Abstract. We study the splitting probabilities for a one-dimensional Brownian motion in a cage whose two boundaries move at constant speeds $c_1$ and $c_2$. This configuration corresponds to the capture of a diffusing, but skittish lamb, with an approaching shepherd on the left and a precipice on the right. We derive compact expressions for these splitting probabilities when the cage is expanding. We also obtain the time-dependent first-passage probability to the left boundary, as well as the splitting probability to this boundary, when the cage is either expanding or contracting. The boundary motions have a non-trivial impact on the splitting probabilities, leading to multiple regimes of behavior that depend on the expansion or contraction speed of the cage. In particular, the probability to capture the lamb is maximized when the shepherd moves at a non-zero optimal speed if the initial lamb position and the ratio between the two boundary speeds satisfy certain conditions.

Keywords: stochastic particle dynamics (theory), Brownian motion, diffusion
1. Introduction

A lamb escapes from a farm and has the bad idea to roam near a precipice. The shepherd wonders what is the best strategy to catch her lamb alive. Indeed, the lamb wanders randomly when the shepherd stays still. However the lamb is skittish and moves away from the shepherd and toward the precipice whenever the shepherd approaches. Should the shepherd stay still and hope the lamb will come to her, or should she walk toward the lamb and hope that she reaches the lamb before it goes over the precipice?

If the shepherd walks toward the lamb with speed $c$, we assume that the lamb moves away at a slower speed $(1 - \alpha)c$, with $0 \leq \alpha \leq 1$, that is superimposed on its diffusive motion. In the reference frame of the shepherd (figure 1(a)), the lamb diffuses and approaches the shepherd with speed $\alpha c$. However, the precipice also approaches the lamb with speed $(1 - \alpha)c$. Initially, the lamb is at $x_0$, the precipice is at $L_0$, while the shepherd is fixed at the origin. The probability that the lamb and shepherd meet before the lamb goes over the precipice coincides with the splitting probability for the lamb to eventually reach the origin. In turn, this latter problem is equivalent to the splitting probability for unbiased diffusion that starts at $x_0' = x_0 - L_0/2$ to reach the left edge of an asymmetrically contracting cage, whose left and right edges are at $-L_0/2 + c_1 t$ and $L_0/2 - c_2 t$, respectively, with $c_1 = \alpha c$ and $c_2 = (1 - \alpha)c$ (figure 1(b)). While the contracting cage is the relevant situation for the lamb capture problem, we also investigate the case of the expanding cage. Although the value of $\alpha$ does not need to be restricted, we study the range $\alpha \in [0, 1]$, where the splitting probability has the richest behavior.

Conditional exit from a fixed interval is a classic problem of random-walk theory [1-4]. The role of a moving boundary has been considered recently, e.g. a diffusing or an oscillating trap at the edge of the interval [5-7]. For ballistically moving boundaries, which is our focus, the infinite-time survival probability in an asymmetrically expanding
cage and the time-dependent survival probability in a symmetrically expanding cage were investigated by Bray and Smith [8,9]. Here we derive exact expressions for the first-passage probability at any time and the splitting probabilities to one of the edges of the cage when each wall moves ballistically at an arbitrary speed. Contracting and expanding cages are considered. The surprising consequence of our results is that the splitting probabilities depend non-monotonically on the speed $c$ for a range of initial conditions and $\alpha$ values.

In section 2, we derive the splitting probability in an expanding cage. In section 3, we determine the first-passage probability at any time and the splitting probability to one of the boundaries for both an expanding and contracting cage. Finally, in section 4, we demonstrate that the splitting probability can have a non-monotonic dependence on the speed $c$. Using these results, we answer the shepherd’s question of what is the best strategy to capture the lamb.

2. Expanding cage

It is convenient to treat the problem in the reference frame of the left boundary (figure 1(a)), where the Brownian particle drifts to the right with speed $\alpha c$ and the right boundary also drifts to the right with speed $c$. Thus the right boundary is located at $L(t) = L_0 + ct > L_0$. We focus on the splitting probability to reach the left edge of an expanding cage $L^e(x_0, L_0)$ as a function of the initial particle position $x_0$ and the initial interval length $L_0$ (with $R^e$ the splitting probability to the right edge). Following the approach of [8], the backward Fokker–Planck equation for the splitting probability is

$$D \frac{\partial^2 L^e}{\partial x_0^2} + \alpha \frac{\partial L^e}{\partial x_0} + c \frac{\partial L^e}{\partial L_0} = 0,$$

or, by introducing the rescaled variables $y = cx_0/D$ and $\lambda = cL_0/D$,

$$\frac{\partial^2 L^e}{\partial y^2} + \alpha \frac{\partial L^e}{\partial y} + \frac{\partial L^e}{\partial \lambda} = 0,$$

with $0 \leq y \leq \lambda$ and the boundary conditions $L^e(0, \lambda) = 1$ and $L^e(\lambda, \lambda) = 0$.

In the spirit of [8], we seek a solution of the form

$$L^e(y, \lambda) = \sum_{n \in \mathbb{Z}} [a_n e^{ny} + b_n e^{-(n+\alpha)y}] e^{-(n+\alpha)n\lambda}.$$  

The left boundary condition $L^e(0, \lambda) = 1$ leads to

$$L^e(0, \lambda) = \sum_{n \in \mathbb{Z}} (a_n + b_n) e^{-n(n+\alpha)\lambda} = 1.$$
Optimal strategy to capture a skittish lamb wandering near a precipice

while the right boundary condition $\mathcal{L}^e(\lambda, \lambda) = 0$ gives

$$
\mathcal{L}^e(\lambda, \lambda) = \sum_{n \in \mathbb{Z}} [a_n e^{n \lambda} + b_n e^{-(n+\alpha)\lambda}] e^{-(n+\alpha)n \lambda} = 0.
$$

By shifting the index of the second sum, $n \to n - 1$, and after some simple algebra, the condition above can be written as

$$
\mathcal{L}^e(\lambda, \lambda) = \sum_{n \in \mathbb{Z}} (a_n + b_{n-1}) e^{n(1-n-\alpha)\lambda} = 0. \tag{3b}
$$

Since equations (3) hold for all $\lambda$, we obtain the following relations for the coefficients in (2):

$$
\begin{aligned}
a_0 + b_0 &= 1, \\
a_n + b_n &= 0 \quad \forall n \neq 0, \\
a_n + b_{n-1} &= 0 \quad \forall n. \quad \tag{4}
\end{aligned}
$$

If the initial cage length $L_0 \to \infty$ and the initial position of the particle is far from either boundary, then the splitting probability $\mathcal{L}^e \to 0$. Using these facts in (2) imposes $a_0 = 0$. Together with the relations (4), we finally obtain the splitting probability to the left edge:

$$
\mathcal{L}^e(y, \lambda) = e^{-\alpha y} + \sum_{n=1}^{\infty} [e^{-(n+\alpha)y} e^{-n(n+\alpha)\lambda}. \tag{5}
$$

Note that the splitting probability to the right edge can be obtained from (5) by $\mathcal{R}^e(y, \lambda)|_{\lambda} = \mathcal{L}^e(y - \lambda, \lambda)|_{\lambda=0}$.

To obtain the solution in the alternative reference frame where an unbiased Brownian particle starts at $x'_0 = x_0 - L_0/2$ in a cage whose boundaries are located at $-L_0/2 - c_1 t$ and $L_0/2 + c_2 t$ at time $t$ (figure 1(b)), we replace $\alpha$, $c$ and $x_0$ with their corresponding expressions in terms of $c_1$, $c_2$ and $x'_0$ to give

$$
\mathcal{L}^e(x'_0, L_0) = e^{-c_1(2x'_0 + L_0)/2D} + \sum_{n=1}^{\infty} e^{-n(n+c_1+c_2)L_0/D} \\
\times \left\{ e^{-n(n+c_1+c_2)(2x'_0 + L_0)/2D} - e^{n(n+c_1+c_2)(2x'_0 + L_0)/2D} \right\}. \tag{6}
$$

When the initial interval length $L_0 \gg 1$, the splitting probability is well approximated by its first term

$$
\mathcal{L}^e(x'_0, L_0) \sim e^{-c_1(2x'_0 + L_0)/2D}, \tag{7}
$$

which is exponentially larger than all higher-order terms in the series in (6).

As a useful counterpoint, we can recover this last result by applying the ‘free approximation’ \cite{4,10}, in which the concentration within the interval is assumed to retain the same Gaussian form as a diffusing particle on the infinite line with no imposed boundary conditions. This approximation relies on the boundaries being outside the range where the probability distribution is appreciable. Thus we assume that the concentration profile is

$$
c(x, t) = \frac{A(t)}{\sqrt{4\pi Dt}} e^{-|x-x_0|^2/4Dt},
$$

\[doi:10.1088/1742-5468/2015/06/P06026\]
Thus the total flux leaving the cage is the sum of the flux at the two boundaries:

$$j = -D \frac{\partial c}{\partial x} = \frac{A(t)(x - x_0')}{\sqrt{16\pi D t^3}} e^{-(x - x_0')^2/4Dt}.$$ 

Thus the total flux leaving the cage is the sum of the flux at the two boundaries:

$$\phi(t) = |j_1| + j_2 = D \frac{\partial c}{\partial x} \bigg|_{x = -\frac{L_0}{2} - c_1 t} - D \frac{\partial c}{\partial x} \bigg|_{x = \frac{L_0}{2} + c_1 t}.$$ 

From the exiting flux, the rate equation for the overall amplitude $A(t)$ is

$$\frac{dA}{dt} = -A \left[ \frac{L_0}{2} - x_0' + c_2 t}{\sqrt{16\pi D t^3}} e^{-(\frac{L_0}{2} - x_0' + c_2 t)^2/4Dt} + \frac{L_0}{2} + x_0' + c_1 t}{\sqrt{16\pi D t^3}} e^{-(\frac{L_0}{2} + x_0' + c_1 t)^2/4Dt} \right]. \quad (8)$$

Integrating this equation to finite time, the amplitude is

$$\ln A(t) = -\frac{e^{-c_2(L_0 - 2x_0')/2D}}{2} \text{erfc} \left( \frac{L_0}{2} - x_0' - c_2 t}{\sqrt{4Dt}} \right) - \frac{e^{-c_1(L_0 + 2x_0')/2D}}{2} \text{erfc} \left( \frac{L_0}{2} + x_0' - c_1 t}{\sqrt{4Dt}} \right). \quad (9)$$

For $t \to \infty$, this expression reduces to

$$A(t = \infty) = \exp \left[ -e^{-c_2(L_0 - 2x_0')/2D} - e^{-c_1(L_0 + 2x_0')/2D} \right] \sim 1 - e^{-c_2(L_0 - 2x_0')/2D} - e^{-c_1(L_0 + 2x_0')/2D} \quad L_0 \to \infty. \quad (10)$$

Here $A(t = \infty)$ represents the large-time limit of the survival probability, namely, the probability that the particle has not touched either of the boundaries. It can thus be written as $A(t = \infty) = 1 - L^c(x_0', L_0) - R^c(x_0', L_0)$, which finally leads to

$$L^c(x_0', L_0) \sim e^{-c_1(L_0 + 2x_0')/2D} \quad R^c(x_0', L_0) \sim e^{-c_2(L_0 - 2x_0')/2D}, \quad (11)$$

in agreement with equation (7).

Unfortunately, this backward Fokker-Planck approach does not seem to be adaptable to a contracting cage. In this case, the general solution involves a complex exponential dependence in $y$. Therefore, the device used to simplify the right boundary condition to the form given in (3) no longer holds. To obtain the splitting probability in this case, we apply a more general framework following the methods of [9,10].

### 3. Contracting and expanding cage

We now turn to the general case of a cage that can be either contracting or expanding. Again, we study the problem in the reference frame of the left boundary that is fixed at $x = 0$. For the expanding cage, the right boundary moves to the right at speed $c$ and the particle drifts to the right with speed $\alpha c$ in addition to its diffusion. For the contracting cage, the right boundary and the particle both drift to the left. Let $x$ denote the position of the particle at time $t$. We first compute the propagator $p(x,t)$ for the particle in this...
cage, viz., the probability for the particle to be at \( x \) at time \( t \), by solving the forward Fokker–Planck equation (see, e.g. [4])

\[
\frac{\partial p}{\partial t} \pm \alpha c \frac{\partial p}{\partial x} = D \frac{\partial^2 p}{\partial x^2},
\]

with the initial and boundary conditions \( p(x,0) = \delta(x-x_0) \) and \( p(0,t) = p(L(t),t) = 0 \), and with \( L(t) = L_0 \pm ct \). Here the upper sign corresponds to the expanding cage and the lower sign to the contracting cage throughout this section. For the contracting cage the process stops when the two boundaries meet at \( t = L_0/c \).

When the boundaries are immobile, so that the cage length \( L(t) = L_0 \) is constant, the elemental solutions of the Fokker–Planck equation with these boundary conditions are well known [4]

\[
f_n(x,t) = \sin \left( \frac{n \pi x}{L_0} \right) \exp \left( \pm \frac{\alpha c x}{2D} - \frac{\alpha^2 c^2 t}{4D} - \frac{n^2 \pi^2 D t}{L_0^2} \right) \quad \text{with} \ n \in \mathbb{N}.
\]

To account for the interval length changing linearly with time, we follow the method employed in [10] and adapted by Bray and Smith [9] and postulate a solution to equation (12) with absorbing boundary conditions at \( x = 0 \) and \( x = L(t) \) of the form

\[
p_n(x,t) = g(x,t) \sin \left( \frac{n \pi x}{L(t)} \right) \exp \left( \pm \frac{\alpha c x}{2D} - \frac{\alpha^2 c^2 t}{4D} \right) \exp \left( - n^2 \pi^2 D \int_0^t \frac{dt'}{L^2(t')} \right).
\]

Substituting this trial function into equation (12), we obtain

\[
\left( D \frac{\partial^2 g}{\partial x^2} - \frac{\partial g}{\partial t} \right) \tan \left( \frac{n \pi x}{L(t)} \right) = - n \pi L(t) \left( 2D \frac{\partial g}{\partial x} \pm \frac{cx}{L(t)} g \right).
\]

We notice, as done in [9], that we can seek a form for \( g(x,t) \) that cancels both the left- and right-hand sides of (14). Thus \( g(x,t) \) must simultaneously solve

\[
\begin{align*}
D \frac{\partial^2 g}{\partial x^2} &= \frac{\partial g}{\partial t}, \\
2D \frac{\partial g}{\partial x} &= \mp \frac{cx}{L(t)} g.
\end{align*}
\]

These equations imply that the function \( g(x,t) \) has the form

\[
g(x,t) = \frac{K}{\sqrt{L(t)}} e^{\pm x^2 c/4DL(t)},
\]

with \( K \) a constant. The general solution can now be written as a superposition of the basis functions \( p_n(x,t) \):

\[
p(x,t) = \sum_{n \in \mathbb{N}} \frac{a_n}{\sqrt{L(t)}} \sin \left( \frac{n \pi x}{L(t)} \right) \exp \left( \mp \frac{x^2 c}{4DL(t)} \pm \frac{\alpha c x}{2D} \right) \exp \left( - \frac{\alpha^2 c^2 t}{4D} - \frac{n^2 \pi^2 D t}{L_0 L(t)} \right).
\]

For the initial condition \( p(x,0) = \delta(x-x_0) \), we use the identity

\[
\sum_{n \in \mathbb{N}} \sin \left( \frac{n \pi x}{L_0} \right) \sin \left( \frac{n \pi x_0}{L_0} \right) = \frac{L_0}{2} \delta(x-x_0),
\]

for \( 0 \leq x, x_0 \leq L_0 \) to finally obtain the solution for the given initial condition as

\[
p(x,t) = \sum_{n \in \mathbb{N}} \frac{2}{\sqrt{L_0 L(t)}} \sin \left( \frac{n \pi x}{L(t)} \right) \sin \left( \frac{n \pi x_0}{L_0} \right) \times \exp \left( \mp \frac{c(x^2 - x_0^2)}{4DL(t)} \pm \frac{\alpha c (x-x_0)}{2D} - \frac{\alpha^2 c^2 t}{4D} - \frac{n^2 \pi^2 D t}{L_0 L(t)} \right).
\]
The first-passage probability $F$ to the left edge of the cage is therefore

$$F(0,t) = D \left. \frac{\partial p}{\partial x} \right|_{x=0} = \sum_{n \in \mathbb{N}} \frac{2n\pi D}{\sqrt{L_0}L^3(t)} \sin \left( \frac{n\pi x_0}{L_0} \right) \exp \left( \pm \frac{c x_0^2}{4DL_0} + \frac{\alpha c x_0}{2D} - \frac{\alpha^2 c^2 t}{4D} - \frac{n^2\pi^2 D t}{L_0L(t)} \right). \quad (18)$$

The splitting probability to the left edge is the time integral of this first-passage probability. As noted previously, the temporal integration range depends on the sign of the speed. Finally, the splitting probabilities for the contracting and expanding cage, $\mathcal{L}^c$ and $\mathcal{L}^e$, respectively, are

$$\mathcal{L}^c(x_0, L_0) = \int_0^{L_0/c} dt \; F(0,t) = \sum_{n \in \mathbb{N}} \frac{2n\pi D}{c\sqrt{L_0}} \sin \left( \frac{n\pi x_0}{L_0} \right) e^{-c(x_0-\alpha L_0)^2/4DL_0}$$

$$\times e^{n^2\pi^2 D/cL_0} \int_0^{L_0} \frac{dL}{L^{3/2}} \exp \left( \frac{\alpha^2 cL}{4D} - \frac{n^2\pi^2 D}{cL} \right), \quad (19a)$$

$$\mathcal{L}^e(x_0, L_0) = \int_0^{\infty} dt \; F(0,t) = \sum_{n \in \mathbb{N}} \frac{2n\pi D}{c\sqrt{L_0}} \sin \left( \frac{n\pi x_0}{L_0} \right) e^{c(x_0-\alpha L_0)^2/4DL_0}$$

$$\times e^{-n^2\pi^2 D/cL_0} \int_0^{\infty} \frac{dL}{L^{3/2}} \exp \left( - \frac{\alpha^2 cL}{4D} + \frac{n^2\pi^2 D}{cL} \right). \quad (19b)$$

Expression (19b) for the splitting probability in an expanding cage can be shown numerically to perfectly match the simpler form (5) derived by the backward Fokker–Planck equation.

However, these splitting probabilities are not convenient for numerical evaluation. Instead, it is expedient to use the Poisson summation formula [11]

$$\sum_{n \in \mathbb{Z}} h(n) = \sum_{m \in \mathbb{Z}} \hat{h}(2\pi m),$$

with $\hat{h}(x) = \int_{-\infty}^{\infty} dt \; e^{-|xt|} f(t)$, to give the alternative expression

$$\mathcal{L}^c(x_0, L_0) = \sum_{m \in \mathbb{Z}} \sqrt{\frac{c}{4\pi D}} e^{-c(x_0-\alpha L_0)^2/4DL_0} \int_0^{L_0} \frac{dL}{(L_0-L)^{3/2}} e^{\alpha^2 cL/4D}$$

$$\times \exp \left[ - \frac{cL(4L_0^2 m^2 + x_0^2)}{4DL_0(L_0-L)} \right] \left\{ x_0 \cosh \left[ \frac{cLx_0m}{D(L_0-L)} \right] - 2mL_0 \sinh \left[ \frac{cLx_0m}{D(L_0-L)} \right] \right\}, \quad (20)$$

which is more suitable for numerical evaluation (and similarly for $\mathcal{L}^e(x_0, L_0)$).

4. Optimal capture criterion

We now turn to our original question: what is the optimal strategy for the shepherd to catch her skittish lamb without driving it over the precipice? In the shepherd’s reference frame, the lamb approaches at speed $\alpha c$ while the precipice approaches at a higher speed $c$. The probability to catch the lamb in this contracting cage is the splitting probability $\mathcal{L}^c(x_0, L_0)$ (19a). What speed $c$ maximizes this splitting probability?

doi:10.1088/1742-5468/2015/06/P06026
Partial conclusions can be drawn by studying the limits of $c \to 0$ and $c \to \infty$. If $c = 0$, the splitting probability $\mathcal{L}^c(x_0, L_0)$ is a linear function of its initial position (see, e.g. [4])

$$\mathcal{L}^c(x_0, L_0) = \frac{L_0 - x_0}{L_0}.$$ 

The qualitative behavior of $\mathcal{L}^c(x_0, L_0)$ when $c \to \infty$ can also be easily understood. In this limit, if the time $x_0/(\alpha c)$ for the lamb to reach the shepherd is smaller than the time $(L_0 - x_0)/[(1 - \alpha) c]$ for the precipice to catch up to the lamb, then $\mathcal{L}^c(x_0, L_0) \to 1$, while $\mathcal{L}^c(x_0, L_0) \to 0$ otherwise. These two times match when $\alpha = x_0/L$. Thus in the limit of large speed, the splitting probability reduces to a step function, with $\mathcal{L}^c(x_0, L_0) \approx 1$ for $x_0/L < \alpha$ and $\mathcal{L}^c(x_0, L_0) \approx 0$ for $x_0/L > \alpha$.

Let us now focus on the first order of the splitting probability for small speeds. In this case, the integral over $L$ in equation (19a)

$$\mathcal{I} \equiv \int_0^{L_0} \frac{dL}{L^{3/2}} \exp \left( \frac{\alpha^2 c L}{4D} - \frac{n^2 \pi^2 D}{c L} \right)$$

can be developed with respect to $c$ by expanding $\exp (\alpha^2 c L/4D)$ and integrating by parts. This yields

$$\mathcal{I} \sim \exp \left( -\frac{n^2 \pi^2 D}{c L_0} \right) \left[ \frac{c \sqrt{L_0}}{n^2 \pi^2 D} - \frac{c^2 L_0^{3/2}}{2n^4 \pi^4 D^2} \left( 1 - \frac{n^2 \pi^2 \alpha^2}{2} \right) \right].$$

Then using

$$\sum_{n=1}^{\infty} \frac{(-1)^n}{n} \sin(nz) = -\frac{z}{2},$$

$$\sum_{n=1}^{\infty} \frac{(-1)^n}{n^3} \sin(nz) = \frac{z^3}{12} - \pi^2 \frac{z}{12},$$

we obtain the small-speed behavior of the splitting probability:

$$\mathcal{L}^{c, c}(x_0, L_0) = \frac{L_0 - x_0}{L_0} + \frac{cx_0}{6D} \frac{L_0 - x_0}{L_0} \left[ (3\alpha - 1) L_0 - x_0 \right] + o(c)$$

where the upper sign refers to the expanding cage and the lower sign to the contracting cage.

Here we also quote the limiting form splitting probability for the expanding cage, which is found from (19b) by the same steps as outlined above.

As a result of the $\alpha$ and $x_0$ dependence of the first-order term in $c$ given above, $\mathcal{L}^c(x_0, L_0)$ is an increasing function of speed at $c = 0$ when $\alpha > \frac{1}{3} (x_0/L_0 + 1)$ and decreasing otherwise. Combining this fact with the limiting behavior for $c \to \infty$, we deduce that the splitting probability can be a non-monotonic function of the speed, for specific values of $x_0$ and $\alpha$. This leads to rich behaviors for the splitting probability, as illustrated in figure 2(a).

We can now give advice to the shepherd. There are four distinct strategies, corresponding to the four zones of figure 2(a):

(i) ‘Dangerous zone’ (lower right). Here, either the lamb is very fearful, $\alpha \ll 1$, or sufficiently close to the precipice, $\alpha < \frac{1}{3} (x_0/L_0 + 1)$ and $\alpha < x_0/L_0$, so that $\mathcal{L}^c$ monotonically decreases with $c$. Thus the optimum strategy for the shepherd is to not move.

doi:10.1088/1742-5468/2015/06/P06026
Optimal strategy to capture a skittish lamb wandering near a precipice

Figure 2. Splitting probability phase diagram for the (a) contracting and (b) expanding cage in the speed ratio ($\alpha$) and initial position ($x_0$) plane. In (a), $L^c \approx 1$ for $c \to \infty$ above the solid line, while $L^c \approx 0$ for $c \to \infty$ below. Above the dashed line $L^c$ is an increasing function of $c$ at $c = 0$ and a decreasing function below. These lines delineate four zones of behavior as discussed in the text. In (b), there are two zones.

(ii) ‘Safe zone’ (upper left). Here, either the lamb is not very fearful or is sufficiently close to the shepherd, $\alpha > \frac{1}{3}(x_0/L_0 + 1)$ and $\alpha > x_0/L_0$, so that $L^c$ monotonically increases with $c$. The shepherd should run as fast as possible to maximize the probability to catch the lamb.

(iii) ‘Optimizable zone’ (upper right). Here, the lamb is close to the precipice but not too fearful, $\alpha > \frac{1}{3}(x_0/L_0 + 1)$ and $\alpha < x_0/L_0$ so that $L^c$ has a maximum as a function of $c$. Thus there is an optimal speed that maximizes the probability for the shepherd to catch the lamb (see figure 3(a)).

(iv) ‘Dilemma zone’ (lower left). Here the lamb is close to the shepherd but also very fearful, $\alpha < \frac{1}{3}(x_0/L_0 + 1)$ and $\alpha > x_0/L_0$. Thus $L^c$ initially decreases with $c$ before eventually increasing. Thus if the shepherd is unfit, she should stay still. However, if she is sufficiently fit, she should run as fast as possible (see figure 3(b)).

For the expanding cage, the splitting probability given in equation (22) is now an increasing function of speed at $c = 0$ for $\alpha < \frac{1}{5}(x_0/L_0 + 1)$. Using this small-speed dependence, together with the limiting behavior $L^c(x_0, L_0) \to 0$ for large speed, gives the phase diagram shown figure 2(b). There again exists a zone in the phase diagram where the splitting probability can be maximized with respect to the speed. Here, the maximum of the splitting probability arises from the interplay between two competing effects from the cage expansion. Indeed, consider the complementary probability that the lamb never reaches the left boundary. The larger the speed, the lower the probability for the lamb to reach the left boundary. At the same time, the larger the speed, the higher the probability for the lamb to also not reach the right boundary, which implicitly increases the probability to reach the left boundary. As a result of these competing effects, there exists an optimal speed of expansion that maximizes the splitting probability.
Optimal strategy to capture a skittish lamb wandering near a precipice

Figure 3. Splitting probability to catch the lamb in the (a) ‘optimizable zone’ and (b) ‘dilemma zone’. In (a), the splitting probability is increased substantially (by more than a factor 3 for $\alpha = 0.92, x_0 = 19,$ and $L_0 = 20$) when the shepherd moves at the optimal speed $c_{opt}$ instead of staying still. In (b), the probability to catch the lamb is diminished if the shepherd runs slower than speed $c^*$. Here the parameter values are $\alpha = 0.08, x_0 = 1$ and $L_0 = 20$.

5. Conclusion

We analytically determined the splitting probabilities for a one-dimensional Brownian motion in a cage whose boundaries move at constant speeds $c_1$ and $c_2$. We analyzed both the cases of contracting and expanding cages. In addition, we calculated the time-dependent first-passage probabilities at each of the boundaries. Intriguing behaviors of the splitting probabilities arise as a consequence of the ballistic boundary motion. Indeed, we found that the splitting probabilities can vary non-monotonically with the relative speeds of the boundaries, depending on the initial position of the Brownian particle and the ratio between the two boundary speeds. In the context of a fearful lamb near a precipice (figure 1), this non-monotonicity defines a non-trivial optimal strategy for the shepherd to catch the lamb.

This approach could be extended to determine the splitting probability to a subset of a growing $d$-dimensional sphere for a particle that starts somewhere within the interior. It would also be interesting to extend the conditional exit problem to the case of non-linear displacements of the boundaries, where the lamb capture probability should also have a non-trivial optimization.
