fertilizer application. This was consistent with previous studies on other plants, such as wheat, *Phoebe bournei* and rice (Bloom et al., 2002; Han et al., 2003; Liu et al., 2018). In rice–wheat rotation farmland ecosystems, following an increase in CO\textsubscript{2} concentration, soil ammonia-oxidizing bacteria decreased, as did the nitrification activity of the dominant strain, whereas the soil NH\textsubscript{4}+–N mass fraction increased (Lin et al., 2005). This trend was similar to the soil NO\textsubscript{3}–N content; overall, the soil NH\textsubscript{4}+–N content in the CO\textsubscript{2} 540–N\textsubscript{150} and CO\textsubscript{2} 540–N\textsubscript{300} treatment groups was lower than that in other CO\textsubscript{2}–N treatment groups.
Compared with the ~0–20 cm soil layer, the NH$_4^+$–N content in the ~20–40 cm soil increased, but not significantly. The soil NH$_4^+$–N content increased with increasing CO$_2$ concentration in the ~20–40 cm soil layer ($P = 0.000$). When the CO$_2$ concentration was elevated, the soil NH$_4^+$–N content was increased in proportion to the N application dosage.

**Discussion**

Studies have shown that elevated CO$_2$ concentration could promote the growth and N absorption of plants (Dijkstra et al., 2010; Xiao et al., 2017). Under the condition of enhancing CO$_2$ concentration, photosynthetic adaptation of C$_3$ plants mainly occurs under the condition of low N conditions (Stitt et al., 1999; Wang et al., 2015). Further research demonstrated that improvement in the availability of N sources and synchronous supply capacity can prevent the occurrence of adaptation (Mitchell et al., 2018).

The effect of elevated atmospheric CO$_2$ concentration on N uptake by plants is related to atmospheric CO$_2$ concentration, plant species and the form of absorbed N as well as other factors. Studies have demonstrated that cotton, wheat, corn, rice and other crops have various degrees of C/N elevation in the body under the high concentration of CO$_2$ and the N content of plants decreased (Lee et al., 2013), while, there was no change
in legumes (Dong et al., 2002; Wang et al., 2010). This may be attributed to the fact that legume plants have \textit{rhizobia}, which can fix N element from the air and supplement the requirement of N nutrition for rapid growth of plants under high CO$_2$ concentration rather than the absence of such functions in non-leguminous plants.

Previous research reported that when the CO$_2$ concentration was elevated to ~500–700 μmol·mol$^{-1}$, higher N fertilizer application promoted the N nutrition absorption and transformation by plants (Xu, 2012). In this study, there was also significant effect on cotton growth and N absorption when CO$_2$ concentration enrichment and N fertilizer application. As the atmospheric CO$_2$ concentration enriched, the biomass and N nutrition accumulation in the cotton increased, whereas the available N content in soil was decreased; this trend was most significant with the high N fertilizer application under a CO$_2$ 540 concentration. Deiglmayr et al. (2004) had found that soil N availability was reduced by elevated CO$_2$, the increase in plant growth may only be possible when plants increase their available nitrogen uptake. Analyzing the correlation between the changes in N content in cotton and soil under different CO$_2$–N combination treatments showed that high N fertilizer application was beneficial to the absorption and utilization of soil N in cotton field, especially NO$_3^-$–N. Changes in the N content of soil are related to the forms of soil inorganic N in different regions. For example, the soil N in northern China mainly occurs in the form of NO$_3^-$–N; thus, cotton grown in northern regions shows the selective absorption of NO$_3^-$–N (Hu et al., 2006; Liu, 2010). In addition, an anaerobic environment is formed by coated cultivation, and hyperthermia and drought environments are caused by CO$_2$ concentrations enrichment, which will affect the activity of nitrifying microorganisms in farmland soil, which could also reduce soil the NO$_3^-$–N content (Chen et al., 2002; Wang et al., 2010).

Conclusions

The results showed that the increase in cotton growth was positively influenced by the increase in N application with increasing CO$_2$ concentration, which was most significant at CO$_2$ 540 concentration treatment. During the flowering and boll-forming stages, the biomass was highest in the buds, followed by leaves, stems, and roots. When the CO$_2$ concentration was elevated, the total N content in the cotton plant was significant increased with the N fertilizer application increasing, and this increase effect was more significant in the CO$_2$ 540 treatment than that in CO$_2$ 720 treatment. The total N accumulation content in buds and bolls was the highest, followed by leaves and then stems, being lowest in the roots. The changes in soil NO$_3^-$–N and NH$_4^+$–N content were also significant with the interaction of CO$_2$ concentration enrichment and N fertilizer application. When the CO$_2$ concentration was elevated to 540 μmol·mol$^{-1}$, the soil NO$_3^-$–N content decreased significantly, the soil NH$_4^+$–N content slightly increased with 0 and 150 kg·hm$^{-2}$ N application. When the CO$_2$ concentration was elevated to 720 μmol·mol$^{-1}$, the soil NO$_3^-$–N content still decreased and the soil NH$_4^+$–N content increased.

Overall, when CO$_2$ concentration was elevated to ~540–720 μmol·mol$^{-1}$, the application of 300 kg·hm$^{-2}$ N fertilizer significantly increased the cotton biomass and the total N content. It also promoted the absorption of soil N, especially of NO$_3^-$–N. This suggests that when N fertilizer supplied effectively, the atmospheric CO$_2$ concentration enrichment could promote the photosynthesis and growth metabolism of cotton, which also increase the absorption and utilization of soil N nutrients by the
plants. Thus, as literature suggests that the N fertilizer application to Xinjiang cotton fields in the future should be increased when atmospheric CO₂ concentration enrichment. However, the impact of CO₂ concentration and N nutrients on cotton growth and available N utilization are governed by complicated physiological and ecological processes. Thus, the interaction of CO₂ concentration and N fertilizer requires further verification, as do the mechanisms involved in the impacts of elevated CO₂ concentration on different forms of N transformation and utilization in cotton–cropping systems.
