Positive Feedback Regulation between \(\gamma\)-Aminobutyric Acid Type A (GABA\(_A\)) Receptor Signaling and Brain-derived Neurotrophic Factor (BDNF) Release in Developing Neurons

Christophe Porcher, Caroline Hatchett, Rebecca E. Longbottom, Kristina McAinch, Talvinder S. Sihra, Stephen J. Moss, Alex M. Thomson, and Jasmina N. Jovanovic

From the 1Institut de Neurobiologie de la Méditerranée, INSERM Unité 901 and Université de La Méditerranée, 13273 Marseille Cedex 09, France, 2Department of Pharmacology, The School of Pharmacy, London, WC1N 1AX, United Kingdom, 3Department of Neuroscience, Physiology and Pharmacology, University College London, London, WC1E 6BT, United Kingdom, and 4Department of Neuroscience, Tufts University, Boston, Massachusetts 02111

During the early development of the nervous system, \(\gamma\)-aminobutyric acid (GABA) type A receptor (GABA\(_A\))-mediated signaling parallels the neurotrophin/tropomyosin-related kinase (Trk)-dependent signaling in controlling a number of processes from cell proliferation and migration, via dendritic and axonal outgrowth, to synapse formation and plasticity. Here we present the first evidence that these two signaling systems regulate each other through a complex positive feedback mechanism. We first demonstrate that GABA\(_A\) activation leads to an increase in the cell surface expression of these receptors in cultured embryonic cerebrocortical neurons, specifically at the stage when this activity causes depolarization of the plasma membrane and Ca\(^{2+}\) influx through L-type voltage-gated Ca\(^{2+}\) channels. We further demonstrate that GABA\(_A\) activity triggers release of the brain-derived neurotrophic factor (BDNF), which, in turn by activating TrkB receptors, mediates the observed increase in cell surface expression of GABA\(_A\)Rs. This BDNF/TrkB-dependent increase in surface levels of GABA\(_A\)Rs requires the activity of phosphoinositide 3-kinase (PI3K) and protein kinase C (PKC) and does not involve the extracellular signal-regulated kinase (ERK) 1/2 activity. The increase in GABA\(_A\)R surface levels occurs due to an inhibition of the receptor endocytosis by BDNF, whereas the receptor reinsertion into the plasma membrane remains unaltered. Thus, GABA\(_A\)R activity is a potent regulator of the BDNF release during neuronal development, and at the same time, it is strongly enhanced by the activity of the BDNF/TrkB/PI3K/PKC signaling pathway.

Fast synaptic inhibition in the adult brain is largely mediated by GABA\(_A\) receptors, members of a large family of GABA-
**GABA<sub>A</sub> Receptor Activity Triggers Ca<sup>2+</sup>-dependent BDNF Release**

Here we provide evidence for a positive feedback mechanism operating between the depolarizing activity of GABA<sub>A</sub>Rs and the secretion of BDNF in developing cerebrocortical neurons. We demonstrate that activation of GABA<sub>A</sub>Rs triggers the Ca<sup>2+</sup>-dependent release of BDNF, which is coupled to the activation of L-type voltage-gated Ca<sup>2+</sup> channels. This, in turn, leads to an increase in the cell surface expression of GABA<sub>A</sub>Rs via the activation of TrkB receptors and downstream signaling pathways mediated by PI 3-kinase and PKC. By specifically inhibiting GABA<sub>A</sub>R endocytosis, BDNF-dependent signaling increases the responsiveness of developing neurons to GABA and, in turn, enhances its own release. The reciprocal augmentation between GABA and BDNF/TrkB signaling is specific for developing neurons and may facilitate the establishment and functional maturation of GABAergic synapses.

**EXPERIMENTAL PROCEDURES**

**Cell Culture**—Primary cortical neuronal cultures were prepared using E16-E17 Sprague-Dawley rats as described previously (47) with minor modifications (38). Dissociated neurons were plated at a density of 60,000 cells/cm<sup>2</sup> in Neurobasal medium containing B27 supplement, glutamine (2 mM), penicillin (100 units), streptomycin (100 µg), and glucose (6 mM; all from Invitrogen) on either 0.1 mg/ml poly-D-lysine-coated culture dishes or 0.1 mg/ml poly-L-lysine-coated glass coverslips. Cultures were then washed with 0.1M PBS (4 °C; pH 7.4) and fixed for 10 min with PFA-sucrose. After fixation, the neurons were incubated in 0.1% Triton, 3% goat serum, PBS for 1 h at room temperature and incubated overnight with a guinea pig anti-vesicular glutamate transporter (VGlut; 1:200; clone bd17, Millipore) to label the receptors expressed for 24 h. The procedure for surface BDNF-GFP immunostaining was similar to that described previously (50). Quantification was performed using ImageJ software to determine the average level of fluorescence of each cell at each time point sampled. ΔF/F was calculated as follows: the basal fluorescence (F<sub>bas</sub>) was obtained by averaging the neuronal fluorescence intensity of the last five frames before application of GABA. Frame fluorescence (F<sub>fr</sub>) was the neuronal fluorescence intensity of the frame. Therefore, ΔF/F = (F<sub>fr</sub> - F<sub>bas</sub>)/F<sub>bas</sub>. The pick value of ΔF/F following GABA application in the absence or presence of bicuculline was used for the statistical analysis.

**Surface GFP-BDNF Immunofluorescence Analysis**—Cortical neurons (4 DIV) plated on glass coverslips were transfected with cDNAs encoding the BDNF-GFP (49) (kindly provided by Dr. V. Lessmann, Institute of Physiology, Otto von Guericke University, Magdeburg, Germany) using Lipofectamine<sup>™</sup> 2000 (Invitrogen). Cultures were incubated at 37 °C in 5% CO<sub>2</sub> for 24 h. The procedure for surface BDNF-GFP immunostaining was similar to that described previously (50). Briefly, after incubation of cells in the absence or presence of muscimol (50 µM; Tocris), TTX (0.5 µM), or muscimol/bicuculline (10 µM; Tocris) for 10 min and a wash with Hanks’ balanced salt solution, the living cultures were incubated at 4 °C for 1 h in the presence of an anti-GFP antibody (10 µg/ml; Invitrogen). Cultures were then washed with 0.1 M PBS (4 °C; pH 7.4) and fixed for 10 min with PFA-sucrose. After fixation, the neurons were exposed to a saturating concentration (10 µg/ml) of Alexa Fluor 555-conjugated anti-rabbit IgG (Invitrogen) for 1.5 h. Immunolabeling confirmed that BDNF-GFP was stored in secretory granules of the regulated pathway of secretion as shown previously (50). Quantification was performed using ImageJ software. The ratio of surface-bound BDNF-GFP to total BDNF-GFP was estimated as the ratio of the area of co-localized Alexa Fluor 555 and BDNF-GFP/total area of BDNF-GFP and expressed as “percentage of co-localized signals” (Fig. 3).

**Phospho-CREB Activation**—The procedure for phospho-CREB activation and immunocytochemistry was similar to that described previously (50). To reduce the basal level of CREB phosphorylation, cultures (5 DIV) were incubated overnight in TTX (0.5 µM). Cultures were then stimulated with BDNF (100 ng; Alomone Labs) or muscimol (50 µM) in the absence or presence of TrkB-IgG (2 µg/ml; Regeneron) or bicuculline (10 µM). Five to 10 min after stimulation, neurons were fixed for 10 min with PFA-sucrose at 4 °C and rinsed several times with PBS. Coverslips were then preincubated in 0.1% Triton, 3% goat serum, PBS for 1 h at room temperature and incubated over-
GABA<sub>A</sub> Receptor Activity Triggers Ca<sup>2+</sup>-dependent BDNF Release

night with mouse anti-CREB (1:1000), rabbit anti-phospho-CREB (pCREB; 1:1000; both from Cell Signaling Technology), and chicken anti-MAP2 (1:2000) antibodies. Immunoreactivities for pCREB, CREB, and MAP2 were visualized and analyzed as described above using the laser scanning confocal microscope (Zeiss LSM 510 Meta). The optical sections were digitized (1024 × 1024 pixels) and processed using ImageJ software. For analysis of the intensity of pCREB staining in neuronal cells, we first created a binary mask from MAP2-positive cells and then analyzed pCREB intensity only in regions overlapping the binary mask. Acquisition parameters were the same for every set of experiments. The pCREB to CREB intensity ratio was expressed as the mean ratio of the pCREB-Alexa Fluor 488/CREB-Alexa Fluor 555 staining intensity. All data were expressed as percentage of control values obtained from sister non-stimulated cultures.

**Determination of GABA<sub>A</sub> Receptor Cell Surface Levels Using ELISA**—Changes in surface and total levels of GABA<sub>A</sub>Rs were analyzed using a cell surface ELISA as described previously (38, 51). Cortical neurons were cultured in 24-well plates at a density of 60,000 cells/cm<sup>2</sup> for 6 DIV. Following treatments, cultures were fixed using PFA-sucrose for 10 min. After washing with Hanks’ balanced salt solution (Invitrogen) and blocking with Hanks’ balanced salt solution/1% BSA/10% rabbit serum for 30 min, cultures were incubated with anti-GABA<sub>A</sub> R<sub>β2/3</sub> antibody (2 μg/ml; MAB341, bd17 clone, Millipore). In those cultures where total levels of GABA<sub>A</sub> R<sub>β2/3</sub>-subunits were evaluated, cells were permeabilized using Hanks’ balanced salt solution/0.5% Triton/1% BSA/10% rabbit serum for 30 min prior to the addition of the primary antibody. Cultures were extensively washed and incubated with a rabbit anti-mouse IgG conjugated to horseradish peroxidase (HRP; 1:5000; Pierce) followed by the addition of 3,3,5,5-tetramethylbenzidine (Sigma-Aldrich). Absorbance was read at λ = 655 nm using a spectrophotometer (Duo 800, Beckman Coulter). Controls lacking the primary antibody were routinely used to determine background levels of peroxidase and the nonspecific binding of the secondary antibody.

**Cell Surface Biotinylation, Endocytosis, and Recycling Assays**—Biotinylation assays were performed as described previously (38, 52). Cultured neurons (6 DIV) were treated, and cell surface proteins were biotinylated using sulfo-NHS-SS-biotin (1 mg/ml; Pierce) at 4 °C. Cells were lysed, and biotinylated proteins were precipitated using UltraLink Immobilized NeutrAvidin biotin-binding protein (Pierce) and resolved by SDS-PAGE. The amount of biotinylated GABA<sub>A</sub> receptor β<sub>2/3</sub>-subunit was determined by quantitative immunoblotting with a β<sub>2/3</sub>-specific antibody (0.5 μg/ml; Phosphosolutions) followed by 125<sup>I</sup>-coupled anti-rabbit IgG (Amersham Biosciences) and subsequent analysis using a phosphorimaging system (Bio-Rad). In endocytosis assays, plasma membrane proteins were first biotinylated using sulfo-NHS-SS biotin at 4 °C and then incubated in the absence (control) or presence of BDNF for 15 or 30 min at 37 °C. In recycling assays, cell surface proteins were first biotinylated using sulfo-NHS-SS biotin and incubated at 37 °C for 30 min to allow the endocytosis to occur. After removing the residual biotin from the cell surface with the reduced glutathione at 4 °C (first cleavage), cells were incubated in the absence (control) or presence of BDNF for 15 or 30 min at 37 °C to allow reinsertion of endocytosed receptors followed by a second round of biotin cleavage from the cell surface with the reduced glutathione. Cells were subsequently lysed, and biotinylated proteins were analyzed as described above. The amount of endocytosed and reinserted GABA<sub>A</sub> R<sub>β3</sub> was calculated as described previously (53).

**Metabolic Labeling**—Cultures were incubated in methionine-free DMEM containing 0.8 mCi of [35S]methionine (PerkinElmer Life Sciences) for 12–14 h followed by lysis in phosphate buffer (PB; 10 mM Na<sub>2</sub>PO<sub>4</sub> pH 7.4, 5 mM EDTA, 5 mM EGTA, 100 mM NaCl, 10 mM sodium pyrophosphate, 50 mM NaF) containing protease inhibitors (100 μM PMSF, 10 μg/ml aprotonin, 10 μg/ml leupeptin, and 1% SDS). SDS was neutralized by 5 volumes of ice-cold PB containing 2% Nonidet P-40 followed by incubation with nonspecific IgG or GABA<sub>A</sub> R<sub>β2</sub>,<sub>3</sub>,<sub>3</sub>-specific antibody (10 μg/ml kindly provided by Prof. W. Sieghart, Centre for Brain Research, Vienna, Austria). Immunoprecipitates were analyzed by SDS-PAGE and visualized using a phosphorimaging system.

**Statistical Analysis**—If not stated otherwise, all population data are expressed as mean ± S.E. A paired Student’s t test was used to determine statistical significance between groups in ELISA experiments, and an unpaired Student’s t test was used to examine the statistical significance of the differences between groups in microscopy analysis; an analysis of variance was used for multiple comparisons. Significantly different values (*, p < 0.05; **, p < 0.001) are indicated by asterisks in figures.

**RESULTS**

**Cell Surface Expression of GABA<sub>A</sub>Rs Is Increased upon Their Activation in Developing Cerebrocortical Neurons**—Disassociative embryonic cerebrocortical tissue forms a heterogenous population of neurons in vitro, the majority of which are glutamatergic, pyramidal-like neurons that are immunopositive for V-Glut and MAP2. These cells also exhibit a diffuse GABA<sub>A</sub>R immunolabeling at the cell surface with sporadic cluster-like accumulations (Fig. 1A, Ctrl). To investigate whether the activity of GABA<sub>A</sub>Rs affects their stability at the cell surface, we used immunocytochemistry and cell surface ELISAs using an antibody specific for the extracellular domain of the GABA<sub>A</sub> R<sub>β2/3</sub>-subunits (MAB314, bd17). At 5 DIV, cerebrocortical cultures were incubated overnight with TTX (0.5 μM) to reduce the spontaneous activity of these neurons. This treatment was followed by the addition of the GABA<sub>A</sub>R agonist muscimol (50 μM) for 10 min. Immunocytochemistry using the GABA<sub>A</sub> R<sub>β2/3</sub>-specific antibody in combination with anti-V-Glut and anti-MAP2 antibodies allowed a semiquantitative analysis of the GABA<sub>A</sub> R levels at the surface of glutamatergic neurons (see “Experimental Procedures”) in which the GABA<sub>A</sub> R<sub>β2/3</sub>/MAP2 ratio and the average intensity were quantified. GABA<sub>A</sub> R<sub>β2/3</sub> cell surface expression in the region of soma and proximal dendrites of these neurons was estimated in control conditions (25 ± 7% surface ratio, n = 24; Fig. 1, A and B). The application of muscimol resulted in a significant increase of GABA<sub>A</sub> R<sub>β2/3</sub> surface levels (153 ± 21%, p < 0.001 compared with control, n = 26; Fig. 1, A and B, Musc), and this effect was abolished in
GABA<sub>A</sub> Receptor Activity Triggers Ca<sup>2+</sup>-dependent BDNF Release

**FIGURE 1.** Muscimol-dependent activation of GABA<sub>A</sub>Rs leads to increase in cell surface expression of these receptors in developing glutamatergic cerebrocortical neurons. A, cultured neurons (6 DIV) in control conditions (Ctrl) or treated with muscimol (Musc) or muscimol plus bicuculline (Musc + bic) immunolabeled with GABA<sub>A</sub>R β<sub>2,3</sub>-specific mouse monoclonal antibody (MAB 314, bd17) to reveal expression at the cell surface (left panel; green) and, following permeabilization, immunolabeled with anti-VGlut guinea pig antibody (middle panel; blue) and anti-MAP2 rabbit polyclonal antibody (right panel; red) to reveal the intracellular distribution of these proteins. The right panels were obtained by merging GABA<sub>A</sub>R β<sub>2,3</sub>-immunolabeled neurons (Ctrl, Musc, Musc + bic) or treated with muscimol (50 μM; 10 min; Musc) or muscimol plus bicuculline (10 μM; 10 min; Musc + bic) in comparison with the vehicle-treated control (Ctrl) is shown. Means ± S.E. are given (n = 25; 2 independent experiments; Student’s t test). B, cell surface levels of GABA<sub>A</sub>Rs measured using ELISA with GABA<sub>A</sub>R β<sub>2,3</sub> subunit-specific antibody demonstrated that the increase in GABA<sub>A</sub>R surface levels was prevented by the application of nifedipine (Fig. 2). C, the effect of muscimol was abolished in the presence of bicuculline (10 μM), indicating that GABA<sub>A</sub>Rs were involved in this process (Fig. 2, A and B).

To determine whether the expression of GABA<sub>A</sub>Rs could, in turn, regulate the Ca<sup>2+</sup>-dependent secretion of BDNF, GFP-tagged BDNF was expressed in cultured cerebrocortical neurons (50, 55). In the vicinity of neurons expressing BDNF-GFP (Fig. 3, A–D, green), the addition of muscimol (50 μM; 10 min) resulted in an increase in immunolabeled extracellular GFP-BDNF (Fig. 3C, red), reflecting an increase in BDNF release. The quantification of this labeling demonstrated that the effect of muscimol was significant (n = 11 cells per condition, 3 independent experiments, p < 0.001 compared with control; Fig. 3E, Musc). This effect was prevented by the addition of bicuculline (10 μM; Fig. 3, D and E, Musc + bic). In the presence of TTX (0.5 μM), a significant reduction in the release of BDNF-GFP was observed (Fig. 3, B and E, TTX; p < 0.001), indicating that the release of BDNF-GFP is also regulated by the spontaneous activity of neurons.

To determine whether GABA<sub>A</sub>R activation can trigger secretion of the endogenous BDNF, we used an indirect approach based on an increase in BDNF/TrkB/ERK-dependent pCREB (50, 56). We therefore tested whether the addition of muscimol (50 μM; 10 min) induces an increase in pCREB immunoreactivity in MAP2-positive neurons (Fig. 4A). Cortical neuronal cul-
GABA<sub>A</sub> Receptor Activity Triggers Ca<sup>2+</sup>-dependent BDNF Release

(A) Representative immunocytochemistry images showing the intracellular BDNF-GFP fluorescence (green) and secreted BDNF-GFP detected using anti-GFP antibody (red) under non-permeable conditions in vehicle-treated controls (Ctrl) and in the presence of TTX, muscimol (50 μM), or muscimol plus bicuculline (10 μM). (B) Quantitative analysis of BDNF-GFP signal bound to the cell surface and overlapping (yellow) with the signal from BDNF-GFP-expressing neurons (green) in vehicle-treated controls (Ctrl) and in the presence of TTX, muscimol (50 μM), or muscimol plus bicuculline (10 μM). Error bars represent standard error of the mean.

**FIGURE 2.** GABA<sub>A</sub>-R-dependent increase in [Ca<sup>2+</sup>]<sub>i</sub> is required for increase in cell surface expression. A, representative images of labeled cells (left) and average change in fluorescence (ΔF/F) produced by bath application of GABA (50 μM) alone or GABA plus bicuculline (50 μM; GABA + bic) (right). B, graph showing the maximum change in fluorescence in the presence of GABA (ΔF/F; GABA) alone or GABA plus bicuculline (ΔF/F; GABA + bic). Means ± S.E. are given (n = 3; **, p < 0.001; Student’s paired t test). C and D, cell surface levels of GABA<sub>A</sub>Rs measured using ELISA with GABA<sub>A</sub>-R<sub>β2</sub> subunit-specific antibody in cultured cortical neurons treated with muscimol (50 μM; 10 min; Musc) or in the presence of L-type VGCC blocker nifedipine (10 μM; 10 min; Musc + Nifedipine) (C) or muscimol alone (50 μM; 10 min; Musc) or in the presence of D-APV and CNQX (10 μM; 10 min; Musc + D-APV + CNQX) (D) and expressed as the percentage of vehicle-treated controls. Means ± S.E. are given (n = 4; **, p < 0.001; Student’s paired t test), n.s., not significant; Ctrl, control. Error bars represent standard error of the mean.

Important points:
- GABA<sub>A</sub> receptor activity triggers Ca<sup>2+</sup>-dependent BDNF release.
- GABA<sub>A</sub>-R-dependent increase in [Ca<sup>2+</sup>]<sub>i</sub> is required for increase in cell surface expression.
- GABA<sub>A</sub>-R-dependent Release of Endogenous BDNF Leads to Increase in Cell Surface Expression—To investigate whether endogenous BDNF, released in response to GABA<sub>A</sub>-R activation, can, in turn, regulate their cell surface levels, we performed immunocytochemistry and cell surface ELISAs in cultures treated with muscimol (50 μM) in the absence or presence of TrkB-IgG. The observed increase in the cell surface staining ratio, GABA<sub>A</sub>-R<sub>β2</sub>/MAP2 (153 ± 21% increase in surface ratio, p < 0.001 compared with control, n = 26; Fig. 5, A and B, Musc), was abolished by TrkB-IgG (2 μg/ml; 109 ± 17%, p < 0.05 compared with muscimol alone, n = 21; Fig. 5, A and B, Musc + bic).

**FIGURE 3.** GABA<sub>A</sub>-R activation triggers secretion of BDNF-GFP. A–D (top), superimposed images showing the intracellular BDNF-GFP fluorescence (green) and secreted BDNF-GFP detected using anti-GFP antibody (red) under non-permeable conditions in vehicle-treated controls (Ctrl) (A), in the presence of TTX (0.5 μM) (B), in the presence of muscimol (50 μM; Musc) alone (C), or in the presence of muscimol plus bicuculline (10 μM; Musc + bic) (D). E (bottom), quantitative analysis of BDNF-GFP signal bound to the cell surface and overlapping (yellow) with the signal from BDNF-GFP-expressing neurons (green) in vehicle-treated controls (Ctrl) or TTX-, muscimol (Musc), or muscimol + bicuculline (Musc + bic)-treated cultures. Means ± S.E. are given (total of 11 cells analyzed per treatment in n = 3 independent experiments; **, p < 0.001; Student’s independent t test), n.s., not significant. Error bars represent standard error of the mean.
**GABA<sub>A</sub> Receptor Activity Triggers Ca<sup>2+</sup>-dependent BDNF Release**

**FIGURE 4.** GABA<sub>A</sub>R activation induces BDNF/TrkB-dependent phosphorylation of CREB. A, immunofluorescence of CREB (left panels; red) and pCREB (middle panels; green) in cortical neurons in control conditions (Ctrl) or treated with muscimol alone (50 μM; Musc), muscimol plus TrkB-IgG (2 μg/ml; Musc + TrkB IgG), or muscimol plus bicuculline (10 μM; Musc + bic). Merged images with MAP2 staining (blue) are shown on the right. Scale bar, 20 μm. B, average pCREB/CREB ratio in four different conditions. Means ± S.E. are given (total of 12–17 cells analyzed per treatment in n = 3 independent experiments; ***, p < 0.001; Student’s independent t test). Error bars represent standard error of the mean.

Musc + TrkB IgG) and was mimicked by the addition of the exogenous BDNF (100 ng/ml; 157 ± 26% increase in surface ratio, p < 0.001 compared with control, n = 20; Fig. 5, A and B, BDNF). The increase in the average intensity of cell surface labeling in the presence of muscimol was also prevented by the addition of TrkB-IgG to the medium (97 ± 10% of control, p > 0.05) and mimicked by the addition of the exogenous BDNF (120 ± 8%, p < 0.05 compared with control; Fig. 5C).

In cell surface ELISA experiments, the increase in surface levels of GABA<sub>A</sub>R β<sub>2,3</sub>-subunit in response to muscimol (141 ± 19% of control unstimulated cultures, p < 0.01, n = 4) was also prevented by TrkB-IgG (2 μg/ml TrkB; 86 ± 13% of control non-stimulated cultures, p < 0.05, n = 4) and mimicked by the exogenous BDNF (100 ng/ml; 131 ± 22% of control non-stimulated cultures, p < 0.001, n = 4; Fig. 5D). No difference was observed in the total levels of GABA<sub>A</sub>R β<sub>2,3</sub>-subunits between control and treated cultures (data not shown).

**FIGURE 5.** GABA<sub>A</sub>R-dependent release of endogenous BDNF mediates increase in cell surface expression. A, cultured cerebrocortical neurons (6 DIV) in control conditions (Ctrl) or treated with muscimol in the absence (Musc) or presence of TrkB-IgG (Musc + TrkB-IgG) or with the exogenous BDNF (100 ng/ml). Neurons were immunolabeled with GABA<sub>A</sub>R β<sub>2,3</sub>-subunit-specific mouse monoclonal antibody (MAB 314, bd17) (left panel; green) to reveal expression at the cell surface and, following permeabilization, immunolabeled with anti-VGlut guinea pig antibody (middle panel; blue) or anti-MAP2 rabbit polyclonal antibody (right panel; red) to reveal the intracellular distribution of these proteins. The right panels were obtained by merging GABA<sub>A</sub>R β<sub>2,3</sub>, VGlut, and MAP2 labeling. Scale bar, 20 μm. The quantification of the surface GABA<sub>A</sub>R β<sub>2,3</sub>/intracellular MAP2 fluorescence ratio (B) and the average intensity of GABA<sub>A</sub>R β<sub>2,3</sub> fluorescence (C) at the surface of VGlut-positive neurons treated with vehicle (Ctrl), muscimol alone (50 μM; 10 min; Musc), with muscimol plus TrkB-IgG (10 μM; 10 min; Musc + TrkB IgG), or with the exogenous BDNF. Means ± S.E. are given (25 neurons were analyzed per condition per experiment; n = 3; **, p < 0.05; ***, p < 0.001; Student’s paired t test). D, cell surface levels of GABA<sub>A</sub>R<sub>s</sub> measured using ELISA with GABA<sub>A</sub>R β<sub>2,3</sub>-subunit specific antibody in neurons treated with muscimol alone (50 μM; 10 min; Musc), with muscimol plus TrkB-IgG (10 μM; 10 min; Musc + TrkB IgG), or with the exogenous BDNF (100 ng/ml) and expressed as a percentage of vehicle-treated controls. Means ± S.E. are given (n = 3; **, p < 0.001; Student’s paired t test). Error bars represent standard error of the mean.

BDNF-dependent Increase in Surface Levels of GABA<sub>A</sub>Rs Is Mediated by PKC and PI 3-Kinase Signaling Pathways—To investigate which of the three main signaling pathways activated downstream of TrkB receptors, the PKC, PI 3-kinase, or ERK 1/2 pathway, mediates the effects of BDNF on GABA<sub>A</sub>Rs, we carried out cell surface biotinylation and quantitative immunoblotting assays using a β<sub>2</sub>-subunit-specific antibody as this subunit was found to be significantly more abundant than the β<sub>3</sub>-subunit in our cultures (Fig. 6A).

We first confirmed that activation of TrkB receptors by BDNF (100 ng/ml; 132 ± 8% of control, n = 7, p < 0.01) or
neurotrophin-4/5 (100 ng/ml; 135/9% of control, n=5, p<0.01) causes a measurable increase in the surface expression of GABA\(_\text{A}\)Rs using this assay (Fig. 6B). This increase was insensitive to GABA\(_\text{A}\)R blockade with bicuculline (10 \(\mu\)M; BDNF alone: 119/3% of control; BDNF/bicuculline: 120/9% of control; Fig. 6C) as expected given that the effects of the exogenous BDNF do not depend on GABA\(_\text{A}\)R activation (Figs. 1 and 5).

The BDNF/TrkB-dependent increase in surface levels of GABA\(_\text{A}\)Rs (150/15% of control, n=5, p<0.05; Fig. 6D) was significantly attenuated by the PKC inhibitor calphostin C (0.5 \(\mu\)M; 126/20% of control, n=5, p<0.05; Fig. 6D) and the PI 3-kinase inhibitor LY 29402 (2 \(\mu\)M; 112/12% of control, n=5, p<0.01; Fig. 6D). However, it was unaffected by the presence of PD 98059 (135/24% of control, n=5, p>0.05; Fig. 6D), an inhibitor of ERK 1/2. Control experiments using the phosphorylation state-specific antibody for ERK 1/2 confirmed that the inhibitor was effective in blocking the activity of these kinases (data not shown).

BDNF Inhibits Endocytosis of GABA\(_\text{A}\)Rs but Has No Effect on Their Reinsertion—To define which steps in GABA\(_\text{A}\)R trafficking may be regulated by BDNF, we carried out the endocytosis and recycling assays using cell surface biotinylation approaches as described previously (53). In controls, 15/2% of the total surface GABA\(_\text{A}\)Rs was internalized within 30 min of incubation at 37 °C. Following incubation with BDNF (100 ng/ml), internalization of GABA\(_\text{A}\)Rs was decreased to 5/2% (Fig. 7, BDNF 15 min). In these experiments, we also monitored the endocytosis of the GluR1 subunit of AMPA receptors. We found that, albeit significantly more robust than GABA\(_\text{A}\)R endocytosis (42/6% of the total surface pool was endocytosed within 30 min), the endocytosis of GluR1 was not affected by BDNF (36/2% of the total surface pool was internalized within 30 min; data not shown).

In neurons, a significant pool of endocytosed GABA\(_\text{A}\)Rs is known to be targeted for reinsertion into the plasma membrane.
These receptors are expected to follow the same intracellular trafficking routes that mediate insertion of newly synthesized receptors (58). In our cultures (at 6 DIV), the reinsertion of endocytosed GABAARβ3-subunit into the plasma membrane was significant with 44% and 51% of the total endocytosed pool being reinserted within 15 and 30 min of incubation at 37 °C, respectively (Fig. 8, A and B). This process, however, was unaffected by the BDNF (Fig. 8, A and B). In parallel experiments, the amount of the reinserted AMPA receptor GluR1 subunit within 15 or 30 min of incubation at 37 °C was 58 ± 7 or 72 ± 2% of the total endocytosed pool, respectively. This process was also unaffected in the presence of BDNF (data not shown).

DISCUSSION

In the developing brain, GABA acts as a trophic factor to regulate multiple steps of neuronal differentiation (59, 60). This activity is primarily mediated by GABAARs, which generate depolarization of the plasma membrane and transient increases in the intracellular calcium (54, 61). Although demonstrably necessary, changes in intracellular calcium appear insufficiently long lasting to support these GABAAR-regulated developmental processes. This ultimately raises a question as to what could be the missing regulatory link operating in this system. Here we provide evidence that at least one such regulatory mechanism involves a positive feedback interaction between the depolarizing activity of GABAARs and the regulated pathway of BDNF secretion.

As schematically depicted in Fig. 9, we demonstrate that activation of GABAARs triggers the Ca2+-dependent BDNF release.
GABA<sub>A</sub> Receptor Activity Triggers Ca<sup>2+</sup>-dependent BDNF Release

![Diagram of GABA<sub>A</sub> and BDNF signaling](image)

Downstream signaling pathways mediated by PI 3-kinase and PKC. By inhibiting specifically GABA<sub>A</sub> R endocytosis, BDNF/TrkB-dependent signaling increases the responsiveness of developing neurons to GABA. However, we hypothesize that this mechanism may be limited by a number of processes, including desensitization of GABA<sub>A</sub> Rs (62), rundown of the chloride gradient due to prolonged activation of these receptors (1), limitations in the amount of BDNF available for release and/or the amount of TrkB receptors available to bind BDNF given that these receptors rapidly internalize upon activation (63, 64), etc.

Changes in the overall number or the surface density of GABA<sub>A</sub> Rs potently modulate the postsynaptic response to GABA (65). This may be particularly important for the developing brain, which lacks tight temporal and spatial control of GABA concentrations before the anatomically defined synapses (18, 19) and the GABA uptake mechanisms are established (20). Under these conditions, GABA is known to operate in a paracrine fashion (20). Embryonic GABA<sub>A</sub> Rs are adapted to such conditions functionally, showing a high affinity for GABA and slow desensitization (66, 67). This is also correlated with a specific repertoire of GABA<sub>A</sub> R subunits expressed at this stage with α<sub>3</sub>/β<sub>2</sub>/γ<sub>2</sub>-subunits being abundant in proliferating neuronal precursors (68, 69) and α<sub>5</sub>/β<sub>2</sub>/γ<sub>2</sub>-subunits being abundant in early differentiating neurons (66, 68, 70). Although mechanisms that regulate embryonic GABA<sub>A</sub> Rs are mostly unknown, it is evident that they can have a significant impact on many aspects of neuronal development known to be regulated by GABA.

BDNF is of particular interest in this regard as it is released in response to GABA<sub>A</sub> R activation, and in return, it is known to regulate the efficacy of transmission at GABAergic synapses (37, 38, 40–42, 44, 71) as well as GABAergic synaptogenesis both in vitro (73–77) and in vivo (46, 78, 79). The increase in cell surface expression of GABA<sub>A</sub> Rs at the postsynaptic membrane reported here may be particularly important during the formation of GABAergic synapses as the postsynaptic expression of GABA<sub>A</sub> Rs and their clustering are the key steps in this process (80). Conversely, the release of BDNF triggered by GABA<sub>A</sub> R activity can have pronounced effects on the presynaptic counterparts as both axonal growth and structural maturation of presynaptic nerve terminals are known to be regulated by BDNF (81). This is in an agreement with the previously published evidence that activity-dependent release of BDNF occurs predominantly from the postsynaptic sites (82).

As demonstrated here, an increase in cell surface expression of GABA<sub>A</sub> Rs results from the inhibition of the receptor endocytosis by BDNF and is mediated by the activation of the TrkB/PI 3-kinase/PKC signaling pathway. It is important to note that the same signaling pathway was found previously to mediate the BDNF-dependent increase in GABA<sub>A</sub> R phosphorylation at Ser-408/409 residues (38). Although phosphorylation of these residues has a positive effect on the gating properties of GABA<sub>A</sub> Rs (83), their dephosphorylation was shown to be directly responsible for a decrease in GABAergic currents in our previous study (38). In the same study, we have also reported an increase in cell surface expression of GABA<sub>A</sub> Rs by BDNF that was long lasting and therefore not correlative with a decrease in GABAergic currents. Thus, our findings described here are consistent with our previously published results. It is also well established that an increase in phosphorylation of Ser-408/409 inhibits the interaction between GABA<sub>A</sub> R subunits and the clathrin AP2 adaptor protein, which mediates the dynamin-dependent endocytosis of these receptors (84). Thus, the inhibition of the receptor endocytosis by BDNF reported here is likely to occur due to an increase in GABA<sub>A</sub> R phosphorylation (38) and subsequent inhibition of their interaction with the AP2 complex.

The BDNF-dependent increase in cell surface expression is specific for early developing neurons where GABA<sub>A</sub> R activation leads to a depolarization of the plasma membrane. In more mature neurons, BDNF appears to reduce the cell surface expression of GABA<sub>A</sub> Rs (40, 41). This shift in the regulation of GABA<sub>A</sub> R surface expression by BDNF (from an increase to a decrease) is accompanied by a shift in the GABA<sub>A</sub> R-dependent regulation of BDNF expression (from an increase to a decrease (85)) as well as its secretion. Importantly, these processes also coincide with the transition in the functional outcome of GABA<sub>A</sub> R activation (depolarization to hyperpolarization) and with the formation of GABAergic synapses (59). As GABA and BDNF are components of the positive feedback mechanism described here, it is possible that they in fact synergize to drive this transition. This may lead to an increase in the expression of the K<sup>+</sup>-Cl<sup>−</sup> cotransporter (KCC2) (12, 86). Consequently, later in development, a KCC2-driven decrease in [Cl<sup>−</sup>], and a shift in the reversal potential for GABAergic currents toward more hyperpolarized levels (15, 54, 87) would result in termination of Ca<sup>2+</sup>-dependent signaling downstream of GABA<sub>A</sub> Rs.

We hypothesize that the positive feedback mechanism operating between GABA<sub>A</sub> Rs and BDNF/TrkB may be restricted to those synapses that show the first signs of activity. By increasing the expression and accumulation of GABA<sub>A</sub> Rs at the postsynaptic sites, BDNF may stabilize these synapses and promote their functional maturation. Emphasizing the crucial role of GABA and BDNF in development, transgenic mouse models with genetic ablation of proteins involved in these signaling cascades display severe physiological and behavioral deficits, severe epi-
GABA<sub>A</sub> Receptor Activity Triggers Ca<sup>2+</sup>-dependent BDNF Release

lepsy, and abnormal neural activity or neonatal death (32, 88–90). As the brain develops further and GABA becomes hyperpolarizing, balancing the maturation of glutamatergic transmission, this feedback loop falls into abeyance. The control of BDNF release comes under the regulation of other signals and GABA<sub>A</sub>R expression, and clustering at the postsynaptic membrane comes under the control of transsynaptic and intracellular protein-protein interactions (72).

Acknowledgments—We thank Prof. Werner Sieghart for help in obtaining GABA<sub>A</sub>R subunit-specific antibodies and A. L. K. Sihra-Jovanovic for technical assistance.
