Combination immunotherapy and active-specific tumor cell vaccination augments anti-cancer immunity in a mouse model of gastric cancer

Natasja K van den Engel††, Dominik Rüttinger††, Margareta Rusan1, Robert Kammerer2, Wolfgang Zimmermann3, Rudolf A Hatz1 and Hauke Winter1

Abstract

Background: Active-specific immunotherapy used as an adjuvant therapeutic strategy is rather unexplored for cancers with poorly characterized tumor antigens like gastric cancer. The aim of this study was to augment a therapeutic immune response to a low immunogenic tumor cell line derived from a spontaneous gastric tumor of a CEA424-SV40 large T antigen (CEA424-SV40 TAg) transgenic mouse.

Methods: Mice were treated with a lymphodepleting dose of cyclophosphamide prior to reconstitution with syngeneic spleen cells and vaccination with a whole tumor cell vaccine combined with GM-CSF (a treatment strategy abbreviated as LRAST). Anti-tumor activity to subcutaneous tumor challenge was examined in a prophylactic as well as a therapeutic setting and compared to corresponding controls.

Results: LRAST enhances tumor-specific T cell responses and efficiently inhibits growth of subsequent transplanted tumor cells. In addition, LRAST tended to slow down growth of established tumors. The improved anti-tumor immune response was accompanied by a transient decrease in the frequency and absolute number of CD4+CD25+FoxP3+ T cells (Tregs).

Conclusions: Our data support the concept that whole tumor cell vaccination in a lymphodepleted and reconstituted host in combination with GM-CSF induces therapeutic tumor-specific T cells. However, the long-term efficacy of the treatment may be dampened by the recurrence of Tregs. Strategies to counteract suppressive immune mechanisms are required to further evaluate this therapeutic vaccination protocol.

Background

Gastric cancer is a common disease in industrial countries and is associated with a poor prognosis. Over 50 percent of potentially curatively operated gastric cancer patients relapse within 5 years. Subsequent chemo- or radiation therapy is mostly insufficient [1]. Therefore, the development of new adjuvant treatments with a favorable "therapeutic index", (i.e., good tolerability and demonstrated anti-tumor activity), are desperately needed. Active-specific immunotherapy (i.e., therapeutic vaccination) may represent such an option.

Active-specific immunotherapy aims to improve the patient's ability to mount a therapeutic immune response against cancer. Nevertheless, inducing an immune response against the tumor is by itself not sufficient, and clinical results with cancer vaccines have been sobering [2], even though the first therapeutic vaccine based on autologous dendritic cells (DCs) called Provenge (sipuleucel-T, Dendreon Corp., Seattle, WA, USA) was recently approved for the treatment of hormone refractory prostate cancer [3]. Few vaccination studies in patients with gastric cancer have been published, which demonstrated antibody responses or peptide-specific IFN-γ responses and cytotoxicity by isolated cytotoxic T cells, but did not show strong clinical responses [4-6].

To increase the frequency of circulating tumor-specific T cells is likely to be one important minimal
requirement for a successful therapy [7]. To obtain sufficient expansion of such lymphocytes, several therapeutic strategies have been adopted, including prior lymphodepleting, non-myeloablative chemotherapy with cyclophosphamide followed by reconstitution of the lymphocyte pool by infusion of autologous immune cells [8-10]. Lymphopenia naturally induces a proliferative response to maintain homeostasis [11,12]. This stimulates antigen-specific T cells directed towards antigens contained in the tumor vaccine. In preclinical models of melanoma, this strategy increased the frequency of tumor-specific T cells in tumor vaccine-draining lymph nodes (TVDLN) extensively and enhanced the therapeutic efficacy of active-specific and adoptive immunotherapy strategies [13-15]. In addition to lymphopenia-induced proliferation, the elimination of regulatory T cells (Treg) and the creation of a beneficial host microenvironment by affecting components of the innate immune system are alternatively proposed as immunomodulatory effects of preparative chemotherapy with e.g. cyclophosphamide [16-18].

A recently introduced strategy to increase the therapeutic efficacy of tumor vaccination is to combine different immunological approaches, i) applying multifaceted antigen vaccines to target a broad spectrum of tumor antigens, ii) providing co-stimulation, iii) reducing or eliminating suppressive immune cells, e.g. Tregs [7], and iv) blocking tumor-induced immune suppression mediated by e.g. TGF-β [19]. Such a multifactorial vaccination approach may be especially suitable for tumor entities that exhibit a low immunogenicity, as has been described for gastric cancer [20]. Only a few tumor-associated antigens, mostly so-called cancer testis antigens, have been identified to be expressed in gastric tumors [21-23], but this has not yet resulted in successful therapeutic approaches targeting these antigens [24].

In order to explore novel therapeutic vaccination strategies for gastric cancer, we have established cell lines from the spontaneously growing gastric tumors of CEA424-SV40 TAg transgenic mice (C57BL/6-1g(CEACAM5-Tag) L5496Wzm) [25,26]. The MCA 310 fibro sarcoma cell line was kindly provided by Dr. B.A. Fox (Portland, OR). Gastric cancer cell lines were cultured in RPMI1640 supplemented with 10% fetal calf serum (FCS “Gold”; PAA Laboratories, Coelbe, Germany), 2 mM L-glutamine, non-essential amino acids and 1 mM sodium pyruvate (Invitrogen, Karlsruhe, Germany). For culturing MCA 310 tumor cells and in vitro assays, the medium was supplemented with 10% FCS from Invitrogen (complete medium, CM).

**Tumor cell vaccination (prophylactic/therapeutic), LRAST**

To determine the immunogenicity of the tumor cells, 10^7 tumor cells were irradiated with 10,000 rad and subcutaneously injected into mice. Two weeks later, the mice were challenged by subcutaneous injection of 3 x 10^6 viable tumor cells into the opposite flank. Experimental groups generally consisted of 5 mice. Tumor development was followed by serial measurements of the tumor diameter and is depicted as tumor size (mm^2) = d x D, where d and D were the shortest and the longest tumor diameter, respectively. Animals were euthanized when D reached 10 mm. Lymphopenia was induced by i.p. injection of cyclophosphamide (Cytoxan, 200 mg/kg; Baxter, Halle, Germany). This dose was chosen since earlier studies have shown an increased proliferation and long-term survival of antigen-specific T cells at this dose of cyclophosphamide, alone or in combination with fludarabine [18,27]. After 24 h, mice were reconstituted with 2 x 10^7 naive syngeneic splenocytes followed by s.c. vaccination with irradiated mGC8 cells (10^7, 10,000 rad) with or without a s.c. injection of GM-
Freund and emulsified with an equal volume of incomplete Freund’s adjuvant (IFA; Sigma-Aldrich, Taufkirchen, Germany) as described elsewhere [28], to induce an active-specific immune response. Naïve, non-lymphopenic mice served as control. In order to treat established s.c. tumors (therapeutic setting), viable mGC8 cells (10⁶) were injected 4 days before vaccination and tumor vaccinations were repeated every two weeks for a total of 4 vaccinations.

**In vitro T cell activation and expansion**

For T cell analyses, mice were vaccinated by s.c. injection with 1.2 × 10⁷ live mGC8 tumor cells on four sites, near the extremities (3 × 10⁶ per injection). Where indicated, lymphodepletion and reconstitution were performed as described above and GM-CSF/IFA was applied at all four vaccine sites (0.25 µg per injection). TVDLNs were harvested nine days after vaccination and lymph node cells were polyclonally activated with an anti-CD3 monoclonal antibody (mAb; 5 µg/ml, 2C11, kindly provided by Dr. H.M. Hu, Portland, OR) for 2 days at 2 × 10⁶ cells/ml in CM in 24-well plates. Subsequently cells were expanded at 2 × 10⁶ cells/ml in CM supplemented with 60 IU/ml of interleukin-2 (IL-2, Proleukin, Chiron, Ratingen, Germany) for 4 days. After 4 days, cytokine release assays were performed as described elsewhere [29] with the following modifications: T cells (10⁶ cells) were washed and cultured alone or stimulated with tumor cells (0.2 × 10⁶ cells), or immobilized anti-CD3 antibody in 1 ml of CM supplemented with gentamycin (Lonza, Cologne, Germany) and 60 IU IL-2/ml in a 48-well tissue culture plate at 37°C, 5% CO₂ for 18 h. The tumor targets included the tumor cell line used for vaccination (mGC8) and a related gastric tumor cell line (424GC). An unrelated, syngeneic tumor cell line (MCA 310) served as a negative control. Supernatants were analyzed by ELISA. TAg-specific peptides T1 and T2 were previously described [30] and added in a final concentration of 10 µg/ml.

**Cell-mediated cytotoxicity assay**

Cell-mediated lysis was determined using standard 4-h ⁵¹Cr-release assays [31]. Cryopreserved TVDLN cells were thawed, stimulated with anti-CD3 for 2 days and IL-2 for 4 days according to the protocol used for the cytokine release assay. Na₂⁵¹CrO₄ (NEN, Boston, MA)-labeled target cells (2000 per well) were incubated with stimulated effector cells for 4 hours at indicated effector-to-target cell ratios in complete medium in round bottom 96-well tissue culture plates. Spontaneous release was determined by incubating target cells alone; total release was determined by directly counting labeled cells. Percentage cytotoxicity was calculated as follows: percentage specific lysis = [experimental counts per minutes (cpm) - spontaneous cpm/total cpm - spontaneous cpm] × 100. Duplicate measurements were done in all experiments.

**ELISA**

For capture and detection of IFN-γ in supernatants by conventional sandwich ELISA, we used mAb R4-6A2 and biotinylated mAb XMG1.2, respectively (BD Biosciences, Heidelberg, Germany). Anti-IL-5 antibodies were purchased from R&D Systems (Wiesbaden-Nordenstadt, Germany). Supernatants were analyzed in duplicate. Extinction was analyzed at 405/490 nm on a TECAN microplate ELISA reader (TECAN, Crailsheim, Germany) with the EasyWin software (TECAN). The detection limit of the ELISA for IFN-γ was 125 pg/ml.

**White blood cell count**

To determine the degree of lymphopenia induced by cyclophosphamide treatment, 10 µl of blood were drawn from the tail vein into heparinized capillaries at different time points. The blood was diluted 1:10 in Türk’s solution (Merck, Darmstadt, Germany) and the white blood cells (WBC) were counted using light-microscopy.

**Flow cytometry**

For surface staining cells were washed with PBS and suspended in PBS supplemented with 0.5% (w/v) bovine serum albumin (BSA) and 0.02% (w/v) sodium azide. Non-specific binding of antibodies to Fc receptors was blocked by preincubation of the cells with rat anti-mouse CD16/CD32 monoclonal antibody 2.4G2 (1 µg/10⁶ cells, BD Biosciences) for 15 min. Subsequently the cells were incubated with the mAb of interest for 30 min at 4°C, washed and analyzed using a FACScan (BD Biosciences). Dead cells were excluded by propidium iodide staining. Collected data were analyzed using the Cell Quest Pro software (Version 4.0.2). The following reagents and mAbs against murine antigens from BD Biosciences were used: phycoerythrin (PE)-conjugated anti-mouse CD11b, PE-conjugated anti-mouse CD4, PE-conjugated anti-mouse CD8 and fluorescein isothiocyanate (FITC)-conjugated anti-mouse Gr1 mAb (RB6-8C5; Ly-6G, Ly6C). Allophycocyanin (APC)-conjugated anti-mouse CD25 mAb was obtained from Invitrogen. For staining of intracellular Foxp3, a FITC-conjugated antibody and buffers were purchased from eBiosciences (San Diego, CA, USA) and staining was performed according to the manufacturer’s instructions.

**Statistical analysis**

Survival curves for tumor-free survival were plotted according to the Kaplan-Meier method and were
compared using the log-rank test. Cytokine responses are presented as mean +/- SE. They were analyzed using a one way analysis of variance (ANOVA) with a Newman-Keuls post hoc test. Tumor sizes were analyzed using the Mann-Whitney-U test. Differences in expression of cellular markers as measured by flow cytometry were compared using the Student’s t test. Statistical analyses were performed using GraphPad Prism software. For all analyses, p values below 0.05 were considered to be significant.

**Results**

**Active-specific tumor cell vaccination alone mostly fails to induce a protective immune response**

To study novel strategies for immunotherapy of gastric cancer, we previously established the gastric cancer cell lines mGC8 and 424GC from CEA424-SV40 TAg-transgenic C57BL/6 mice [25]. These cell lines express epithelial cell markers and form tumors in 100% of mice when transplanted subcutaneously (s.c.) at 300,000 cells per injection into C57BL/6 mice [25]. To test the immunogenicity of the cell lines, C57BL/6 mice were vaccinated s.c. with $10^7$ irradiated mGC8 cells and challenged two weeks later with a single s.c injection of $3 \times 10^6$ live mGC8 cells. In the majority of the immunized mice, tumor growth progressed similar to the control group (Figure 1A). Only four of fifteen (27%) vaccinated mice were completely protected against a subsequent tumor challenge during the observation period of 55 days (Figure 1B). None of the control mice without vaccination was protected and their s.c. tumors were detectable within 20 days after tumor challenge.

![Figure 1](http://www.translational-medicine.com/content/9/1/140)
In further experiments, we tested the potential of the mGC8 vaccine to induce cross-protection against the syngeneic gastric tumor 424GC. One of ten vaccinated mice (10%) was protected after challenge with live 424GC cells, indicating some cross-reactivity between these tumor cell lines (Figure 1C). In contrast, vaccination with irradiated 424GC cells failed to induce protection against challenge with 424GC cells (Figure 1D). However, a delay in tumor growth was observed in 50% of the mice. Based on these data we concluded that the cell line mGC8 does exhibit low immunogenicity and we hypothesized that under optimized conditions mGC8 may have the potential to induce a protective immune response.

**LRAST enhances anti-tumor immunity induced by tumor cell vaccination resulting in a long-term protection against s.c. tumor challenge**

To optimize therapeutic efficacy of the mGC8 tumor cell vaccine we administered the vaccine during lymphopenia-induced T cell proliferation combined with GM-CSF to stimulate local antigen presentation. First, we determined whether cyclophosphamide (200 mg/kg, i.p.) followed by reconstitution with syngeneic splenocytes (LP) had the desired effect on white blood cell depletion and recovery. A single i.p. injection of cyclophosphamide caused lymphopenia in the peripheral blood within one day. The lymphopenia was obvious until day 4, confirming the findings in peripheral blood and spleens in other studies [16,32]. Peripheral leukocyte cell numbers recovered within 9 days (Additional file 1, Figure S1). The tumor vaccine was applied early in the immune recovery phase in order to create optimal conditions for the induction of a systemic immune response against tumor antigens during homeostatic proliferation.

To further enhance the induction of tumor-specific T cells, vaccines are generally combined with adjuvants like GM-CSF, KLH or CpG [33-36]. Gene-modified tumor cells that continuously secrete low levels of GM-CSF have been successfully used to generate effective immune responses [37,38]. In order to mimic the continuous GM-CSF secretion without the necessity to genetically modify the tumor cells, we mixed GM-CSF with IFA to get a creamy emulsion. This emulsion was injected s.c., adjacent to the vaccine site. To investigate the impact of lymphopenia driven proliferation, we compared s.c. tumor growth in mice after vaccination with either mGC8 alone or mGC8 combined with an injection of GM-CSF in IFA, or the latter vaccination following treatment with cyclophosphamide and reconstitution with naïve splenocytes (LRAST, Figure 2A). Although vaccination with mGC8 GM-CSF/IFA without lymphodepletion seemed to delay s.c. tumor growth when compared to the mGC8 vaccination alone, the overall protective effect was low with 3 of 5 and 4 of 5 mice developing s.c. tumors within 50 days, respectively (Figure 2B). In contrast, induction of lymphopenia followed by reconstitution with naïve splenocytes and mGC8 vaccination in the presence of GM-CSF (LRAST) clearly improved the protective effect of the vaccination with only one of five mice developing a s.c. tumor (Figure 2B). In contrast, lymphodepletion, reconstitution and GM-CSF/IFA alone without tumor vaccination was not protective since all mice developed a s.c. tumor (Figure 2B). The percentage of tumor-free mice was significantly increased in the LRAST group (80%) as compared to the group vaccinated with mGC8 alone (20%), \( p = 0.045 \) (Figure 2C). The tumor-free survival of mice treated with mGC8 GM-CSF/IFA was significantly enhanced compared to LP GM-CSF/IFA-treated mice (\( p = 0.045 \)), indicating the necessity of the tumor cells in the LRAST treatment.

In order to determine whether the protected (tumor-free) mice had developed a systemic, long-term anti-tumor immunity, we injected live mGC8 tumor cells into the flank opposite to the first tumor injection site at day 60. Only mice treated with LRAST (2 out of 3) showed complete protection during the observation period of 3 months after the rechallenge (66%, Figure 2D), suggesting the induction of a long-term protective immune response in these mice. Tumor-free mice of the treatment groups without lymphodepletion developed s.c. tumors within 12 days after rechallenge, which was comparable to the tumor development in control mice that had not been vaccinated (Figure 2D).

**Increased tumor-specific IFN-\( \gamma \) release and cell-mediated cytotoxicity by tumor vaccine-draining lymph node (TVDLN) cells after vaccination with mGC8 cells and GM-CSF/IFA**

We hypothesized that the mice in the LRAST group would harbor more tumor-specific T cells in their tumor vaccine-draining lymph nodes as compared to mice treated with the mGC8 vaccine alone. To compare the effect of the different treatment strategies on the generation of tumor-specific T cells, TVDLN cells were isolated nine days after vaccination (Figure 2A) and analyzed in a cytokine release assay. While cytokine responses after restimulation with the syngeneic unrelated tumor cell line MCA 310 were low, all vaccinated mice showed release of IFN-\( \gamma \), but not IL-5 after restimulation with mGC8 and 424GC tumor cells (Figure 3A and not shown, respectively). Addition of IFA to the mGC8 vaccine did not change the tumor-specific IFN-\( \gamma \) release of the TVDLN cells, however, lymphodepletion tended to increase tumor-specific IFN-\( \gamma \) release (Figure 3A). Significant increase of IFN-\( \gamma \) secretion was detected in the group that was vaccinated.
with mGC8 GM-CSF/IFA compared with the control group that was vaccinated with mGC8 alone, the group vaccinated with mGC8 IFA as well as the lymphodepleted group that was vaccinated with mGC8 IFA \( (p < 0.05) \), but not compared with the LRAST-treated group \( \text{LP mGC8 GM-CSF/IFA} \). Hence, GM-CSF seemed to be the main factor that caused significant enhancement of the tumor-specific immune response induced by the tumor vaccine. However, GM-CSF alone could not improve the mGC8 vaccine to induce a significant and durable protective antitumor immune response \textit{in vivo} (Figure 2D).

To determine whether the tumor-specific IFN-\(\gamma\) release mainly resulted from a response to the TAg, which is a foreign protein in C57BL/6 mice, we restimulated TVLN from mice vaccinated with mGC8 with the TAg-specific peptides T1 and T2. IFN-\(\gamma\) release by TVLN cells restimulated with T1 or T2 was not above the levels produced by non-stimulated or MCA 310-stimulated cells and was therefore not tumor specific (Figure 3B).

From three groups, isolated TVLN cells were abundant and could be cryopreserved to test for cytotoxicity at a later time point. Cells from mGC8 IFA-treated
mice demonstrated non-specific lysis since cytotoxicity occurred in mGC8 cells and MCA310 cells to a similar level (Figure 3C). In contrast, LN cells from mGC8 GM-CSF/IFA-treated mice induced specific lysis of mGC8 cells at an E:T ratio of 500:1 and 250:1. The specific lysis of mGC8 cells by LN cells from LRAST-treated mice at an E:T ratio of 500:1 did not appear to be significantly different from that of MCA310 cells in a repeated experiment. Thus, the cytotoxicity data confirm the results of the IFN-γ release assay in that cells from mGC8 GM-CSF/IFA-treated mice show the highest secretion of IFN-γ and the highest specific lysis.

**LRAST potentially also impacts tumor growth of established s.c. tumors**

After identifying LRAST as an effective treatment to protect against s.c. growing gastric tumors (prophylactic setting), we determined the efficacy of this strategy against the growth of 3-days established s.c. tumors (therapeutic setting, Figure 4A). In the LRAST-treated group, two of five mice showed a clear delay in s.c. tumor development (Figure 4B). In the group treated without cyclophosphamide (mGC8, GM-CSF/IFA) all tumors developed without delay (Figure 4C). Similar tumor growth was seen in the no treatment control (Figure 4D). Thus, although the mean growth of the s.c. tumors was not significantly different between the treatment groups, LRAST tended to delay tumor growth of established s.c. tumors (Figure 4E). Since the mGC8 tumor cells originate from gastric tumors, which developed spontaneously in CEA424-SV40 TAg-transgenic mice, we tested in a pilot experiment whether our vaccination strategy inhibits the spontaneous development of these gastric tumors and thus affects the survival of the transgenic mice. Treatment was started when the mice were 8 weeks of age (n = 6).
and weight loss was used as a surrogate marker for the development of the gastric tumor. Mice rapidly lost weight between 95 and 105 days of age and we detected no difference between vaccinated mice and untreated controls (data not shown).

The efficacy of LRAST is accompanied by a decrease of Tregs. Several publications report on a decrease in regulatory T cells in spleens and lymph nodes (defined as CD4+ CD25+ cells) and subsequent enhancement of the anti-tumor
response when including cyclophosphamide in an immu-
notherapeutic strategy [16,17]. We analyzed splenocytes
from mice in the LRAST group and in the group treated
with mGC8 GM-CSF/IFA without lymphodepletion for
the presence of CD4+ CD25+ FoxP3+ cells (referred to as
Tregs). All mice had 3-days established s.c. tumors at
treatment start and were analyzed at day 9 after tumor
challenge (Figure 4A). Spleen cells from LRAST mice
revealed a 2-fold decrease in the frequency of CD4+ CD25+
FoxP3+ cells compared with vaccinated mice without
lymphodepletion (Figure 5A). Similarly, the absolute
number of CD4+ CD25+ FoxP3+ cells was significantly
lower in LRAST mice (Figure 5B). As a consequence the
ratio of CD8+ T cells to CD4+ CD25+ FoxP3+ Tregs and
the ratio of CD4+ non-Tregs to CD4+ CD25+ FoxP3+ Tregs were increased in LRAST-treated mice (Figure 5C
and 5D). The decrease of Tregs appeared to be transient
since analysis of splenocytes two months after therapy
start showed an increased frequency of CD4+ CD25+
FoxP3+ Tregs in LRAST-treated mice similar to the fre-
quency detected in mGC8 GM-CSF/IFA-treated mice and
control mice without vaccination (data not shown).

![Figure 5](image-url)
As has been published before, cyclophosphamide treatment can lead to an increase in Gr1+CD11b+ myeloid-derived suppressor-like cells (MDSC) in the spleen [18]. We detected a more than 10-fold increase in the frequency Gr1+CD11b+ cells in LRAST mice compared with mGC8 GM-CSF/IFA-treated mice at day 9 after vaccination, but they decreased to similar frequencies as in control mice without vaccination at two months after start of the treatment (data not shown).

**Discussion**

Several reports have shown that active-specific tumor vaccination administered to a lymphopenic host may result in significantly enhanced anti-tumor immune responses [8,13]. Meanwhile, this study design has been translated into early phase clinical trials for several tumor entities [7,9]. However, there are neither preclinical nor clinical studies that address this therapeutic strategy in gastric cancer. The goal of active-specific tumor vaccination is to induce a systemic tumor-specific immune response especially against low- or non-immunogenic tumors. The aim of this study was to increase the therapeutic efficacy of a vaccination with the low immunogenic gastric tumor cell line mGC8. Consistent with previous reports on other tumor entities [8,15,39], we demonstrate here for the first time that the treatment with cyclophosphamide prior to tumor vaccination in the presence of GM-CSF can efficiently induce long-term protection against subcutaneous tumor growth in a gastric cancer model.

In earlier publications, tumor cell lines genetically modified to secrete GM-CSF or other immunostimulatory cytokines were compared with regard to their effectiveness as a cancer vaccine [37,40]. GM-CSF-secreting tumor vaccines appeared to be most potent to induce long-lasting tumor-specific immunity and have been used in clinical studies [41,42]. Due to the presence of GM-CSF at the vaccine site, antigen-presenting cells (APC) are recruited, activated and capable of activating tumor-specific T cells in the vaccine-draining lymph nodes [33,37]. A future aim of our immunotherapeutic approaches is to use autologous tumor samples for vaccination instead of cell lines. Since gene transfer into freshly derived tumor cells is laborious and may not be very efficient [43], we aimed to apply GM-CSF separately to the tumor cells. The easiest way to do this would be the co-administration of recombinant GM-CSF to the irradiated tumor cells. However, this would require frequent applications of the cytokine due to its short half-life in vivo [44], and would probably yield less potent anti-tumor responses compared to GM-CSF secreting cells [33,45]. Approaches that encapsulate or modify GM-CSF to provide sustained release locally at the vaccine site have been shown to result in anti-tumor immune responses comparable to that of GM-CSF-secreting tumor cells [44,46]. In addition, emulsions with IFA have been described to induce a strong and long-term immune response and were suggested to be stable for a few weeks [47,48]. Therefore, emulsified GM-CSF in IFA and we applied the emulsion subcutaneously at the vaccine site in order to enhance the immune response. Indeed, we found that application of emulsified GM-CSF, but not IFA alone, during vaccination increased the induction of tumor-specific T cells as measured by tumor-specific IFN-γ release from TVDLN cells. In addition, mice vaccinated with irradiated tumor cells in the presence of GM-CSF/IFA showed a significant enhancement of tumor-free survival as compared to lymphodepleted mice treated with GM-CSF/IFA without the tumor vaccine. This indicates the necessity of the presence of tumor antigens for successful LRAST treatment.

While low doses of GM-CSF as an adjuvant have been described to increase vaccine-induced immune responses (reviewed in [49]), in our model the induction of a long-term therapeutic immune response in vivo resulted only from the combination of cyclophosphamide treatment with GM-CSF application and not from GM-CSF alone. This emphasizes the expected potency of lymphodepletion applied prior to vaccination to enhance the therapeutic efficacy of a vaccination.

Unexpectedly, application of cyclophosphamide and reconstitution with naive syngeneic splenocytes prior to the tumor vaccination with GM-CSF (LRAST) did not further increase but rather tended to decrease the tumor-specific immune response in vivo as determined by tumor-specific IFN-γ secretion and specific lysis of mGC8 tumor cells by TVDLN cells. This discrepancy between in vitro and in vivo observations may in part be explained by the fact that significantly less T cells could be recovered from TVDLN following LRAST as compared to TVDLN from other treatment groups. It is conceivable that the remaining LN cells may be more sensitive towards further handling than LN cells that were not affected by cyclophosphamide and that therefore the results do not reflect in vivo CTL activity in our setting. On the other hand, the in vivo CTL response may be influenced by other mechanisms, e.g. Treg, which do not necessarily have an inhibitory effect when studying CTL activity in vitro. Since the mGC8 GM-CSF/IFA-treated group shows a higher number of Treg than the LRAST group, it is conceivable the in vivo anti-tumor response is suppressed in the former group.

At least two mechanisms have been proposed for the positive effect of cyclophosphamide pre-treatment on tumor vaccination: (i) increased homeostatic expansion of antigen-specific T cells in a lymphopenic...
environment and (ii) depletion of regulatory T cells. We addressed the first mechanism by analyzing the tumor-specific cytokine release in T cells isolated from TVDLN 9 days after vaccination. TVDLN cells from LRAST-treated and LP mGC8 IFA-treated mice tended to secrete increased levels of tumor-specific IFN-γ compared with TVDLN cells from control mice. Considering the enhancement of anti-tumor immunity after the LRAST treatment, one may anticipate that an augmented secretion of IFN-γ reflects an increase in the number of tumor-specific T cells in the LRAST-treated mice. However, alternatively an increase in cytokine expression per cell may have occurred as well. A preliminary ELISpot analysis suggested that TVDLN from LRAST-treated mice had both a larger number of IFN-γ producing cells and released more tumor specific IFN-γ per cell as compared to control mice (not shown).

Several studies have reported on a depletion of Tregs as another mechanism to explain the beneficial effect of cyclophosphamide treatment [8,16-18]. Tregs are known to efficiently down-modulate immune responses and depletion of these cells has been shown to enhance the anti-tumor immune response in various tumor models [50,51]. Consistent with other reports, we observed a rapid decline in white blood cells one day after a single i.p. application of cyclophosphamide and a gradual recovery of the cell numbers during the following week [32]. Although the absolute numbers of lymphocytes in the peripheral blood normalized after 9 days (Additional file 1, Figure S1), the frequency and the absolute number of FoxP3+ CD25+ CD4+ Treg cells were decreased in the spleen of LRAST-treated mice as compared to vaccinated mice without lymphodepletion (Figure 5A and 5B). This is consistent with previous findings that describe a transient reduction of Tregs in the spleens of mice in the first 10 days after cyclophosphamide (100 mg/kg) treatment [16]. In that study, in addition to a reduction of CD4+ CD25+ cells after cyclophosphamide treatment, a loss of FoxP3 and GITR gene expression as well as a reduction of Treg function was reported. In our experiments, the decline in the number of Tregs, the increase in the ratio of CD8+ T cells to FoxP3+ CD25+ CD4+ Tregs and the lymphopenic environment after cyclophosphamide treatment favor enhanced priming of tumor-specific immune responses during vaccination. This is consistent with the efficacy of the LRAST treatment against s.c. tumor growth in vivo (Figure 2). The precise role of Treg in the induction of anti-tumor immunity is subject of planned investigations in our laboratory and will be analyzed by depletion of Treg from the cell population used for reconstitution as well as by adoptive transfer of Treg after cyclophosphamide treatment.

In the experiments using a therapeutic setting we aimed to boost the tumor-specific immune response by giving repeated vaccinations. Although some mice in the LRAST group showed benefit by displaying a delayed tumor growth, the mean growth was not significantly different from the group without cyclophosphamide treatment. We observed that approximately two months after LRAST treatment, the proportion of FoxP3+ CD25+ CD4+ T cells had increased again to the frequencies of the other treatment groups without lymphodepletion. Thus, it seems that an initial decrease in Tregs after vaccination was followed by a secondary “induction” of Tregs. Interestingly, we also observed higher numbers of FoxP3+ CD25+ CD4+ T cells in mice that showed a long-term protective response after LRAST (data not shown). Therefore, we assume that a later increase of Tregs does not necessarily affect the anticancer effect of the treatment. It remains to be determined whether late appearance of Tregs actually has an impact on the therapeutic efficacy of the overall anti-tumor response. A recent study reported that the use of multiple vaccinations had a negative effect on the generation of therapeutic effector T cells [52]. The authors showed that multiple vaccinations increased the absolute number of CD4+ Foxp3+ Tregs in the peripheral blood and in the spleens, which decreased the therapeutic efficacy of splenocytes when adoptively transferred into tumor-bearing mice. In support of these results, we have recently observed that repeated vaccination with irradiated autologous tumor vaccines did not maintain a long-term reduction of Foxp3+ Tregs in the peripheral blood of non-small cell lung cancer patients after lymphodepleting chemotherapy (Van den Engel et al., manuscript in preparation).

Consistent with a previous report [18], we detected high numbers of CD11b+Gr1+ cells in the spleen 9 days after pretreatment with cyclophosphamide. This increase in Gr1+CD11b+ cells in cyclophosphamide-treated mice suggests the presence of myeloid-derived suppressor cells that could limit the immune response, as has been suggested in several reports [53,54]. In contrast, other reports suggest a beneficial effect through inhibition of tumor growth by the MDSC [18,55]. It remains to be determined whether these cells have inhibitory influence on the immune response that is elicited by LRAST.

Recently, a related s.c. gastric cancer mouse model was used to test the therapeutic efficacy of a dendritic cell vaccine loaded with irradiated gastric tumor cells in combination with CpG oligonucleotides [56]. In that study, tumor cells from the cell line mGC3 were used as the antigen source in the DC vaccine. The cell lines mGC3 and mGC8 were established from CEA424-SV40 TAg tumors and both cell lines display similar expression levels of epithelial cell surface markers, MHC class I molecules and the large-T antigen [25], which suggests that they may exhibit comparable therapeutic potential. Indeed, prophylactic vaccination with the DC vaccine...
improved survival in wild type mice injected with mGC3 tumor cells and caused long-term protection, similarly to our results with LRAST using the cell line mGC8. However, neither active immunization using the DC tumor cell vaccine nor adoptive transfer of tumor-reactive splenocytes did change survival of transgenic CEA424-SV40 TAg mice developing spontaneous gastric tumors, suggesting immunological tolerance toward multiple tumor-associated epitopes in these mice [56]. Correspondingly, we did not see a survival benefit in CEA424-SV40 TAg mice treated with LRAST in a pilot experiment (not shown). Therefore, we support the view that developing an immunotherapy, which is clinically effective in these transgenic mice will be challenging and will require additional immune-activating approaches, for example by inactivating cells that suppress immune responses.

Conclusions

Our data show that induction of lymphopenia, followed by reconstitution with naïve spleen cells and GM-CSF application during vaccination leads to a sustained protection against gastric tumors. We observed that this approach (LRAST) increases the systemic anti-tumor immune response and initially reduces the number of FoxP3+CD25+CD4+ Tregs. Induction of regulatory cellular mechanisms like MDSC and recurrence of Tregs may, in turn, dampen the therapeutic efficacy of LRAST on the long term. Modulation or depletion of the suppressive cell populations may be a promising way to further improve the therapeutic strategy of LRAST.

Additional material

Additional file 1: Figure S1 Changes in WBC count after induction of lymphopenia with cyclophosphamide. Mice were treated with cyclophosphamide at day 0 (200 mg/kg, i.p.). After 24 h, mice were reconstituted with $2 \times 10^7$ naive syngeneic splenocytes. The control group did neither receive cyclophosphamide nor splenocytes. WBC were counted at day 0, 1 (before reconstitution), 4 and 9; n = 5 per group. *p < 0.05, using Student’s t-test.

List of abbreviations

LRAST: lymphopenia, reconstitution and active-specific tumor cell vaccination; GM-CSF: granulocyte macrophage colony-stimulating factor; IFN: incomplete Freund’s adjuvant; mAb: monoclonal antibody; DC: dendritic cell; LP: induction of lymphopenia followed by reconstitution with spleen cells; Tregs: regulatory T cells; MDSC: myeloid-derived suppressor cells; TVDLN: tumor vaccine-draining lymph node.

Acknowledgements and Funding

The authors would like to thank Drs. B.A. Fox and H.-M. Hu for providing the control cell line MCA310 and the antibody 2C11 and Dr. E. Noessner for her help with the cytotoxicity assays. We thank Ilka Assmann for her assistance with the i.v. injections and Nina Schupp and Matthias Schiller for expert technical assistance. This work is part of the doctoral thesis of M.R.
