Abstract: A multidisciplinary study (U–Pb sensitive high-resolution ion microprobe geochronology, Hf and O isotopes in zircon, Sr and Nd isotopes in whole-rocks, as well as major and trace element geochemistry) has been carried out on granitoid samples from the area west of Valcheta, North Patagonian Massif, Argentina. These confirm the Cambrian age of the Tardugno Granodiorite (528 ± 4 Ma) and the Late Permian age of granites in the central part of the Yaminué complex (250 Ma). Together with petrological and structural information for the area, we consider a previously suggested idea that the Cambrian and Ordovician granites of northeastern Patagonia represent continuation of the Pampean and Famatinian orogenic belts of the Sierras Pampeanas, respectively. Our interpretation does not support the hypothesis that Patagonia was accreted in Late Palaeozoic times as a far-travelled terrane, originating in the Central Transantarctic Mountains, and the arguments for and against this idea are reviewed. A parautochthonous origin is preferred with no major ocean closure between the North Patagonian Massif and the Sierra de la Ventana fold belt.

Supplementary material: U–Pb SHRIMP analytical data, geochemical analyses and sample global position-ing system locations are available at www.geolsoc.org.uk/SUP18722.

The hypothesis that Patagonia originated as a far-travelled terrane that became accreted to the rest of South America in Late Palaeozoic times (Ramos 1984) has proved remarkably resilient. It poses collision of a Patagonian terrane with the rest of South America along a hypothetical suture now buried beneath the Río Colorado basin (Fig. 1), causing NE-vergent deformation in the Palaeozoic sedimentary succession of the Sierra de la Ventana (Sierras Australes) and SW-vergent thrusting in northern Patagonia (von Gosen 2003, and references therein). Nevertheless, despite years of further investigation, relevant evidence is still scarce and sometimes inconclusive. Whereas some geophysical surveys have been claimed to show a major crustal discontinuity along the proposed suture zone (e.g. Chernicoff & Zappettini 2004), others have emphasized the complexity of the underlying block structure and the importance of east–west displacements, but did not indicate an overall difference in gravimetric signature across the boundary (Kostadinoff et al. 2005; Gregori et al. 2008). Palaeomagnetic data permit, but do not require, a small separation of the landmasses on either side in Devonian times (Rapalini 2005). Other researchers have argued that Patagonia was an autochthonous part of South America (e.g. Varela et al. 1991; Dalla Salda et al. 1992). Rapela & Pankhurst (2002) and Pankhurst et al. (2003) supported the idea that the Early Palaeozoic Pampean and Famatinian magmatic belts of the Sierras Pampeanas might be traced continuously into the basement of the Sierra de la Ventana and northeastern Patagonia, respectively. Pankhurst et al. (2006) emphasized the idea that the North Patagonian Massif at least was an autochthonous part of South America, with a Carboniferous collision zone farther to the SW. A compromise parautochthonous scenario was proposed by López de Luchi et al. (2010) and Rapa-lini et al. (2010), but the discovery of blocks of archaeocyathid-bearing limestone in the Early Palaeozoic sedimentary rocks of NE Patagonia has reinvigorated the case for a distant source, adja-cent to the central Transantarctic Mountains (González et al. 2011). This paper presents new geochronological and geochemical evidence from the granites of northernmost Patagonia that is con-sistently in agreement with the continuity of two separate Early Palaeozoic magmatic belts across the Río Colorado, and confirms the absence of Late Palaeozoic pre-collisional subduction magmatism required by accretion through ocean closure.

Magmatism, subduction and collision in northern Patagonia

The Palaeozoic (Cambrian? to Permian) siliciclastic rocks of the Sierra de la Ventana (Harrington 1972) are generally correlated with those of the Cape Fold Belt of southern Africa, representing a predominantly passive margin sequence, so that the collision model of Ramos (1984, 2008) has always been based on ocean closure by SW-dipping subduction during Late Palaeozoic times, followed by Carboniferous or Permian collision. This implies subduction-related magmatism in northern Patagonia preceding collision, for
which an age span has been invoked as 310–285 Ma (Ramos 2008) or 395–300 Ma (Ramos & Naipauer 2012). However, the Carboniferous attribution of widespread granites in the North Patagonian Massif underpinning the initial hypothesis was dis-pelled by the Rb–Sr isochrons of Pankhurst et al. (1992), who showed that they are predominantly Permo-Triassic (subsequently confirmed by U–Pb zircon dating), partly sub-volcanic, and related to extensive felsic volcanism (Rapela & Llambias 1985). The Permo-Triassic magmatism of northern Patagonia has been inter-preted as emplaced during an extensional phase, in keeping with the normal interpretation of the Choiyoi volcanism, a widespread event farther north in South America (e.g. Kay et al. 1989).

U–Pb zircon dating (both conventional and sensitive high-resolution ion microprobe (SHRIMP)) has also established the presence of Ordovician granitoids in the extreme NE of the massif (Varela et al. 2005; Pankhurst et al. 2006; Rapalini et al. 2013), often referred to as the Punta Sierra suite (mostly 470–480 Ma). Pankhurst et al. (2006) presented firm evidence of Carboniferous magmatism, but on the western margin of the massif, where c. 330 Ma I-type granitoids were followed by c. 325 Ma anatectic granites, suggesting co-lision following NE-dipping subduction, but not along the Rio Colorado; a scenario more consistent with the long-lived subduction of proto-Pacific crust beneath western Gondwana (Cawood 2005).

Ramos (2008) subsequently modified the allochthonous hypothesis to include subduction zones on both NE and SW margins of the North Patagonian Massif, and two separate collisions, with Carboniferous accretion of a western terrane (the Antarctic Peninsula?) preceding Early Permian collision of the amalgamated Patagonian terrane in the original sense. He reaffirmed the idea of a Carboniferous–Early Permian subduction-related magmatic arc along the northern part of the North Patagonian Massif, as noted above (see also Ramos & Naipauer 2012). The principal evidence cited for the antiquity of this northern arc came from U–Pb zircon ages obtained by Basei et al. (2002) of 305 ± 31 Ma for granitoids of the Yaminué complex and 300 ± 6 Ma for the Tardugno Granodiorite, both located west of Valcheta (Fig. 2), and both pre-viously thought to be Precambrian (Caminos et al. 1994; Chernicoff & Caminos 1996). Unfortunately, these U–Pb data, obtained from multi-grain zircon samples, are scattered and not very convincing. The present study was initially undertaken to re-collect and date samples from the same critical localities. Meanwhile, the first U–Pb SHRIMP ages on zircon to be carried out in this area have been published: Chernicoff et al. (2013) obtained a new age of 261 ± 3 Ma for zircon from granite from the western part of the Yaminué complex, and Rapalini et al. (2013) have reported an Ordovician age of 467 ± 7 Ma for the southernmost sector of the complex and a Cambrian age of 529 ± 4 Ma for the Tardugno Granodiorite. These widely differing ages emphasize the need for more comprehensive study incorporating geochronology, geochemistry and isotope data to characterize the evolution and nature of Yaminué–Tardugno magmatism, which we have attempted to address here.

The Yaminué complex

The Yaminué complex (sensu López de Luchi et al. 2010, and ref-erences therein) occurs near the northern margin of the massif and largely consists of foliated granitoids and locally undeformed N–S to NNW–SSE-trending leucogranitic dykes. The poorly exposed host rock is a biotite–muscovite schist or gneiss in the northern sector, whereas in the southern sector deformed granitoids are in assumed tectonic contact with marbles of unknown age. Chernicoff et al. (2013) described and dated as post-Mississippian the depositi-onal protolith of biotite schist from near Puesto Peynecura in the southern sector, which they considered to be synsedimentary with the marbles. The igneous rocks of the complex are mostly shallowly NE-dipping sheet-like bodies of foliated porphyritic biotite grano-diorite–monzogranite (with scarce amphibole), and less common equigranular to porphyritic biotite tonalite. These are separated by sub-concordant sheets of mostly tonalitic biotite orthogneiss, a fine-grained equigranular to porphyritic leucogranite and some pegmatite sills. In the central part of the complex, less-foliated amphibole–biotite tonalite and granodiorite with mafic microgranular enclaves occur. The porphyritic granitoids are megacryctic (plagioclase in the tonalite and K-feldspar in the granodiorite–mon-zogranite, both set in a coarse-grained quartz–feldspar matrix). Biotite is the main mafic mineral, with apatite, epidote and opaque minerals as accessories. Deformation, either synmagmatic or solid state while still at high temperature, developed a penetrative planar fabric and parallel high-strain zones, including metre- to-decimetre sheets of mostly tonalitic orthogneiss.

The Tardugno Granodiorite

Chernicoff & Caminos (1996) defined the Tardugno Granodiorite as a porphyritic granodiorite variantly affected by heterogeneous foliation. The granodiorite is in contact with the Nahuel Niyeu Formation metasedimentary rocks along a steeply dipping NE–SW-trending mylonitic shear zone. Kinematic indicators demonstrate top-to-the-SW sense of shear of the hanging wall (von Gosen 2003).
The main rock type is porphyritic biotite granodiorite–monzo-granite orthogneiss with perthitic K-feldspar megacrysts, partially converted to microcline. The dominant fabric is of S–C type, defined by biotite (partly chloritized), chlorite and trails of dynamically recrystallized quartz; kinked and bent muscovite occurs locally. K-feldspar porphyroclasts generally lack fracturing and micro-kink bands but locally show core-and-mantle structures cut by narrow shears with intense grain-size reduction zones. In more deformed areas, the porphyroclasts are polygonized with well-developed triple points between the crystals. At high strain a compositional layering is produced with alternation of fine-grained mica-rich domains and fine-grained quartz–feldspar aggregates and polycrystalline quartz ribbons. There is evidence of both grain-boundary migration and sub-grain rotation recrystallization. The coexistence of recrystallized feldspar and quartz suggests peak metamorphic temperatures of 400–500 °C (Passchier & Trouw 2005). Chlorite and epidote record retrogression of the original magmatic minerals during low-temperature deformation. Shear-sense indicators suggest dextral displacement in the mylonites. The Tardugno Granodiorite is intruded by mostly undeformed biotite tonalite–granodiorite, which exhibits a WNW–ESE magmatic fabric dipping 20° NE and a subhorizontal strike-parallel lineation (López de Luchi et al. 2010).

This rock is medium-grained, equigranular and hypidiomorphic, consisting of plagioclase (50%), quartz (20%), K-feldspar (15%) and mafic minerals (15%, dominantly biotite and less abundant magnetite). Accessory minerals include abundant apatite, titanite, zircon and scarce allanite. Variably developed parallel orientation of plagioclase laths and biotite flakes defines a magmatic flow foliation, as interstitial spaces as well as original crystalline shapes are preserved. The characteristic mineral assemblage is subhedral zoned plagioclase (andesine to oligoclase), two generations of biotite and locally subhedral micro-perthitic K-feldspar. Quartz is mostly undeformed and interstitial. Biotite appears both as large flakes with inclusions and in aggregates of tiny flakes that could be pseudomorphs of amphibole. Accessory minerals are apatite, titanite and scarce isolated crystals of allanite. Zircon is abundant and mostly euhedral, associated either with biotite (with pleochroic haloes) or with magnetite.

The Valcheta pluton

The Valcheta pluton is exposed as small, isolated outcrops intruded into the Nahuel Niyeu Formation for more than 40 km north and west of the town of Valcheta (Fig. 2). The magmatic association

Fig. 2. Yaminué–Tardugno–Valcheta area with sample localities and geochronological results: values in normal type are U–Pb zircon SHRIMP ages; black boxes indicate results presented here; others are from Pankhurst et al. (2006), Chernicoff et al. (2013) and Rapalini et al. (2013). Ages in italics are Ar–Ar or K–Ar ages from Tohver et al. (2008), Gozalvez (2009) and Rapalini et al. (2013).
comprises muscovite granites with very fine-grained granite dykes; the former are grey or pinkish, equigranular and allitromorphic leucogranites composed of quartz (48%), orthoclase–microcline (30%), weakly zoned oligoclase (15%), muscovite (5%), scarce variably chloritized biotite and zircon, apatite and opaque minerals. Minor amounts of garnet were described by Gozalvez (2009). As muscovite is a primary magmatic phase, pressure would have exceeded 3.5 kbar during emplacement. Although no penetrative planar fabric was observed.

K–Ar and Ar–Ar cooling ages for the Valcheta granites fall in the interval 470–430 Ma (López de Luchi et al. 2008; Tohver et al. 2008; Gozalvez 2009; Rapalini et al. 2013). The oldest ages correspond to the more central parts of the pluton whereas the youngest cooling age (430 ± 6 Ma) was obtained from a pink aplo-pegmatitic monzogranite dyke located close to the eastern contact (Rapalini et al. 2013). The Valcheta pluton may be assumed to be contemporaneous with the Early Ordovician Punta Sierra granites to the SE, although because the only ages refer to cooling it could conceivably be somewhat older.

Samples

Two areas were sampled south of the main RN 23 highway from Valcheta to Ingeniero Jacobacci (Fig. 2). Roads in this area are narrow unclassified dirt roads and outcrops are small and sparse.

Western sector

Exposures south of the town of Ministro Ramos Mexia (Fig. 2) constitute the main area of the Yamínú complex, consisting of both deformed and undeformed granitoids and minor metasedimentary rocks.

(1) Arroyo Yamínú, 600 m north of Puesto Peynecura. VAL004 is a foliated and strongly deformed biotite granodiorite, interlayered with pink leucogranite to pegmatite. Rapalini et al. (2013) obtained a U–Pb SHRIMP zircon age of 467 ± 7 Ma for granodiorite at this locality. VAL005 is a similar rock from 120 m to the SW; VAL006 is a 50 cm pink leucogranite dyke cutting the granodiorite.

(2) Arroyo Yamínú, 7 km north of Puesto Peynecura. VAL007 is a pink biotite leucogranite sheet interlayered with foliated tonalite–granodiorite VAL008 was originally thought to be equivalent to VAL004, although the foliation is slightly weaker and dips gently to the southwest.

(3) At 30 km SSE of Ministro Ramos Mexia on the road to Rincón de Treneta. VAL009 is a porphyritic biotite granodiorite with K-feldspar megacrysts (<4 cm) and a variable foliation that gently to the southwest.

Eastern sector

The area south of the small town of Nahuel Niyeu (Fig. 2) is dominated by the Early Permian Navarrete granite and the Early Palaeozoic meta-sedimentary Nahuel Niyeu Formation, whereas the southwestern part consists of the highly deformed or mylonitized Tardugno Granodiorite, with a probable faulted contact against the latter. Rapalini et al. (2013) reported a U–Pb SHRIMP zircon age of 529 ± 4 Ma for a sample ascribed to the Tardugno Granodiorite (SA114, see Fig. 2; it should be noted that this age was published as 528.5 ± 3.5 Ma).

(1) Arroyo Treneta, 11 km SSW of Nahuel Niyeu, 5 km west of Puesto Navarrete. VAL010 is a porphyritic biotite granite with 3 cm feldspar phenocrysts and strong deformation; effectively an augen-gneiss.

(2) At 9 km west of Puesto Navarrete, where the road crosses a small tributary of Arroyo Treneta. This is the site from which Basei et al. (2002) obtained a lower intersection age of 300 ± 6 Ma for a tonalite sample (AB203). The main rock type here is a highly deformed and mylonitized granodiorite, VAL011, which could be a more deformed equivalent to VAL010. However, on the SW corner of the crossing we found a relatively undeformed tonalite, VAL012, which more closely matches the description of the dated sample of Basei et al. (2002).

(3) Samples were taken from the Valcheta pluton in two cuttings on the highway between Nahuel Niyeu and Valcheta: VAL013 and VAL014. VAL013 is a pink muscovite leuco-monzogranite, which yielded a K–Ar age of 449 ± 7 Ma (López de Luchi et al. 2008), whereas VAL014 is a medium-grained light grey leucogranite, which has given an Ordovician 40Ar–36Ar plateau muscovite age of 468 ± 5 Ma (Rapalini et al. 2013).

Analytical methods

Geochronological protocols followed those of Pankhurst et al. (2006). Samples were jaw-crushed, sieved to 1 cm and washed. Zircon was separated at BGS, Keyworth using disc-mill, super-panner, heavy liquids and magnetic processes. U–Pb ages were obtained on hand-picked zircon mounts using SHRIMP II at the Research School of Earth Sciences, Canberra, where Hf and oxygen isotopes were determined on a selection of dated grains; the former by inductively coupled plasma mass spectrometry (ICP-MS) using a Neptune system (Munizaga et al. 2008) and the latter with SHRIMP II in negative ion mode (Ickert et al. 2008).

A separate aliquot of the washed jaw-crushed material for each sample was further ground to powder for Rb–Sr and Sm–Nd isotope analyses at Centro de Apoyo a la Investigación de Geocronología y Geoquímica Isotópica, Universidad Complutense de Madrid (UCM) using a VG-Micromass 54 mass spectrometer. Rb/Sr ratios were determined by X-ray fluorescence (XRF) at the CAF of Difracción de Rayos X (UCM).

Whole-rock powders prepared in La Plata from unsieved jaw-crushed material were sent to ACTLABS, Canada for major and trace element analysis using lithoborate fusion and ICP and ICP-MS methods.

Results

U–Pb zircon dating

Processed data (Ludwig 2001, 2003) are plotted in Figure 3. The crystallization ages reported below are quoted at the 95% confidence level, including uncertainty in the calibration. For samples VAL010 and VAL011 it was found possible to correct for common Pb using the measured 204Pb; for the other samples the 238U/206Pb and 207Pb/206Pb ratios were used, so that for these there is no test of discordance.

VAL008. Zircons are mostly clear grains and prismatic needles up to 400 µm long with aspect ratios of 3:1–4:1, but the CL images show that the majority have complex discordant cores, and many show signs of subsequent low-luminescence overgrowths and embayments. Eighteen areas were targeted for analysis (two cores, one overgrowth and 15 zoned rims). The results show low levels of common Pb, with highly variable U contents up to 6600 ppm. Ignoring the highest-U area (415.1), 238U/206Pb ages are in the range 248–256 Ma, with a weighted mean of 251 ± 1 Ma, which is taken as the crystallization age of the granodiorite. The overgrowth (Th/U = 0.07) shows no significant age difference.
VAL009. Zircon grains are short pink needles and fragments up to 400 µm long and with an aspect ratio of about 3:1. CL images show multistage concentrically zoned crystals with small amounts of met-amorphic overgrowth, especially on fragment terminations. Twenty areas were analysed, including a variety of cores, with U contents up to 1400 ppm. Three of the cores gave $^{238}\text{U}/^{206}\text{Pb}$ ages of 530, 1440 and 1800 Ma, but four others gave ages indistinguishable from the concentrically zoned igneous zircon, in the range 241–255 Ma: these 17 ages have a weighted mean of 249 ± 2 Ma. One overgrowth with low Th/U (0.09) gave an anomalous older age of 262 Ma.

VAL010. These zircons are short, euhedral, cloudy pink needles with inclusions, typically 150–200 µm long and 100–150 µm wide. Concentric zonation is well developed on complex cores, but metamorphic overgrowths are thin or absent. One rim gave a spurious $^{238}\text{U}/^{206}\text{Pb}$ age of 312 Ma attributable to Pb loss, whereas those of the remaining 18 (and one core) fall in the range 514–537 Ma, with a weighted mean of 526 ± 3 Ma (see the concordia (sensu Ludwig 2003) plot of Fig. 3). Several of these areas have Th/U ratios <0.1 with Th contents of about 50 ppm, but oscillatory zonation shows that they are magmatic, so that the age is that of emplacement of the granodiorite. Nineteen zircon cores were also analysed, many from grains in which the rims yielded the Cambrian crystallization age. These have normal igneous U and Th contents (typically 350 and 100 ppm, respectively) and yielded ages in the range 528–2260 Ma. A probability plot of these

---

Fig. 3. New SHRIMP U–Pb data for samples from the Tardugno Granodiorite (data corrected for common Pb using measured $^{204}\text{Pb}$) and Yaminué complex granites (uncorrected data). White ellipses represent data omitted from age calculation.
inherited core ages is also shown in Figure 3 excluding the oldest, which is strongly discordant.

VAL011. This sample has mostly clear pink prismatic needles 150–200 µm long, some white and turbid, as well as many smaller fragments. The grains show concentric zonation discordant to complex and varied cores, but many are fractured or with inclusions, so that only the outer concentric zones were easily targeted for SHRIMP analysis. The 20 areas analysed have similar U and Th contents and \(^{238}\text{U}/^{206}\text{Pb}\) ages to those in the igneous rims of sample VAL010, but with rather more scatter. There is a strong suggestion of bimodality in the age distribution: a group of five gave ages at around 490 Ma, which could represent Pb loss during an Ordovician event, but the remaining 15 analyses yield a concordia age of 522 ± 4 Ma, indistinguishable from that of VAL010.

VAL012. Some grains are cracked fragments of pink needles whose original length was mostly >300 µm; others are smaller and there are rounded fragments. Concentric zonation is developed on highly discordant and varied cores. Metamorphic overgrowths are rare, but many grains are corroded. We analysed 15 clean concentrically zoned outer areas, which had highly variable U contents (24–1069 ppm) and high Th/U (mostly >1.0), but which yielded consistent \(^{238}\text{U}/^{206}\text{Pb}\) ages of 238–261 Ma. Ignoring the two youngest ages, which appear to have been affected by some Pb loss, the weighted mean gives an acceptable crystallization age of 252 ± 3 Ma.

**Implications.** These results together with those of Chernicoff et al. (2013) and Rapalini et al. (2013) demonstrate that magmatism in the area was confined in age to c. 520–530 Ma (Cambrian), 470–480 Ma (Ordovician) and 250–280 Ma (Permian). The Early Cambrian age of the Tardugno Granodiorite is confirmed; the mean of our two ages and that of Rapalini et al. (2013) is 528 ± 4 Ma. The possibility that the Cambrian and Ordovician events could be equivalent to the Pampean (Rapela et al. 1998; Iannizzotto et al. 2013) and Famatinian (Pankhurst et al. 1998) magmatic belts of northern and western Argentina is critically assessed here.

**Major and trace element geochemistry**

**Cambrian granite.** Geochemical analyses were obtained for four samples (VAL010 and VAL011 dated here, V10 and V13 previously unpublished); they are classified as granodiorite or granite with 68–73% SiO\(_2\). In alumina saturation and Peacock plots (Fig. 4) they fall on the calcalkaline or calcic trends defined by the c. 530 Ma granitoids of the Eastern Sierras Pampeanas, towards the siliceous end, where there is overlap between pre-tectonic S-types and post-tectonic I-types. This comparison extends to Harker plots of major and trace elements, such as CaO, FeO, Ga, Nb and Zr (not shown); overlap is also apparent with the field of Early Cambrian metasedimentary rocks from the Sierras Pampeanas (e.g. Puncoviscana Formation). As noted above, some of the primary biotite is partly chloritized, but this does not appear to have resulted in major mobility of the alkali metals as the K\(_2\)O average concentration in the Tardugno Grano-diorite is similar to that in the I-type granites of Sierras Pampeanas: this and the coherent behaviour of immobile elements lead us to believe that the geochemical analyses still closely reflect primary igneous characteristics. Trace element plots show the relative depletion in Nb, P and Ti characteristic of subduction-related magmas (Fig. 5); some Sr depletion is also shown by the Sierras Pampeanas granites (both I-type and S-type with inferred pelitic sources). Low Nb and Ga (both <20 ppm) clearly distinguish this plutonic suite from the Late Cambrian peralkaline rhyolites of the Sierra de la Ventana (Rapela et al. 2003), as do the REE patterns (Fig. 6), which are moderately enriched in light REE (LREE), with only a small negative Eu anomaly. They are dissimilar to the more mafic Cambrian granitoids of the El Carancho complex of La Pampa province (Chernicoff et al. 2012), but have strong similarities to Cambrian granites from the Saldania belt of southern Africa (Jordaan et al. 1995; Da Silva et al. 2000; Chemale et al. 2011).

**Ordovician granites.** Chemical analyses were obtained for samples VAL004 and VAL005 from the outcrop dated at 467 ± 7 Ma by Rapalini et al. (2013), and VAL013 and VAL014 from the Val-cheta pluton. In the variation diagrams, the data are plotted for
comparison with synchronous Early to Mid-Ordovician granites from the Punta Sierra suite of northeastern Patagonia and Pichi Mahuida in the Río Colorado (Pankhurst et al. 2006), and from the central segment of the Famatinian belt (Pankhurst et al. 1998). Scattered outcrops of Famatinian meta-igneous rocks occur in the south of La Pampa province (around Paso del Bote; see Fig. 1), with U–Pb SHRIMP ages of 476 ± 2 Ma and 466 ± 4 Ma, and a possible metamorphic overprint at 454 ± 2 Ma (Chernicoff et al. 2010); the geochemical compositions of these rocks are very similar to those of equivalent rocks of the central segment with the same silica content. Compositions are more calcic than in the Cambrian granitoids (Fig. 7). Casquet et al. (2012) demonstrated the presence of juvenile mafic magmas in the Early Ordovician suites of the Sierras Pampeanas, which thus may be bimodal in both composition and origin, but the Patagonian granites are mostly comparable with the evolved Famatinian I-types.

Permian granites. Chemical analyses were obtained for pink leucogranite sheets cutting dated Ordovician and Permian granodiorites in the southern part of the Yaminué complex as well as the dated undeformed tonalite intruding the Tardugno Granodiorite. They are subalkaline granites, with a more restricted range of silica contents than the Ordovician and Cambrian granitoids (Fig. 8). They also exhibit higher Sr, Sr/Y, La/Yb and Tb/Yb in the range 60–70% SiO₂. The less siliceous samples have moderately negative Eu anomalies (Eu/Eu* 0.9–0.7) indicating plagioclase fractionation. Total REE contents are higher in the less evolved rocks. The high Ga/Al ratio of >2 is transitional from the I-type to the A-type granite field (Whalen et al. 1987).

Sr and Nd isotopes
Rb–Sr isotope data are given in Table 1. Initial 87Sr/86Sr ratios (at 530 Ma) for the two analysed samples of the Tardugno Granodiorite are distinctly radiogenic, 0.7129 and 0.7104 but fall within the wider range shown by the Cambrian granites of the Sierras Pampeanas (0.7060–0.7237, with no obvious distinction between pre- and post-tectonic plutons, Iannizzotto et al. 2013). The εNd values at 530 Ma are –3.7 to –3.0. Sierras Pampeanas plutons, especially the post-tectonic S-types, generally have εNd values around 5.5, but range up to –1.8; their crust-derived depleted-mantle model ages range 1400–1700 Ma compared to 1500 Ma for the Tardugno Granodiorite.

Rb–Sr and Sm–Nd were obtained for foliated Ordovician granitoids of the western Yaminué complex (VAL004 and VAL005) and two samples of the undeformed Valcheta granite. Three of the samples have low initial 87Sr/86Sr of 0.7046–0.7063 (at 470 Ma), εNd values of –3.3 to –3.9 and TDMNd model ages of 1450–1500 Ma.
The fourth sample (VAL013) has a more crustal composition, yielding values of 0.7149, –5.0 and 1585 Ma, respectively. Thus initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratios are rather lower than the values of >0.706 shown by most of the Famatinian granites in the Sierras Pampeanas (Dahlquist et al. 2008) and the Punta Sierra granites of northeastern Patagonia (Pankhurst et al. 2006). However, in terms of Sm–Nd isotope systematics (Fig. 9) the Patagonian samples compare well with the I-type Ordovician plutonic rocks from the Sierras Pampeanas (Pankhurst et al. 1998; Dahlquist et al. 2013), especially the later Famatinian granitoids of Sierra de Valle Fértil (Casquet et al. 2012).

Permian igneous rocks from the Yaminué complex also have low to moderate initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratios of 0.7075–0.7097 (the value of 0.7027 for leucogranite vein VAL006 is considered unreliable owing to its high Rb/Sr ratio requiring a huge time-correction). Corresponding $\varepsilon$Nd values at 250 Ma are uniformly low at –5.0 to 8.7, yielding Nd model ages of c. 1450–1700 Ma. These characteristics are equivalent to those of previously analysed Permian
granites from the North Patagonian Massif (mostly 87Sr/86Sr 0.7045–0.7085, εNd –2 to –10, Nd model ages 1400–1800 Ma; Fig. 9).

Hf and O isotopes in zircon

Dated zircon grains from one Cambrian and one Permian sample were investigated for O- and Hf-isotope compositions (Table 2, Fig. 10).

Igneous zircons formed during crystallization of the Tardugno Granodiorite have a well-defined mean δ18O value of +10‰, showing magma derived from (or heavily contaminated with) pre-existing crustal material. This is confirmed by εHf values between +0.2 and –12.6 but concentrated at c. –3.2. Hf model ages based on derivation from an inferred crustal source indicate separation of the source material from depleted mantle at c. 1600 Ma, which is comparable with the calculated Nd model age (Fig. 10). With one exception the inherited zircon cores have δ18O values <10‰, although only the oldest grain (c. 1840 Ma) has a value compatible with mantle derivation and one has a low value of +4.6‰ suggesting hydrothermal alteration. A crustal origin for most of these inherited zircons is confirmed by Hf isotope data: Neoproterozoic cores have εHf values of 0 to +5 and crust-derived model ages of c. 1.4 Ga; the ‘Grenville-age’ cores >1100 Ma have lower εHf and model ages of c. 1.8 Ga; finally, the two oldest grains with crystallization ages of c. 1800 Ma have low εHf values and model ages of 2.4 and 2.7 Ga. Only ‘Grenville-age’ cores <1100 Ma have juvenile εHf of +7.1 and +8.2, but nevertheless have model ages of 1.3–1.4 Ga. These data testify to the presence of continuously re-cycled older crustal material in the source region of the Tardugno Granodiorite.

Zircon in the 250 Ma granite sample VAL009 shows a range of δ18O from +5.8‰ to +7.8‰, which does not overlap with mantle compositions (Fig. 10). εHf values are uniformly and strongly negative (–7.0 to –9.2, with one at –11.4) and crust-derived model ages average 1.70 ± 0.07 Ga. Three inherited zircon cores in this sample gave crustal δ18O values of +6.5 to +9.8‰, εHf –2.7 to +6.3, and source model ages of c. 1.4, 1.7 and 2.3 Ga. This strong variability, together with the notable difference between the zircon Hf and whole-rock Nd model ages (Fig. 10), implies a mixture of old crust and more juvenile material in the source region of the Permian granite. A juvenile component would also be consistent with the occurrence in these rocks of mafic microgranular enclaves and syenitic diorite dykes as well as two possible stages of crystallization, as suggested by the zonation of plagioclase.

Discussion

Ages of magmatism in northern Patagonia

U–Pb SHRIMP zircon dating has provided a new framework for the interpretation of older data and their reliability. The results presented here, together with those of Pankhurst et al. (2006), Chernicoff et al. (2013) and Rapalini et al. (2013), largely confirm and extend the Rb–Sr results of Pankhurst et al. (1992) and the conventional U–Pb data of Varela et al. (2005). They reveal a consistent picture of three main periods of Palaeozoic igneous activity in northern and northeastern Patagonia: Cambrian (530–520 Ma), Ordovician (480–465 Ma) and Permian (280–250 Ma). The first two were relatively short-lived, whereas the Permian may be divisible into separate early (c. 280 Ma) and late (c. 260–250 Ma) phases, the latter extending into the Triassic. Carboniferous magmatism is restricted to the western and southwestern margin of the North Patagonian Massif and is clearly absent from the region bordering the Río Colorado. Earlier multi-grain zircon U–Pb dating by Basei et al. (2002) that suggested ages of c. 300 Ma in the Yaminué and Tardugno areas is best explained by a failure to resolve polygenetic zircon that crystallized in the Early Palaeozoic and late Permian, exemplified by the c. 250 Ma granite with older inheritance within the outcrop of the Cambrian Tardugno Granodiorite.

Magma sources

Isotope data for the Tardugno Granodiorite (Sr and Nd in whole-rocks and O- and Hf-isotopes in zircon, as well as the U–Pb evidence of inherited zircon) all indicate that its parent magma contained abundant pre-existing crustal material. The general calc-alkaline geochemistry with relative Nd and Ti depletion suggested that the primary magma may have been of more primitive...
subduction-related composition, but the preservation of pre-emplacement zircon cores shows that the magma temperature during their incorporation did not exceed that at which such cores would either melt or become isotopically equilibrated. The U–Pb ages of these incorporated zircons (Fig. 4) include elements of ‘Brasiliano’ (c. 630 Ma) and ‘Grenville’ (900–1300 Ma) and scarce Palaeoproterozoic (c. 1850 Ma); two Cambrian cores dated at 545 ± 6 and 528 ± 7 Ma, the latter indistinguishable from the coexisting igneous rim age, may represent local isotopic homogenization. Because the Th/U ratios and O- and Hf-isotope data indicate that the incorporated zircons were mostly igneous but all of crustal provenance, the source of this material was almost certainly an Eocambrian or late Neoproterozoic mature sediment or metasediment representing poly-recycled Gondwana-margin material in the upper crust. The correspondence between whole-rock Nd model ages of 1450–1500 Ma and the c. 1400 Ma Hf model ages of many of the analysed zircons suggests an ultimate origin from a crustal reservoir of this age, but the 1850 Ma inherited zircon cores show that even older material contributed to the magma source.

Genesis of the Ordovician magmatism of Patagonia is less clear, as there are as yet no dedicated studies of inherited zircon and no zircon O- or Hf-isotope data. The existing U–Pb dating and whole-rock element and isotope geochemistry support the involvement of upper crustal anatectic for the Early Ordovician magmatism of the Sierras Pampeanas, the Pichi Mahuida and Punta Sierra suites of northern Patagonia (Pankhurst et al. 2006). The geochemistry of the Ordovician granite of Puesto Peynecura in the Yaminué complex cannot be distinguished from this general pattern.

The Permian granites in the Yaminué complex share geochemical and isotope characteristics with previously dated Permian igneous rocks of northern Patagonia, again demonstrating a major

*Nd model age calculated for crustal precursor (DePaolo et al. 1991).
bulk Earth plutonism, back to at least analysed show similar inheritance to the Cambrian contribution. As noted above, the few zircon cores

Oxygen isotope ratios (±0.025%) normalized relative to FC1 = 5.4‰. ¹⁷⁶Hf decay constant of 1.865 × 10⁻⁹ (Söderlund et al. 2004), ¹⁷⁷Hf/¹⁷⁷Hf and ¹⁷⁸Lu/¹⁷⁷Hf of CHUR values of 0.282785 and 0.0336 (Bouvier et al. 2008). Depleted mantle values: ¹⁷⁷Hf/¹⁷⁷Hf = 0.283225 and ¹⁷⁸Lu/¹⁷⁷Hf = 0.0385 (Vervoort & Blichert-Toft 1999); Bulk Earth ¹⁷⁸Lu/¹⁷⁷Hf = 0.015 (Goodge & Vervoort 2006). TDM ages are two-stage calculated values.

crustal component, albeit with some juvenile contribution. As noted above, the few zircon cores analysed show similar inherit-ance to the Cambrian plutonism, back to at least c. 1800 Ma. Chernicoff et al. (2013) analysed a 260 Ma Permian gneissic gran-itite in the Yaminué complex that contained significant Archaean inheritance (cores U–Pb dated at 2600–2700 Ma; Hf model ages for both Permian and inherited zircon consistently in the range 1900–3900 Ma); in contrast, they did not find Archaean provenance in biotite schist from the Yaminué complex (mostly Palaeozoic, espe-cially Ordovician). We have found no indications of Archaean inheritance in our samples of the Permian granites (and only a sin gle zircon Hf model age of 2700 Ma in the Cambrian Tardugno Granodiorite), although several Hf model ages fall in the range 1900–2400 Ma, which could in principle suggest derivation from Palaeoproterozoic or older crust. The Permo-Triassic granites from northern Patagonia analysed by Pankhurst et al. (2006) have whole-rock Nd model ages of 1230–1800 Ma; Hf model ages for emplace-ment-age zircons in these rocks are consistently 1000–1600 Ma (Fanning et al. 2011) and the oldest inherited zircon so far dated is 1800 Ma, although there has been no comprehensive study of zircon cores. The discrepancy between our data and those of Chernicoff et al. (2013) from an oucrop apparently less than 5 km away is not easy to explain unless the Permian magmas were derived from extremely heterogeneous source material. The asso-ciation of strongly negative εNd values with relatively low initial ⁸⁷Sr/⁸⁶Sr ratios compared with the Cambrian and Ordovician plut-ons (Fig. 9), as well as high Sr and high Sr/Y ratios (Fig. 8), sug-gests that the source of the Permian magmas had relatively low Rb/Sr ratios (or high Sr contents), a characteristic normally associated with higher-grade metamorphic rocks and hence deeper crustal
levels. Comparatively high Ga/Al ratios (Fig. 8) are usually ascribed to granulitic residues remaining in the lower crust (Whalen et al. 1987). These features, which persist into the Mesozoic magmatism, are compatible with magma genesis through widespread partial melting of the lower crust of the North Patagonian Massif, ascribed by Pankhurst et al. (2006) to slab break-off and subsequent asthenospheric mantle upwelling.

Sediment deposition

Detrital zircon ages were determined for samples from the western outcrops of the Early Palaeozoic Nahuel Niyeu Formation by Pankhurst et al. (2006) and Rapalini et al. (2013); a provenance pattern combining both SHRIMP datasets is shown in Figure 11. This shows a dominant peak at 526 Ma (the maximum age of sedimentation), a minor one at 635 Ma and a broader one at c. 1040 Ma, corresponding to Pampean, Brasiliano and ‘Grenville’ orogenies respectively, with very rare older input indicated by single zircon ages. The other main metasedimentary unit of NE Patagonia, the El Jagüelito Formation, has essentially the same provenance pattern (Pankhurst et al. 2006). The main peak is indistinguishable from the age of the Tardugno Granodiorite, strongly suggesting that equivalent local basement rocks were the main source of the sedimentary detritus. The slight ‘shoulder’ at the younger end of the pattern is due to three grains dated at 480–500 Ma, but we do not think these are sufficiently robust to indicate Ordovician deposition as claimed by Chernicoff et al. (2013); a Late Cambrian age still seems probable. The provenance is not, however, diagnostic for the location of the sedimentary basin, as these three orogenies (in varying degrees) are the main contributors to Middle to Late Cambrian sediments in the Sierras Pampeanas (Augustssohn et al. 2011; Steenken et al. 2011) and the upper Byrd Group of the Transantarctic Mountains (Goodge et al. 2004).

Correlation of Early Palaeozoic magmatism

The isolated exposures of Early Palaeozoic granitic rocks in the North Patagonian Massif are important to the reconstruction of the proto-Gondwana margin. Their times of emplacement and geochemical, isotopic and tectonic signatures need to be tested for possible connections to known magmatic belts in South America, South Africa and Antarctica.

A comparison of the chronology of Cambrian magmatism in southwestern Gondwana is shown in Figure 12. The closest comparisons for the Tardugno Granodiorite are with the Pampean granites of the Sierras Pampeanas (pre-deformation granite 537 ± 4 Ma; post-deformational granite 530 ± 4 Ma), the basement of the Sierra de la Ventana (524–531 Ma; Rapela et al. 2003) and the basement granitoids beneath the Magallanes basin of southernmost Patagonia (529 ± 8, 521 ± 4, 538 ± 6, 522 ± 4, 521 ± 6 Ma; Söllner et al. 2000; Pankhurst et al. 2003; Hervé et al. 2010). The latter in turn may be correlated with Cambrian granites in the Saldania belt of South Africa (summary by Chemale et al. 2011), where early S-type granites (550–527 Ma) are followed by I-type granites (540–530 Ma) and then post-tectonic A-type granites (530–500 Ma). We have shown that the major and trace element characteristics of the Tardugno Granodiorite are of mixed (heavily contaminated) I-type, which might correspond to the main phase of I-type granites in the Saldania belt. As yet there are no geochemical studies or Hf-in-zircon isotope data for the Sierra de la Ventana or Magallanes basement granites.

A compilation of ages for Ross magmatism in the central Transantarctic Mountains made by Goode et al. (2012) shows a wide range of ages (Fig. 12) among which the oldest are for foliated...
bodies at c. 550 Ma (in one case 589 ± 5 Ma), and a single pegmatite dated at 524 ± 5 Ma. There is a strongly defined peak at 490 Ma for the main post-tectonic granites, which does not coincide either with the c. 528 Ma Tardugno Granodiorite or, as pointed out by Rapalini et al. (2013), with the undeformed Ordovician granites of the 470–480 Ma Punta Sierra suite of Patagonia. More extensive U–Pb dating than is currently available could show that the magmatic history of any of the areas considered here is more extended in time, but at present neither Cambrian nor Ordovician granites of northern Patagonia seem to be synchronous with any stage of Ross orogeny magmatism in the central Transantarctic Mountains.

Conclusions: evidence for and against allochthonous Patagonia

(1) There is no evidence for pre-collisional subduction magmatism in northern Patagonia that could be related to Carboniferous ocean closure to the north. Ramos (2008) proposed an active arc from 310 to 285 Ma, and Ramos & Naipauer (2012) enlarged this range to 395–300 Ma; there are no igneous rocks of such ages anywhere in northeastern Patagonia near the Río Colorado and the only known Devonian–Carboniferous granitoids occur west of the North Patagonian Massif in the proto-Andean margin. The only remaining conceivable candidate for a pre-collisional magmatic arc in northern Patagonia would be the earliest Permian (281 ± 3 Ma) Navarrete granite (Figs 2 and 8). However, there are several strong arguments against this possibility, as follows.

(a) The granite in its type area close to the Tardugno Granodiorite is essentially undeformed.

(b) The granite (281 ± 3 Ma) was essentially synchronous with ash-beds in the Tunas Formation (uppermost Sierra de la Ventana sequence), dated by SHRIMP at 282 ± 3 Ma (Tohver et al. 2008) and 281 ± 2 Ma (López-Gamundi et al. 2013). According to palaeomagnetic evidence, the Tunas Formation underwent folding contemporaneous with deposition (Tomezzoli & Vilas 1999), suggesting that by the time the Navarrete pluton was emplaced, deformation of the Sierra de la Ventana sequence was well under way.

(c) Choyoi Group volcanic rocks at San Rafael (Fig. 1) also show extended Permian magmatism: an early andesitic stage at 282 ± 3 Ma and later rhyolitic episodes at 265 ± 1 Ma and 252 ± 3 Ma (Rocha-Campos et al. 2011); that is, the same timing as plutonism in the North Patagonian Massif. However, occurring more than 500 km north, Choyoi volcanism cannot be related to continental collision along the Río Colorado corridor. Moreover, the relatively short period from 280 to c. 260 Ma that would be available for pre-collisional subduction is not consistent with the closure of a major ocean necessary for the translation of Patagonia from the Central Transantarctic region throughout the Early Palaeozoic. Mafic microgranular enclaves and synplutonic dioritic dykes in the Late Permian granitoids of the Valcheta–Yaminué area suggest hybridization of acid and mafic magmas, the juvenile magmatic
component perhaps being indicative of the heat source that triggered melting of the lower crust.

(2) The Navarrete granite cuts, and shows a contact aureole against, the deformed Nahuel Niyeu metasedimentary rocks of the SW-vergent thrust sheets described by von Gosen (2003). Within the present study area, rocks mapped as Nahuel Niyeu Formation are intruded by the essentially undeformed Ordovician Valcheta pluton. Metamorphism and deformation here are therefore pre-Permian in age, probably pre-470 Ma, and cannot be synchronous with NNE-vergent folding in the Sierra de la Ventana. Similar relationships are found in the Punta Sierra area, where the c.470 Ma unmetamorphosed Punta Sierra granites intrude El Jagüelito Formation metasediments, and metamorphic zircon rims in the Mina Gonzalito amphibolite-grade granite gneiss (to the SE of our study area) were dated at 472 ± 5 Ma (Fig. 1: see Pankhurst et al. 2006).

(3) On the other hand, whereas the 281 ± 3 Ma Navarrete granite in the Tardugno area appears to be post-deformational, the younger Permian granites of the Yaminué complex (c. 250 Ma) are strongly foliated and form shallow NE-dipping sheets that could be inter-pretated as due to thrusting towards the SW (López de Luchi et al. 2010). Deformation occurred at high temperature, possible with a later lower temperature reactivation. The complex local variations in deformational style and timing remain unexplained in detail but suggest a picture of heterogeneous crustal domains during compressive deformation contemporaneous with crustal melting. Local response to deformation may also be enhanced by thinned crust in northern Patagonia inherited from the Late Cambrian rifting epi-sode recorded in the Sierra de la Ventana basement (see below and Rapela et al. 2003).

(4) The Late Permian NE-vergent fold-and-thrust belt of the Sierra de la Ventana is strong evidence for a crust-shortening event. Detailed geophysical study of the offshore extension of the Colorado basin (Fig. 1) by Pánaro & Ramos (2013) shows the fold belt continuing for at least 600 km along strike, where they postulated a large area of pre-Permian strata with no detectable Late Palaeozoic deformation. This lack of deformation is interpreted as due to northward displacement of the orogenic front on a regional detachment thrust, in a similar way to the occurrence of undeformed Cretaceous strata between the Jura Mountains and the high-grade deformed Alps. However, in the latter case, associated with a major continent–continent collision, the maximum width of this displacement zone over the pre-existing European basement is c. 100 km (e.g. Sommaruga 1999), whereas in the present case it would need to be c. 400 km, and the basement is unknown. It is also necessary to assume that the collision of an allochthonous Patagonia terrane was equally responsible for deformation of the Cape Fold Belt of South Africa and the Ellsworth Mountains of Antarctica (see Curtis 2001). Such a tectonic model has not yet been devel-oped, and would also need to accommodate the probability that the Antarctic Peninsula was close to southern Africa in Late Carboniferous time (Brashaw et al. 2012). On the other hand, Dalziel et al. (2000) argued that the fold belt may have formed through the interaction of a mantle plume with a distant subduction zone, without the need for any continental collision.

(5) From chronological, geochemical and isotopic points of view, the Cambrian and Ordovician granites of northern Patagonia could be regarded as representing continuity of the Pampenan and Famatinian belts of the Sierras Pampeanas through Patagonia as part of the Early Palaeozoic margin of Gondwana, as previously proposed by Rapela & Pankhurst (2002), Pankhurst et al. (2003), Gregori et al. (2008) and Rapalini et al. (2013). However, Late Cambrian (510 Ma) alkaline volcanism in the basement rocks of the Sierra de la Ventana was interpreted as representing rifting and the possible separation of a southern block (Rapela et al. 2003). If the margin remained essentially continuous through the Early Palaeozoic, this would probably be better interpreted as intra-continental rifting without the opening of a major ocean. Some tectonic readjustment must have occurred, as the Cambrian Tardugno Granodiorite is now found to the west of the Ordovician Punta Sierra granite suite (the opposite sense to the relationship between the Pampean and Famatinian belts of the Sierras Pampeanas). A curved continental margin in NE Patagonia may be one way to resolve this problem (Rapalini et al. 2013).

(6) The occurrence of fossil archaeocyathids in limestone blocks within the post-535 Ma El Jagüelito Formation of northeastern Patagonia has been interpreted as evidence of juxtaposition against the Central Transantarctic Mountains (González et al. 2011), and the Ordovician granites of the former region have been suggested as correlatives of Ross magmatism in the latter. However, the geochronological comparisons made here (Fig. 12) do not support this magmatic correlation. Perhaps further discoveries will revise the extent of this Australo-Antarctica faunal realm.

(7) The presence of detrital Archaeaen zircon grains in the metasedimentary rocks of the Yaminué complex (and in a Permian granite that intrudes them) demonstrated by Chernicoff et al. (2013) has not been substantiated by the present work: the oldest age of inheritance observed in both Cambrian and Permian samples is c. 1850 Ma. A single Archaeaen Hf model age was obtained from one zircon grain in the Cambrian Tardugno Granodiorite; as in previous studies of Pampean and Famatinian granites, the predominant Nd and Hf model ages presented here are Mesoproterozoic or late Palaeoproterozoic (1.1–2.0 Ma), which is consistent with the exposed and inferred basement geology of southern South America (e.g. Martínez Dopico et al. 2011).

The various lines of evidence discussed in this paper point to an origin of the North Patagonian Massif as a crustal block genetically related to, and probably structurally continuous with, the South American crustal blocks to the north from Early Palaeozoic time, as previously maintained by other researchers (e.g. Rapalini et al. 2013). Overall, we regard the case for the origin of Patagonia as a far-travelled allochthonous block as doubtful, if not yet finally resolved. The observed geology would be equally explicable in terms of crustal shortening across the junction between parautochthonous blocks, without the closure of a major ocean. The data presented here provide a strong factual basis for future refinement of the evolution of northern Patagonia.
