Abstract - We experimentally investigate shear thickening in dense granular suspensions under oscillatory shear. Directly imaging the suspension-air interface, we observe dilation beyond a critical strain $\gamma_c$ and the end of shear thickening as the maximum confining stress is reached and the contact line moves. Analyzing the shear profile, we extract the viscosity contributions due to hydrodynamics $\eta_h$, dilation $\eta_d$ and sedimentation $\eta_s$. While $\eta_h$ governs the shear thinning regime, $\eta_d$ and $\eta_s$ together determine the shear thickening behavior. As the suspending liquid’s viscosity varies from 10 to 1000 cSt, $\eta_s$ is found to compete with $\eta_h$ and soften the discontinuous nature of shear thickening.

Introduction. – Dense suspensions can increase their viscosity under rapid shear; i.e., they exhibit shear thickening (ST) [1–11]. To understand the origin of this ST transition, several mechanisms have been proposed. A hydro-cluster picture ascribes mild, continuous thickening to particle groups formed by viscous hydrodynamic interactions [12–14]. Dense granular suspensions can exhibit a much stronger shear thickening, so that the viscosity can increase discontinuously with the shear rate as a critical packing fraction is approached [15–17]. Recent works have related this to frictional particle interactions and dilation [2,3,18,19], similar to dry granular materials. In this scenario, the Laplace pressure due to surface tension at the suspension-air interface keeps the suspension contained. Since granular systems prefer to dilate when made to flow, the normal stress and, subsequently, the friction between suspension and shear plate dramatically increases beyond a certain applied stress. Thus, the measured flow resistance shoots up as long as dilation is counteracted by confinement.

In this granular mechanism, the frictional stress between solid particles is the dominant contributor to ST. The suspending liquid mainly acts as a boundary constraint to prevent expansion. Nevertheless, viscous hydrodynamic interactions, as another dissipation mechanism, still exist in the bulk [4,8,9], and lubrication and viscous drag could become significant when the suspending liquid is highly viscous. So far, however, an experimental characterization of how the hydrodynamics couples with dilation and affects the shear thickening of nearly jammed granular suspensions has been lacking.

In this letter, we address this issue by investigating dense granular suspensions across a wide range of suspending liquid viscosities. The suspended particles are chosen to be sedimenting so that the friction between particles can provide a known scaling for the onset stress of shear thickening [5]. To finely control the relative displacement between particles, oscillatory shear with controlled amplitude is applied to the samples. Measuring both global rheology and local shear profile, we quantitatively extract the contributions from viscous hydrodynamics, confinement (“frustrated dilation”) and sedimentation to the measured flow resistance.

Experimental setup and protocol. – Dense granular suspensions were prepared by adding ZrO$_2$ particles ($\rho_{ZrO_2} = 3.92$ g/ml, 200 ± 10 $\mu$m) and glass beads ($\rho_{glass} = 2.55$ g/ml, 22±5 $\mu$m) to silicone oils, with packing fraction $\phi \approx 54–55\%$. The particles were too large to exhibit measurable Brownian motion. Rheological measurements were performed in an Anton Paar rheometer with a 25 mm diameter parallel-plate geometry allowing us to conveniently access the global normal force. The gap size $d$ was varied from 1 to 2 mm. The top plate was set to apply a sinusoidal strain, $\gamma = \gamma_0 \sin(\omega t)$, to the sample. We fit the measured shear stress to an oscillating waveform...
to obtain its the amplitude $\tau_0$ [20–22]. The magnitude of the complex viscosity is defined as $|\eta^*| = \eta_0/(\omega \gamma_0)$, the ratio of shear stress amplitude to applied strain rate. Before each measurement, the sample was pre-sheared to ensure repeatability. We used Vision Research Phantom V9 cameras with a macro lens (Nikon Micro 105 mm) to capture the dilation process. The frame rate was kept at 300 fps with spatial resolution $\sim 12 \mu m/\text{pixel}$. The samples were illuminated from the front by two white-light sources (12 V/200 W, Dedolight).

Rheology. – We first focus on a ZrO$_2$ suspension with oil viscosity of 350 cSt. The rheology is quantified by ramping the strain amplitude $\gamma_0$ while keeping $\omega$ fixed in each round of measurement (fig. 1). At the beginning of a ramp, $|\eta^*|$ decreases with $\gamma_0$, that is, the samples shear-thin. Beyond a critical strain $\gamma_c \approx 0.50$, $|\eta^*|$ starts to increase with $\gamma_0$, indicating shear thickening. Our oscillatory measurements show that shear thickening will not occur until two neighboring particles experience relative displacement $\Delta r_c$. As previously observed by Fall et al. [23], the value of $\gamma_c$ does not change with $\omega$. To rule out slip [24], we performed the tests varying gap size and plate roughness (with a sand paper). No shift of $\gamma_c$ was observed.

Fig. 1: (Color online) Rheological characterization of the viscosity $|\eta^*|$ as a function of the applied oscillatory strain amplitude $\gamma_0$ for (a) ZrO$_2$ particles (200 $\mu$m) in 350 cSt silicone oil and (b) glass spheres (22 $\mu$m) in 100 cSt silicone oil at different oscillation frequencies $\omega$. Shear thickening starts at $\gamma_c \approx 0.50$ (a), and $\gamma_c \approx 0.22$ (b), independently of $\omega$. Inset: storage modulus $G'(\omega)$ vs. $\omega$ measured by fixing $\gamma_0$ at $\gamma_c$.

The onset of ST at $\gamma_c$ can be related to a stress scale. In oscillatory measurements, the onset stress is $\tau_{\min} = \omega \gamma_c |\eta^*|_{\gamma=\gamma_c}$. From each flow curve in fig. 1, we calculate $\tau_{\min}$ and find that the suspension has $\tau_{\min} \approx 0.75 \text{Pa}$, independently of $\omega$. At the same time, the elastic modulus $G'(\omega)$ stays around $G'_0 \approx 1.4 \text{ Pa}$ for $\omega$ from 0.1 to 10 rad/s (inset of fig. 1(a)). Since the measured loss modulus is much smaller ($\sim 0.1 \text{ Pa}$) in the same regime, the critical strain $\gamma_c$ is given by $\tau_{\min}/G'_0$ ($\approx 0.5$).

Qualitatively similar results were also found for suspensions of small glass beads (22 $\mu$m, see fig. 1(b)). A frequency-independent onset strain, $\gamma_c(\approx 0.22)$, is also measured, confirming that, while varying the relative ratio of the gap to a particle size from about one-hundred to ten, the shear thinning and thickening behaviors remain unchanged [25].

Imaging of the interface and shear profile. – To quantify the particle dynamics and confirm the occurrence of dilation in the suspensions, we image the liquid-air interface while the strain is ramped up. For these experiments, the ZrO$_2$ suspensions with their larger diameters were used in order to be able to track individual particles. The solid points in fig. 2(a) show the rheological curve at $\omega = 1 \text{ rad/s}$. Figures 2(b)–(e) present an image sequence of the interface evolution. At $\gamma_0 = 10.0$, particles are completely contained in the liquid and no protrusions are observed at the surface (see fig. 2(b)). As $\gamma_0$ approaches $\gamma_c \approx 0.50$, the shape of individual particles becomes visible (fig. 2(c)). The local deformation of the interface can also be seen from the change of image brightness.

The vertical red line in fig. 2 represents the initial position of the contact line between suspension and substrate. By tracking the outermost edge of suspension on the substrate, we plot the radial contact line position $h$ against
Shear thickening in highly viscous granular suspensions

Fig. 3: (Color online) Shear profile and stress scales. (a), (b): front-view images of 54% ZrO$_2$ (200 μm) in 350 cSt silicone oil at γ$_0$ = 1.0 and 8.0. (c) For the ZrO$_2$ suspension shown in fig. 2, the time-averaged velocity profiles $v/v_p$, normalized by the speed of the top plate, are plotted against the normalized depth $z/d$ for different γ$_0$. Here $z = 0$ corresponds to the top plate. The data points are obtained from PIV and the solid lines are fits to eqs. (2)–(4). (d) Shear (hollow squares) and normal stress (hollow triangles) amplitude together with the viscosity curves (solid circles).

γ$_0$ in fig. 2(a) (hollow circles). At γ$_0$ = 3.2, the edge has moved out about one particle diameter $a$ and $|η^*|$ starts to turn down (fig. 2(d)). Thus, shear thickening stops when a full particle has been pushed out. This implies that the maximum confining stress from surface tension has been reached [16]. As a result, at higher strains or shear rates, the suspension thins, i.e. $|η^*|$ decreases and approximately scales as $\sim 1/γ_0$. With continuing increase of γ$_0$, the bottom portion of the suspension is further expanded (fig. 2(e), γ$_0$ = 10.0). At the same time, the upper portion retracts as well (red arrow in fig. 2(e))$^1$. The reduction of contact area can provide up to 15% uncertainty to the viscosity beyond the peak point. Qualitatively similar results were found for the 22 μm glass spheres, although here we could not resolve individual particles.

To extract the shear profile, a second camera was placed right in front of the suspension. Figures 3(a) and (b) show typical images at $γ_0 = 1.0$ and 8.0. The bottom layers in (b) are out of focus due to the expansion. From the recorded videos, the time-averaged velocity fields are obtained by PIV (Particle Image Velocimetry). The resulting shear profile $v/v_p$ is plotted against $z/d$ for different γ$_0$ in fig. 3(c), where $v_p$ is the plate velocity and $z$ is the depth into the suspension, measured from the top. Before the onset of shear thickening, a shear band near the top plate is observed, extending a distance $d_s$. As γ$_0$ increases, the band gradually expands until spanning the entire gap ($d_s \sim d$ at $γ_0 \gtrapprox 0.5$). With continuing increase of γ$_0$, particles near the bottom are pushed out and form effectively static layers that no longer participate in shear ($γ_0 = 3.2$ and 10.0).

Result analysis. – In order to understand the evolution of the shear profile shown in fig. 3(c) quantitatively, a microscopic constitutive relation has to be considered that accounts for the local stresses in the suspension. Quite generally, the shear stress $τ_0$ contains contributions from hydrodynamic and inter-particle forces that could arise from a variety of sources [2,11]. For dense granular suspensions of hard, non-Brownian particles, the dominant inter-particle forces arise from direct, frictional contact [2–4,9,18]. Thus, given a local, $z$-dependent shear rate $γ_0(z)$,

$$τ_0 = η_0 γ_0(z) + τ_g z/d + τ_c(γ_0).$$  

Here, the first term represents the viscous hydrodynamic stress, contributing an amount $η_0$ to the measured overall viscosity, while the shear-rate–independent remainder reflects the inter-particle forces. We have split this remainder into two parts to separate out the frictional stresses originating from sedimentation ($τ_g$) due to gravity and frictional contacts ($τ_c$) due to shear [18].

The second term in eq. (1) scales linearly with $z$ due to gravity. To move the particles at the bottom layer ($z = d$), the required stress is at least $τ_g$. In a suspension of hard non-Brownian particles, $τ_g = μ_s Δρ g d/15.3$, where $μ_s$ is the friction coefficient ($\sim 0.8$ for ZrO$_2$), and gives the magnitude of the onset stress for our system [18]. The last term in eq. (1), $τ_c$, is written as a function of the global shear rate $γ_0 = ω γ_0$ but is independent of the local quantity $γ_0$. Therefore, by integrating $γ_0$ over $z$, we obtain the velocity profile:

$$v/v_p = \frac{τ_g}{2ω γ_0 η_0} \left(\frac{d_s - z}{d}\right)^2 \quad (d_s < d),$$  

$$v/v_p = \frac{(τ_0 - τ_g - ω γ_0 η_0)(d - z)}{ω γ_0 η_0 d} + \frac{τ_g}{2ω γ_0 η_0} \left(\frac{d - z}{d}\right)^2 \quad (d_s > d).$$  

Here, $d_s = (τ_0 - τ_g)/τ_g$ is the depth of the sheared layers and $η_0 = τ_c/(ω γ_0)$ indicates the contribution to the viscosity caused by dilation against confining boundaries. Equation (2) thus corresponds to shear banding and
correspond to the large-strain regime, where we directly calculate plotted in blue, red and green, respectively. The solid data points are obtained by the fit to eqs. (2) and (3). The open symbols correspond to the large-strain regime, where we directly calculate the suspending oil viscosity is changed. The shear thinning and sedimentation contributions from different viscosity components to \(|\eta^*|\) are from eq. (4) together with \(\eta_c = \mu_c \tau_{N0}/(\omega \gamma_0)\). As we compare the two procedures within the same range of 1.0 < \(\gamma_0 < 2.0\), the results from the fit and calculation consistently follow the same trend in the plot, suggesting that the assumption of frictional contacts and \(\tau_0 \approx \mu_c \tau_{N0}\) is reasonable. As shown in fig. 4(b), the increase of \(\eta_c\) is in general steeper than \(\eta_h\). During the ST transition (0.5 < \(\gamma_0 < 4.0\)), the ratio of \(\eta_c\) and \(\eta_h\) reaches a factor up to two, indicating that dilation is still a more important factor to shear thickening than the increase of hydrodynamic interactions.

In addition, we define \(\eta_g = |\eta^*| - \eta_c - \eta_h\) as the viscosity component due to sedimentation. Considering eq. (1), \(\eta_g\) can be written as

\[
\eta_g = \eta_h \left[ \frac{d(\nu/ \nu_p)}{d(z/d)} \bigg|_{z=0} - 1 \right].
\]

This term is determined by the slope of the shear profile near the top plate \((z = 0)\). In the presence of sedimentation, the shear profiles are non-linear. For very small \(\gamma_0\), the velocity gradient is significant at \(z = 0\) since the shear flow is localized within a very small layer of the suspension near the top plate. Therefore, \(\eta_g\) is sufficiently large to be dominant in this regime (green triangles). As \(\gamma_0\) increases, the flow region expands and the shear profile becomes less steep, such that \(\eta_g\) decreases and the system shear-thins until dilation and hydrodynamic effects set in.

Panels (a) and (c) in fig. 4 show the behavior if the suspending oil viscosity is changed. The shear thickening regime is always dominated by \(\eta_h\). Shear thickening, however, is determined by both \(\eta_c\) and \(\eta_h\). While \(\eta_c\) remains roughly the same, \(\eta_h\) changes substantially when varying the suspending liquid viscosity from 10 to 1000 cSt. For 10 cSt oil (fig. 4(a)), \(\eta_h \gg \eta_h\), which explains why ST in this regime can be described by frustrated dilation alone [4,8,18]. For 1000 cSt oil, on the other hand, \(\eta_h\) has increased about two orders of magnitude and we

Fig. 4: (Color online) The viscosity components due to hydrodynamics (\(\eta_h\)), dilation (\(\eta_c\)) and sedimentation (\(\eta_g\)) in the rheological measurement. While the black lines is the measured viscosity \(|\eta^*|\) recorded by the rheometer, \(\eta_h\), \(\eta_c\) and \(\eta_g\) are plotted in blue, red and green, respectively. The solid data points are obtained by the fit to eqs. (2) and (3). The open symbols were varied to be (a) 10 cSt, (b) 350 cSt and (c) 1000 cSt. The dashed lines indicate the Bagnoldian scaling: \(|\eta^*| \sim \gamma_0\).
have $\eta_h > \eta_c$ for the entire measurement range. Thus, in the highly viscous regime, hydrodynamics starts to play an important role in controlling ST.

Specifically, the increase in $\eta_h$ affects the steepness of the flow curve and softens the discontinuous nature of ST. For 10 cSt oil (fig. 4(a)), the slope in ST regime is steeper than the dashed lines, which represent the classical Bagnoldian scaling, $|\eta^*| \sim \gamma_0$ [7,9]. While increasing the oil viscosity to 1000 cSt (fig. 4(c)), for instance, ST is found to be weaker than the Bagnoldian scaling since $\eta_h$ becomes crucial but increases in a way less steep than $\eta_c$.

In the discussion above, even though we separate the measured viscosity into different factors, hydrodynamics ($\eta_h$), dilation ($\eta_d$) and sedimentation ($\eta_s$), it is important to realize that the frictional and viscous forces that contribute to these three components are mutually coupled [3,4]. Equation (5), for example, shows that the rheology associated with sedimentation ($\eta_s$) is coupled with viscous interactions ($\eta_h$) while the shear profile is non-linear. Besides that, from inspecting the data of $\eta_c$ in fig. 4, one can tell that, with the increase of solvent viscosity, the difference between the experimental data (red solid points) and direct calculation (red hollow data) becomes discernible. It suggests that the effective frictional coefficient between particles becomes smaller. Thus, strictly speaking, the effective frictional coefficient $\mu_e$ depends on $\eta_0$.

**Discussion.** – To track more systematically the effect of increasing the hydrodynamic contributions, we plot the ratio of $\eta_h$ to $\eta_c$ at the upper bound of the ST regime (where $|\eta^*|$ reaches the maximum), $(\eta_h/\eta_c)_{\text{max}}$, against the suspending oil viscosity, $\eta_0$, in fig. 5. While varying the particle size $a$ from 125 to 300 $\mu$m, the curves remain of the same shape. This independence from the particle size can be qualitatively explained as follows. The maximum dilational stress is balanced by the Laplace pressure over the local menisci at the suspension-air interface, and thus $\tau_c|_{\text{max}}$ approximately scales as $1/a$ [16]. Since the maximum strain amplitude within the ST regime, $\gamma_0|_{\text{max}}$, is also found to scale as $1/a$ (see fig. 5(b)), $\eta_c|_{\text{max}} = (\tau_c/\omega\gamma_0)|_{\text{max}}$ is independent of $a$. On the other hand, if the hydrodynamic viscosity is mainly due to lubrication, $\eta_h \sim \eta_0 a/\delta$, where $\delta$ is the inter-particle distance [12,27]. For a fully developed thickening flow, $a/\delta$ is a function of the packing fraction, such that $\eta_h$ is also independent of $a$. As a result, $(\eta_h/\eta_c)|_{\text{max}}$ does not vary with the particle size.

Physically, the plot in fig. 5 shows a crossover from a granular regime, where $\eta_c$ dominates the viscosity, to a hydrodynamic regime when $\eta_h$ dominates. Near $\eta_h \sim \eta_c$, the suspensions exhibit both granular and hydrodynamic characters.

**Conclusions.** – Under oscillatory shear, the ST onset in dense granular suspensions can be characterized by a critical strain $\gamma_c$ (fig. 1) that signals the onset of dilation against a confining interface. ST sets in as particles begin to protrude through the interface and stops when the contact line between suspension and substrate starts to move, reflecting that the maximum confining stress has been reached (fig. 2). Modeling the shear flow by a local constitutive relation, we quantified the contributions from different sources to the measured viscosity (figs. 3 and 4). With increasing viscosity of the suspending liquid, the hydrodynamic contributions can become sufficiently large so that they compete with the effects from frustrated dilation (fig. 5) and soften the discontinuous nature of ST in dense granular suspensions.
