The exclusive queueing process (EQP) has recently been introduced as a model for the dynamics of queues which takes into account the spatial structure of the queue. It can be interpreted as a totally asymmetric exclusion process of varying length. Here we investigate the case of deterministic bulk hopping $p = 1$ which turns out to be one of the rare cases where exact nontrivial results for the dynamical properties can be obtained. Using a time-dependent matrix product form we calculate several dynamical properties, e.g. the density profile of the system.

I. INTRODUCTION

The one-dimensional asymmetric exclusion process, which can be regarded as the prototypical stochastic interacting particle system [1], has been intensively studied in view of its non-equilibrium properties [2], exact solvability [3, 4] and applicability to practical problems [5]. The state space for the exclusion process is the set of configurations of particles (in other words, the exclusion process has a “spatial structure”), and each particle can hop to its nearest neighbor sites only if the target site is empty (“excluded-volume effect”).

On the other hand, the queueing process is one of the basic stochastic processes in the field of operations research [6–8]. In addition to its practical relevance it often appears as effective model, e.g. in all kinds of jamming phenomena. Usually the spatial structure of the queue is neglected, i.e. the queues are regarded as “compact”. However, often this assumption is not justified, e.g. in pedestrian queues. Therefore, recently a queueing process with excluded-volume effect (exclusive queueing process, EQP) has been proposed [9–11]. On a semi-infinite lattice, particles enter the system at the left site next to the leftmost occupied site and leave the system at the rightmost site. In the bulk the particles move according to the rules of the totally asymmetric exclusion process (TASEP), see Fig. [1].

The EPQ can be interpreted as a TASEP with varying system length which allows to analyze its stationary-state properties [9–11]. In a more recent paper [12], dynamical properties of the EQP were analyzed. Especially, for the deterministic bulk hopping case, dynamical behaviors of the average system length and the average number of particles were investigated exactly. In this paper we derive more detailed results for the dynamical properties.

The stationary state of the TASEP and some of its generalizations have been solved by means of the matrix product ansatz in the recent two decades [4]. The application of the matrix product ansatz to the calculation of non-stationary states is quite challenging and has been achieved only in a few cases so far, see e.g. [13–17]. In this paper we will introduce a matrix product dynamical state for the EQP, providing an explicit representation for the matrices. We utilize it for calculating typical quantities both in queueing theory and exclusion processes.

Here we define the EQP as a discrete-time Markov process on a semi-infinite chain where sites are labeled by natural numbers from right to left (Fig. [1]). A new particle enters the chain with probability $\alpha$ only at the leftmost site next to the leftmost occupied site ($j = L$). If there is no particle on the chain, a new particle enters at the (fixed) rightmost site ($j = 1$) with probability $\alpha$. Each particle on the chain necessarily hops to its right nearest neighbor site if it is empty, i.e. we consider the limit of deterministic bulk hopping ($p = 1$). A particle on the rightmost site leaves the system with probability $\beta$. These transitions occur simultaneously within one time step, i.e. we apply the fully parallel update scheme. Since we restrict our consideration to the case of deterministic bulk hopping $p = 1$ (the so-called rule 184 cellular automaton), the stochasticity of the model is due to only the injection and extraction probabilities $\alpha$ and $\beta$.

In [10–12], the phase diagram of the EQP was derived. The parameter space is divided into two regions...
In this paper, we investigate the dynamical (i.e. time-dependent) properties of the EQP in more detail. In the next section we write down the dynamical state (solution to the master equation) in a matrix product form. Using this form we investigate the waiting time, which is one of the basic quantities in queueing theory, in Sec. III. In Sec. IV we determine the density profile and the particle current profile. Concluding remarks are given in Sec. V.

In Appendix we review results on the usual (i.e. without excluded-volume effect) discrete-time queueing process.

II. EXACT DYNAMICAL STATE

For each site $j$ we define the state variable $\tau_j = 1$ or 0 corresponding to being occupied or unoccupied, respectively. For simplicity we impose the initial condition that there is no particle in the system, i.e. an empty chain. The state space is

$$\tilde{S} = \{\emptyset\} \cup \{\sigma_1 \cdots \sigma_\ell | \ell \in \mathbb{N}, \sigma_j \in \{1,0 \} \}$$

$$= \{0,1,10,11,101,1010,111,\ldots \}$$

which is a subset ($\tilde{S} \subset S$) of

$$S = \{0,1\} \cup \{1\tau_{L-1} \cdots \tau_1 | L-1 \in \mathbb{N}, \tau_j \in \{1,0 \} \} .$$

The element $\emptyset$ corresponds to the state where there is no particle in the system. Note that, for $p = 1$, the sequence 00 never appears if the system starts from the empty chain. For simplification, we do not write the infinite number of 0’s left to the leftmost particle. We denote the probability of finding a state $\tau \in \tilde{S}$ at time $t$ by $P_t(\tau)$, and the initial condition is written as $P_0(\emptyset) = 1$ and $P_0(\tau) = 0$ ($\tau \in \tilde{S} \setminus \{\emptyset\}$). We denote the system “length” for the state $\tau \in \tilde{S}$ or $\tau \in S$ by $|\tau|$, which is nothing but the position of the leftmost particle (Fig. 1). In particular we define $|\emptyset| = 0$.

For the generic choice of the parameters $0 < \alpha < 1$ and $0 < \beta < 1$, the process is irreducible and non-periodic on $\tilde{S}$. The master equation is simply written as

\begin{align}
P_{t+1}(\emptyset) &= (1-\alpha)\beta P_t(1) + (1-\alpha)P_t(\emptyset), \\
P_{t+1}(1) &= (1-\alpha)P_t(10) + (1-\alpha)(1-\beta)P_t(1) + \alpha P_t(\emptyset), \\
P_{t+1}(u10) &= (1-\alpha)\beta P_t(u1) + (1-\alpha)\beta P_t(10u1) + \alpha \beta P_t(u1), \\
P_{t+1}(u101) &= (1-\alpha)P_t(1u10) + (1-\alpha)P_t(10u10) + \alpha P_t(u10), \\
P_{t+1}(u11) &= (1-\alpha)(1-\beta)P_t(u1) + (1-\alpha)(1-\beta)P_t(10u1) + \alpha(1-\beta)P_t(u1)
\end{align}

for $u \in \tilde{S}$. In particular, for $u = \emptyset$ we set $\emptyset 10 = 10$, $101 = 11$, and so on. This simple form is due to the deterministic hopping $p = 1$.

We derive an exact dynamical state, beginning with the factorization ansatz

$$P_t(\tau) = Q_t(|\tau|)Y(\tau).$$

The first part $Q$ depends only on time and the system length, and the second part $Y$ is independent of time and

satisfies the following relations:

\begin{align}
Y(u_1101u_2) &= \beta Y(u_11u_2), \\
Y(u_11u_2) &= (1-\beta)Y(u_11u_2), \\
Y(u_10) &= \beta Y(u_11), \\
Y(1) &= 1, \\
Y(\emptyset) &= 1.
\end{align}
One can easily see that the solution to these relations is
\[ Y(\tau_L \cdots \tau_1) = \beta^\#(\tau_1=0)(1-\beta)^{2\#(\tau_1=1)}L - \tau_1 \]  
(14)
for \( \tau_L \cdots \tau_1 \in \tilde{S} \setminus \{\emptyset\} \). The relations \([9][12]\) also have the following matrix product representation, which is more convenient later:
\[
Y(\tau_L \cdots \tau_1) = \langle W'|X_{\tau_L} \cdots X_{\tau_1}|V \rangle
\]  
(15)
with
\[
X_1 = D = \begin{pmatrix} 1 - \beta & 0 \\ \sqrt{\beta} & 0 \end{pmatrix}, \quad X_0 = E = \begin{pmatrix} 0 & \sqrt{\beta} \\ 0 & 0 \end{pmatrix},
\]
(16)
\[
\langle W \rangle = \begin{pmatrix} 1 \sqrt{\beta} \end{pmatrix}, \quad |V \rangle = \begin{pmatrix} 1 \end{pmatrix}.
\]
(17)
These are essentially the same matrices and vectors as for the matrix product stationary state for the EQP with \( p = 1 \) \([11]\). The first part \( Q_t(L) \) gives the probability that the system length is \( L \) at time \( t \) since
\[
\sum_{\tau \subseteq S} Y(\tau) = \sum_{\tau \subseteq S} Y(\tau) = \langle W|D(D + E)^{L-1}|V \rangle = 1.
\]  
(18)
Note that we can replace \( \tilde{S} \) by \( S \) in the above equation thanks to \( E^2 = 0 \). Inserting the relations \([9][12]\) into the master equation \([3][7]\), we obtain
\[
Q_{t+1}(0) = (1-\alpha)Q_t(0) + \beta(1-\alpha)Q_t(1),
\]
\[
Q_{t+1}(L) = \alpha Q_t(L) + (1-\alpha)(1-\beta)Q_t(L) + (1-\alpha)\beta Q_t(L+1).
\]
(19)
(20)
These equations actually agree with Eqs. (65) and (66) in \([12]\) which were derived in a different way. The solution to this recurrence formula with the initial condition
\[
Q_0(0) = 1, \quad Q_0(L) = 0 \quad (L \in \mathbb{N})
\]  
(21)
is given by \([12]\)
\[
Q_t(L) = C_{z^L} \frac{1 - \Lambda}{1 - z} \Lambda^L
\]  
(22)
where \( C_{z^L}F(z) \) denotes the coefficient of \( z^L \) in the Laurent series for the function \( F(z) \), that is \( C_{z^L}F(z) = \frac{\partial}{\partial z} \frac{z^L F(z)}{\pi} \). Inserting the relations (9)-(12) into
\[
E_1 \left( \frac{1}{2} \sum_{\tau \subseteq S} Y(\tau) \right) = 1
\]  
(23)
\[
\sum_{\tau \subseteq S} \tau \in \tilde{S} \setminus \{\emptyset\} \end{pmatrix}, \quad \beta(1-\alpha)
\]
(24)
\[
\Lambda = \frac{1 - (1 - \alpha)(1 - \beta)z - r}{2(1 - \alpha)\beta z},
\]
(23)
\[
r = \sqrt{[1 - (1 - \alpha)(1 - \beta)z]^2 - 4(1 - \alpha)\alpha \beta z^2},
\]
(24)
\[
\langle L_t \rangle = \sum_{L \geq 0} LQ_t(L) = C_{z^L} \frac{\Lambda}{(1 - z)(1 - \Lambda)}
\]  
(25)
\[
\approx \begin{cases} \beta - \alpha - \alpha \beta & (\alpha < \frac{\beta}{1+\beta}), \\ 2\sqrt{\frac{\beta t}{\pi(1+\beta)}} & (\alpha = 0), \\ (\alpha - \beta + \alpha \beta)t & (\alpha > \frac{\beta}{1+\beta}), \end{cases}
\]
(26)
for \( t \to \infty \).

Inserting Eqs. (15) and (22) into Eqn. (8), we obtain the matrix product dynamical state
\[
P_t(\emptyset) = C_{z^L} \frac{1 - \Lambda}{1 - z}.
\]
(27)
\[
P_t(\tau_L \cdots \tau_1) = C_{z^L} \frac{1 - \Lambda}{1 - z} \Lambda^L \langle W|X_{\tau_L} \cdots X_{\tau_1}|V \rangle.
\]
(28)
When \( \alpha < \frac{\beta}{1+\beta} \) (convergent phase), the matrix product dynamical state converges to the matrix product stationary state \([11]\)
\[
\lim_{t \to \infty} P_t(\emptyset) = \lim_{z \to 1} (1 - \Lambda) = \frac{\beta - \alpha - \alpha \beta}{\beta(1 - \alpha)},
\]
(29)
\[
\lim_{t \to \infty} P_t(\tau_L \cdots \tau_1) = \lim_{z \to 1} (1 - \Lambda) \Lambda^L \langle W|X_{\tau_L} \cdots X_{\tau_1}|V \rangle
\]
(30)
\[
= \frac{\beta - \alpha - \alpha \beta}{\beta(1 - \alpha)} \left( \frac{\alpha}{(1 - \alpha)^2} \right)^L \langle W|X_{\tau_L} \cdots X_{\tau_1}|V \rangle.
\]

III. WAITING TIME

The waiting time is one of the most important quantities in queueing theory, which corresponds to the number of time steps that a particle needs to leave the system after entering the system.

Before we derive the waiting time distribution we determine the distribution of the number \( N \) of particles in the system. In standard queueing theory \( N \) is always identical to the length \( L \) of the system since the queue has no internal structure. In the EQP we only know that, by definition, \( N \) can not be larger than \( L \). The probability that the number of particles is \( N = 0 \) at time \( t \) is, of course, equal to \( Q_t(0) \). For \( N \in \mathbb{N} \), we find
\[ P_t^{A+B}(N) = P_t^A(N) + P_t^B(N) = \sum_{\tau_L, \ldots, \tau_Y \in \mathbb{N}_{\#(\{\tau_T\}) = N}} P_t(\tau_L \cdots \tau_Y) = C_z, \frac{1 - \Lambda}{1 - z} \langle W | (\Lambda D + \Lambda^2 D^2)^N | V \rangle \]
\[ = C_z, \frac{\Lambda(1 - \Lambda)(1 + \beta \Lambda)}{(1 - z)^N} [\Lambda(1 - \beta + \beta \Lambda)]^{N-1}, \tag{31} \]

where \( P_t^A(N) \) [resp. \( P_t^B(N) \)] is the probability of finding \( N \) particles in the system and the site 1 being occupied (resp. empty) at time \( t \). We calculate \( P_t^A(N) \) and \( P_t^B(N) \) as well:
\[ P_t^A(N \in \mathbb{N}) = C_z, \frac{1 - \Lambda}{1 - z} \langle W | (\Lambda D + \Lambda^2 D^2)^{N-1} \Lambda D | V \rangle = C_z, \frac{\Lambda(1 - \Lambda)}{(1 - z)^N} [\Lambda(1 - \beta + \beta \Lambda)]^{N-1}, \tag{32} \]
\[ P_t^B(N \in \mathbb{N}) = P_t^{A+B}(N) - P_t^A(N) = C_z, \frac{\beta \Lambda^2(1 - \Lambda)}{1 - z} [\Lambda(1 - \beta + \beta \Lambda)]^{N-1}, \tag{33} \]
\[ P_t^B(0) = Q_t(0) = C_z, \frac{1 - \Lambda}{1 - z}. \tag{34} \]

We also set \( P_t^A(0) = 0 \). Indeed Eqs. (31), (32) and (33) agree with the results derived in [12] in a more complicated way. By using the result (31), the average number of particles at time \( t \) is found to be [12]
\[ \langle N_t \rangle = \sum_{N \geq 1} NP_t^{A+B}(N) \]
\[ = C_z, \frac{\Lambda}{(1 - z)(1 - \Lambda)(1 + \beta \Lambda)} \]
\[ \approx \begin{cases} \alpha(1 - \alpha) & (\alpha < \frac{\beta}{1+\beta}), \\ 2 \sqrt{\frac{\beta}{(1+\beta)^2}} & (\alpha = \frac{\beta}{1+\beta}), \\ \alpha - \beta + \alpha \beta \frac{2\beta}{1+\beta} & (\alpha > \frac{\beta}{1+\beta}), \end{cases} \tag{35} \]
for \( t \to \infty \).

Now we turn to the waiting time, i.e. the time that a new particle stays in the system. For a given number \( N \) of particles in the system, the probability that the waiting time is \( T \in \mathbb{N} \) is given by
\[ (A): \binom{T - N}{N} \beta^{N+1}(1 - \beta)^{T-2N} = A(T, N), \tag{37} \]
\[ (B): \binom{T - N - 1}{N} \beta^{N+1}(1 - \beta)^{T-2N-1} = B(T, N). \tag{38} \]

Here \( A \) (resp. \( B \)) corresponds to the case where the rightmost site is occupied (resp. empty). Note that \( \binom{a}{b} \) denotes the binomial coefficient, which should not be confused with a two-dimensional column vector. The average waiting times for given \( N \) in the cases \( A \) and \( B \) are, respectively,
\[ \langle T_{N,A} \rangle = \sum_{T \geq 2N} TA(T, N) = \frac{N + 1}{\beta} + N - 1, \tag{39} \]
\[ \langle T_{N,B} \rangle = \sum_{T \geq 2N+1} TB(T, N) = \frac{N + 1}{\beta} + N. \tag{40} \]

This result can be interpreted as follows:
- For each particle, it takes one time step to move from site 2 to site 1. For \( N + 1 \) particles, it takes, in total, \( N \) time steps (resp. \( N + 1 \) time steps) for the case \( A \) (resp. \( B \)).
- For each particle, it takes \( 1/\beta \) time steps in average to leave the system after arriving at site 1. For \( N + 1 \) particles, it takes, in total, \( \frac{N + 1}{\beta} \) time steps.
- A new particle entering the system at time \( t \) does not wait during time \( t \) and \( t + 1 \). Thus we have to subtract 1 from the above.

Let us consider the probability \( W_t(T) \) of the waiting time \( T \) for a particle entering the system at time \( t \). Using Eqs. (32), (33), (34), (37) and (38), we find
\[ W_t(T) = \sum_{N=0}^{\lfloor T/2 \rfloor} [A(T, N)P_t^A(N) + B(T, N)P_t^B(N)] \]
\[ = C_z, \frac{\beta(1 - \Lambda)}{1 - z} (1 - \beta + \beta \Lambda)^{T-1}, \tag{41} \]
where \( \lfloor \cdot \rfloor \) denotes the floor function, i.e. \( \lfloor T/2 \rfloor = T/2 \) (if \( T \in 2\mathbb{N} \)) or \( \lfloor T/2 \rfloor = (T - 1)/2 \) (if \( T \in 2\mathbb{N} - 1 \)). In the convergent phase, \( W_t(T) \) converges to the stationary distribution of the waiting time
\[ \lim_{t \to \infty} W_t(T) = \lim_{z \to 1} \beta(1 - \Lambda) (1 - \beta + \beta \Lambda)^{T-1} = \beta - \alpha - \alpha \beta \left( \frac{1 - \beta + \alpha \beta}{1 - \alpha} \right)^T, \tag{42} \]
which agrees with the result in [10].

To finish this section, we investigate the average wait-
ing time:

\[
\langle T_i \rangle = C' \frac{1}{\beta(1-z)} \sum_{T \geq 1} T(1-\beta + \beta \Lambda)^{T-1}
\]

\[= C' \frac{1}{\beta(1-z)(1-\Lambda)}. \tag{43}\]

The order of the closest singularity \( z = 1 \) to the origin depends on the parameters \((\alpha, \beta)\) \[12\]:

\[
\lim_{z \to 1} \frac{1-z}{\beta(1-z)(1-\Lambda)} = \frac{1-\alpha}{\beta - \alpha - \alpha \beta} \quad (\alpha < \frac{\beta}{1+\beta}), \tag{44}\]

\[
\lim_{z \to 1} \frac{(1-z)^{\frac{1}{2}}}{\beta(1-z)(1-\Lambda)} = \frac{1}{\beta(1+\beta)} \quad (\alpha = \frac{\beta}{1+\beta}), \tag{45}\]

\[
\lim_{z \to 1} \frac{(1-z)^{\frac{1}{2}}}{\beta(1-z)(1-\Lambda)} = \frac{\alpha - \beta + \alpha \beta}{\beta} \quad (\alpha > \frac{\beta}{1+\beta}), \tag{46}\]

and thus we have

\[
\langle T_i \rangle \to \frac{1-\alpha}{\beta - \alpha - \alpha \beta} \quad (\alpha < \frac{\beta}{1+\beta}), \tag{47}\]

\[
\langle T_i \rangle = 2 \sqrt{\frac{t}{\pi\beta(1+\beta)}} + o(\sqrt{t}) \quad (\alpha = \frac{\beta}{1+\beta}), \tag{48}\]

\[
\langle T_i \rangle = \frac{\alpha - \beta + \alpha \beta}{\beta} t + o(t) \quad (\alpha > \frac{\beta}{1+\beta}), \tag{49}\]

as \( t \to \infty \). We note that one of the central results of queueing theory, Little’s theorem \[6\], is indeed satisfied in the convergent phase \((\alpha < \frac{\beta}{1+\beta})\) \[10\]:

\[
\alpha \lim_{t \to \infty} \langle T_i \rangle = \lim_{t \to \infty} (N_i). \tag{50}\]

We also notice that, in the divergent phase and on the critical line \((\alpha \geq \frac{\beta}{1+\beta})\) as well as in the convergent phase, there is a physically natural relation between the average waiting time and the average number of particles:

\[
J_{it} \cdot \langle T_i \rangle \approx \langle N_i \rangle \quad (t \to \infty). \tag{51}\]

Here \( J_{it} \) is the current of particles passing through the exit (outflow), which will be derived in the next section. Note that this relation also holds for the usual queueing process, see Appendix.

\section{IV. DENSITY AND CURRENT}

We consider the probability \( \rho_{jt} \) that the site \( j \) is occupied at time \( t \), i.e. the density profile. The initial condition implies that \( \rho_{jt} = 0 \) for \( j > t \) and \( \rho_{tt} = \alpha t \). The density profile for general \( j \) and \( t \) can be calculated as

\[
\rho_{jt} = \sum_{\tau_k=0,1} P_t(1\tau_{j-1} \cdots \tau_1) + \sum_{\tau_k=0,1, \ell \geq j+1} P_t(1\tau_{L-1} \cdots \tau_j+1\tau_{j-1} \cdots \tau_1)
\]

\[
= Cz' \frac{1-\Lambda}{1-z} \Lambda^j \langle W | D(D+E)^{j-1} | V \rangle + \sum_{\ell \geq j+1} \Lambda^\ell \langle W | D(D+E)^{\ell-j}D(D+E)^{j-1} | V \rangle \tag{52}\]

\[
= Cz' \frac{1-\Lambda}{1-z} \Lambda^j \left\{ \langle W | D(D+E)^{j-1} | V \rangle + \Lambda \langle W | D[1 - \Lambda(D+E)]^{j-1}D(D+E)^{j-1} | V \rangle \right\}
\]

\[
= Cz' \frac{1-\Lambda}{1-z} \Lambda^j \frac{\Lambda}{1+\beta \Lambda}. \tag{53}\]

By definition, the particle current \( J_{it} \) passing through the exit (the right end) during \( t \) and \( t+1 \) is given by

\[
J_{it} = \beta \rho_{it}. \tag{55}\]

The particle current \( J_{jt} \) through the bond between the sites \( j \geq 2 \) and \( j-1 \)

\[
J_{jt} = \sum_{\tau_k=0,1} P_t(10\tau_{j-2} \cdots \tau_1)
\]

\[
+ \sum_{\tau_k=0,1, \ell \geq j+1} P_t(1\tau_{L-1} \cdots \tau_{j+1}0\tau_{j-2} \cdots \tau_1) \tag{54}\]

also satisfies the relation

\[
J_{jt} = \beta \rho_{jt} \tag{55}\]

since \( DE(D+E)^{j-2} | V \rangle = \beta D(D+E)^{j-1} | V \rangle \).

For the generic choice of parameters \( \alpha \) and \( \beta \), the density profile near the right end converges as

\[
\rho_{jt} \to \lim_{z \to 1} \frac{\Lambda^j}{1+\beta \Lambda} = \begin{cases} \frac{1}{1+\beta} \left\{ \frac{\alpha}{(1-\alpha)^{\beta}} \right\}^{\beta}, & (\alpha \geq \frac{\beta}{1+\beta}) \\
(1-\alpha) \left\{ \frac{\alpha}{(1-\alpha)^{\beta}} \right\}^{\beta}, & (\alpha < \frac{\beta}{1+\beta}) \end{cases} \tag{56}\]
for $t \to \infty$. Here we took the limit with the site number $j$ independent of time $t$. In particular, for $j = 1$, we have

$$\lim_{t \to \infty} \rho_{1t} = \begin{cases} \frac{1}{\alpha+\beta} (\alpha > 1), \\ \frac{1}{\alpha} (\alpha < 1), \end{cases}$$

$$\lim_{t \to \infty} J_{1t} = \begin{cases} \frac{\beta}{\alpha+\beta} (\alpha > 1), \\ \frac{\alpha}{\alpha} (\alpha < 1), \end{cases}$$

confirming the relation (51).

Let us now consider rescaled density profiles in the divergent phase and on the critical line, where the average system length grows of order $t$ and $\sqrt{t}$, respectively [see Eqn. (20)]. First we observe that the density profile $\rho_{jt}$ can be interpreted as the expected number of noninteracting asymmetric random walkers at time $t$ on site $j$ since the expression (52) satisfies the equation

$$\rho_{j,t+1} = \alpha \rho_{j-1,t} + \gamma \rho_{jt} + \delta \rho_{j+1,t}$$

with $\gamma = (1-\alpha)/(1-\beta)$ and $\delta = (1-\alpha)\beta$, which is the same as for $Q_t(L)$ [cf. (20)]. We extend the domain $j \in \mathbb{N}$ to $j \in \mathbb{Z}$ so that $\rho_{jt}$ can be regarded as the expected number of walkers with the initial condition that a random walker exists at each site $i \in \mathbb{Z}_{\leq 0}$ with probability

$$\rho_0 = \frac{1}{1+\beta} + (1-\alpha) \left[ \frac{\alpha}{(1-\alpha)\beta} \right] - \frac{1-\alpha-\alpha\beta}{1+\beta} \frac{1}{(-\beta)\delta}.$$

Each walker at site $j$ hops to its left site $j+1$ with probability $\alpha$, to the right site $j-1$ with probability $\delta$, or stays at site $j$ with probability $\gamma (\alpha+\gamma+\delta = 1)$, see Fig. 3. Let $\rho_0(i)$ be the probability that the walker starting from the site $i$ is in site $j$ at time $t$, which is distributed around $Vt + i$ as

$$\rho_0(i) \approx \frac{1}{\sqrt{2\pi \sigma t}} \exp \left[ -\frac{(j-Vt-i)^2}{2\sigma t} \right]$$

for the generic case $0 < \alpha < 1$ and $0 < \beta < 1$. Here $\sigma = \alpha + \delta - (\alpha - \delta)^2$, and $V = \alpha - \delta$ which is equal to the velocity for the system length, see Eqn. (20). The density profile is expressed as

$$\rho_{jt} = \sum_{i \leq 0} \rho_0(i) \epsilon_{jt}.$$

In the divergent phase $\alpha > \frac{\beta}{1+\beta}$ (with $\alpha < 1$ and $0 < \beta < 1$), noting the initial condition

$$\lim_{i \to -\infty} \rho_0 = \frac{1}{1+\beta}$$

and the form (61), we find that the density profile with rescaling of the position $j = xt$ converges as

$$\rho_{xt,t} \to \begin{cases} \frac{1}{1+\beta} (0 < x < V), \\ 0 (V < x < 1), \end{cases}$$

Figure 4 gives an example for the rescaled density profile in the divergent phase.

On the critical line $\alpha = \frac{\beta}{1+\beta}$ ($0 < \beta < 1$), noting the initial condition

$$\lim_{i \to -\infty} \rho_0 = \frac{2}{1+\beta}$$
and the form (61) with $V = 0$, we find that the density profile (62) with the rescaling $x = 1/t$ converges as

$$
\rho_{x=\sqrt{\pi t},t} \to \frac{1}{1 + \beta} \text{erfc} \left( \frac{x}{\sqrt{2}} \frac{1 + \beta}{\beta} \right). \quad (66)
$$

Here erfc is the complementary error function: $\text{erfc}(x) = \frac{2}{\sqrt{\pi}} \int_{x}^{\infty} e^{-y^2} dy$. Figure 5 gives an example for the rescaled density profile on the critical line.

Now we consider some special cases. When $\alpha = 1$, the position of the leftmost particle is $t$ by definition, and we have $\rho_{t,t} = 1$. In this case, $\Lambda = z$ and the density profile becomes simply

$$
\rho_{j,t} = C_z \frac{z^j}{(1-z)(1+\beta z)} = \frac{1 - (-\beta)^{t-j+1}}{1 + \beta} \quad (67)
$$

In particular, the density profile observed by the leftmost particle is independent of time $t$, and exhibits oscillations. When $\beta = 1$ and $\alpha > \frac{1}{2}$, another oscillation occurs. Since $\gamma = 0$, the walker starting from the site $i$ can exist on the site $j$ at time $t$ only if $j - i - t \in 2\mathbb{Z}$, and is distributed around $V t + i$ at time $t$ as

$$
\rho^{(i)}_{j,t} \simeq \sqrt{\frac{2}{\pi \sigma t}} \exp \left[ -\frac{(j - V t - i)^2}{2 \sigma t} \right]. \quad (68)
$$

We also note that the initial condition for the walker on site $i$ converges as

$$
\lim_{i \to -\infty} \rho_{i,0} = 1 - \alpha, \quad \lim_{i \to +\infty} \rho_{i,0} = \alpha. \quad (69)
$$

In the limit $t \to \infty$ with the scaling $x = t$, we have

$$
\rho_{j,t} \to \begin{cases} 
1 - \alpha & (0 < x < 2\alpha - 1, j - t \in 2\mathbb{Z} + 1), \\
\alpha & (0 < x < 2\alpha - 1, j - t \in 2\mathbb{Z}), \\
0 & (2\alpha - 1 < x < 1).
\end{cases} \quad (70)
$$

V. CONCLUDING REMARKS

We have studied dynamical properties of the EQP with deterministic bulk hopping $p = 1$. We found the exact dynamical state in matrix product (MP) form with a two-dimensional representation of the matrices and vectors. The MP dynamical state approaches the MP stationary state in the convergent phase $\alpha < \frac{1}{1+\beta}$ as $t \to \infty$. We have obtained the time-dependent distributions of the system length $L$ (22), the number of particles $N$ (31) and the waiting time $T$ (11), and the time-dependent density (62) and current (63) profiles of site $j$. An interesting point is that essentially they are given in the form

$$
C_z \Psi(z) \Phi(z)^{x} \quad (x = L, N, T, j) \quad (71)
$$

with functions $\Psi$ and $\Phi$ including the square root $r$ [cf. (24)].

We found that the asymptotic density profile in the divergent phase (with the generic choice of parameters) is flat. In contrast, the density profile for $p < 1$ is nontrivial [19]. One of the important tasks for future studies is to determine the form of the density profile and its dependence on the system parameters for the general case. The stationary state for the EQP with probabilistic hopping.
$p < 1$ has a matrix product form with infinite dimensional matrices [11]. This fact makes us expect that the MP dynamical state can be extended to the $p < 1$ case, which approaches the MP stationary state in the limit $t \to \infty$ as in the following diagram:

\[ \text{dynamical state } \quad p \to 1 \quad \text{MP dynamical state of unknown form} \]
\[ t \to \infty \quad \downarrow \quad t \to \infty \]
\[ \text{MP stationary state } \quad p \to 1 \quad \text{MP stationary state with 2D matrices} \]

with $2D$ matrices $\mathbf{MP}$ dynamical state can be extended to the $\mathbf{MP}$ stationary state as in the following diagram:

\[ \text{dynamical state } \quad p \to 1 \quad \text{MP dynamical state of unknown form} \]
\[ t \to \infty \quad \downarrow \quad t \to \infty \]
\[ \text{MP stationary state } \quad p \to 1 \quad \text{MP stationary state with 2D matrices} \]

In the probabilistic hopping case $p < 1$, however, the master equation cannot be simplified similar to Eqs. [5]-[7], and the factorization ansatz [8] is no longer valid [10].

What we have investigated here is a very basic model of queue with excluded-volume effect. Apart from the generalization to $p < 1$ one can consider various other generalizations of the EQP, for example multi-lane queues with some types of queue-changing rules.

### Appendix A: Results on the usual queueing process

The usual queueing process is characterized by the number $N$ of particles which is equal to the length of the system since its spatial structure is not taken into account. We denote the probability that the number of particles is $N$ at time $t$ by $P_t(N)$. At each time, a particle enters the system with probability $\alpha$. When a particle leaves the system at time $t-1$, the next particle can leave the system at time $t$ with probability $\beta$. If a new particle enters the system at time $t$ and there is no other particle, this new particle can leave the system simultaneously. The critical line for the usual queueing process is $\alpha = \beta$, and the system is convergent or divergent if $\alpha < \beta$ or $\alpha > \beta$, respectively. The dynamical solution to the master equation

\[ P_{t+1}(0) = [(1-\alpha) + \alpha \beta]P_t(0) + (1-\alpha)\beta P_t(1), \quad (A1) \]
\[ P_{t+1}(N) = (1-\alpha)\beta P_t(N+1) \]
\[ + [(1-\alpha)(1-\beta) + \alpha \beta]P_t(N) \]
\[ + \alpha(1-\beta)P_t(N-1) \]
\[ (N \in \mathbb{N}) \]

with the initial condition
\[ P_0(0) = 1, \quad P_0(N) = 0 \quad (N \in \mathbb{N}) \]

is given by
\[ P_t(N) = C_{zt} \frac{1 - \Theta}{1 - z} \Theta^N, \quad (A3) \]

where
\[ \Theta = \frac{1 - (1-\alpha - \beta + 2\alpha \beta)z - s}{2(1-\alpha)\beta z}, \quad (A5) \]
\[ s = \sqrt{[1 - (1-\alpha - \beta + 2\alpha \beta)z]^2 - 4\alpha \beta (1-\alpha)(1-\beta)z^2}. \quad (A6) \]

When $\alpha < \beta$, the system approaches the stationary state

\[ \lim_{t \to \infty} P_t(N) = \lim_{z \to 1} (1-\Theta)\Theta^N \]
\[ = \frac{\beta(1-\alpha)}{\beta - \alpha} \left[ \frac{\alpha(1-\beta)}{\beta(1-\alpha)} \right]^N. \quad (A7) \]

The average number of particles at time $t$ is

\[ \langle N_t \rangle = \sum_{N \geq 1} NP_t(N) = C_{zt} \frac{\Theta}{(1-z)(1-\Theta)} \]
\[ \simeq \left\{ \begin{array}{ll}
\frac{(1-\beta)}{\beta - \alpha} & (\alpha < \beta), \\
2 \sqrt{\frac{(1-\alpha)(1-\beta)}{(\alpha - \beta)t}} & (\alpha = \beta), \\
\frac{(1-\alpha)}{\alpha - \beta} & (\alpha > \beta),
\end{array} \right. \quad (A8) \]

The particle current leaving the system (outflow) $J_t$ at time $t$ is given by

\[ J_t = \alpha \beta P_t(0) + \beta \sum_{N \geq 1} P_t(N) = C_{zt} \frac{\beta[\Theta + \alpha(1-\Theta)]}{1 - z} \]
\[ \to \left\{ \begin{array}{ll}
\alpha & (\alpha < \beta), \\
\beta & (\alpha \geq \beta),
\end{array} \right. \quad (A9) \]

for $t \to \infty$. Note that, in the EQP case, $\lim_{t \to \infty} J_t$ [58] is not equal to the exit probability $\beta$ in the divergent phase since the rightmost site can be empty. The probability of the waiting time $T$ for a given number $N$ of particles is $\frac{T}{N} \beta^{N+1}(1-\beta)^{T-N}$ from which we find the probability of the waiting time for a given time $t$:

\[ \sum_{N=0}^T P_t(N) \frac{T}{N} \beta^{N+1}(1-\beta)^{T-N} \]
\[ = C_{zt} \frac{\beta(1-\Theta)}{(1-z)(1-\beta + \beta\Theta)}T. \quad (A10) \]

The average waiting time is then

\[ \langle T_t \rangle = C_{zt} \frac{\beta(1-\Theta)}{(1-z)} \sum_{T \geq 1} T(1-\beta + \beta\Theta)^T \quad (A11) \]
\[ = C_{zt} \frac{1 - \beta + \beta\Theta}{\beta(1-z)(1-\Theta)} \simeq \left\{ \begin{array}{ll}
\frac{1-\Theta}{\beta} & (\alpha < \beta), \\
\frac{2(1-\alpha)(1-\beta)}{\alpha - \beta} & (\alpha = \beta), \\
\frac{(1-\alpha)(1-\beta)}{\alpha - \beta} & (\alpha > \beta),
\end{array} \right. \]

and the relation $J_t \langle T_t \rangle \simeq \langle N_t \rangle \quad (t \to \infty)$ holds.
