We consider a dipolar Bose-Einstein condensate trapped in an array of two-well systems with an arbitrary orientation of the dipoles relative to the system’s axis. The system can be built as a chain of local traps sliced into two parallel lattices by a repelling laser sheet. It is modelled by a pair of coupled discrete Gross-Pitaevskii equations, with dipole-dipole self- and cross-interactions. When the dipoles are not polarized perpendicular or parallel to the lattice, the cross-interaction is asymmetric, replacing the familiar symmetric two-component discrete solitons by two new species of cross-symmetric ones, viz., on-site- and off-site-centered solitons, which are strongly affected by the orientation of the dipoles and separation between the parallel lattices. A very narrow region of intermediate asymmetric discrete solitons is found at the boundary between the on- and off-site families. Two different types of solitons in the $\mathcal{PT}$-symmetric version of the system are constructed too, and stability areas are identified for them.

I. INTRODUCTION

Bose-Einstein condensates (BECs) composed of dipolar atoms and molecules is a broad research area in low-temperature physics. This type of BEC, dominated by anisotropic long-range magnetic or electric dipole-dipole interactions (DDIs), is significantly different from usual condensates, whose intrinsic dynamics is determined by “point-blank” inter-atomic collisions. Studies of dipolar BEC have produced a large number of specific experimental and theoretical results, which have been summarized in Refs. [1–3].

In addition to the fact that the atomic or molecular dipoles can be polarized by external dc electric or magnetic fields, the sign of the DDI can be switched by the ac rotating field [4]. These features lend dipolar BECs a great deal of tunability. In addition to the use of atoms or molecules carrying permanent magnetic or electric moments, condensates can be made of particles with dipole moments locally induced by the same dc fields which polarize the moments, the latter setting with spatially nonuniform fields being especially interesting [5]. These properties enhance the potential offered by dipolar BECs for fundamental and applied studies. One significant direction in these studies is the use of dipolar condensates for emulation of various phenomena which occur in a more complex form in other physical media, such as rotons [6], ferrofluidity [7, 8], Faraday waves [9], supersolids [10], anisotropic superfluidity [11], anisotropic collapse [12], mesoscopic droplets stabilized by quantum fluctuations [13], spin-orbit coupling in dipolar media [14], and others [15–18].

Another noteworthy ramification is the use of collective nonlinear modes in dipolar BEC for the creation of solitons in nonlocal media. This topic was originally introduced in optics, where nonlocal nonlinearities of other types occur [19, 20]. Various forms of bright [21], dark [22], vortex [23] and discrete [24] solitons were predicted in dipolar condensates. Recently, stable two-dimensional solitons were predicted in the dipolar BEC with spin-orbit coupling [25]. In addition to BEC, it was demonstrated that the DDI can create solitons in the ultracold bosonic gas of the Tonks-Gigardeau type [26].

A specific phenomenon which can be realized in dipolar BEC is the spontaneous symmetry breaking (SSB), and the related phase transition, alias the symmetry-breaking bifurcation, of modes created by such long-range anisotropic interactions. The SSB is a ubiquitous effect, which occurs in all areas of nonlinear physics [27]. Because the nonlinearity often creates solitons, a natural subject of the analysis is the SSB of solitons in symmetric systems. In particular, many theoretical and experimental results on this subject have been reported in photonic and matter-wave settings, where
the nonlinearity is an inherent feature, and symmetry is frequently provided by dual-core or double-well structures \[28\]. The SSB for solitons in systems with local nonlinearity has been studied in detail theoretically, [29]-[46], including discrete systems, which represent parallel arrays of coupled waveguides [47]. The study of the SSB for solitons in systems with nonlocal interactions is a problem of considerable interest too, as the nonlocality strongly affects the outcome of the competition between the nonlinear self-focusing of the fields and linear mixing between them, which leads to the SSB when the nonlinearity strength exceeds a critical value [28]. Thus far, only few works have addressed this topic. In particular, the SSB transformation of solitons in the dual-core coupler with nonlocal optical nonlinearity of the thermal type was considered in Ref. [48]. Unlike the optical systems, dipolar BEC features not only the intra-core nonlocal nonlinearity, but also the inter-core DDI, which makes the situation essentially different, as was first shown in the model for the effectively 1D dual-core coupler filled by the dipolar condensate [49]. In that work, different types of SSB, sub- and supercritical ones (i.e., symmetry-breaking phase transitions of the first and second kinds, respectively) were demonstrated, as the result of the competition of the DDIs with strong or weak hopping between the cores. However, the analysis was performed in Ref. [49] only for a single polarization of the dipoles, namely, along the cores. However, the external magnetic field can polarize the dipoles in any direction; once the dipoles are not parallel or perpendicular to the core, nonlocal cross-interaction induced by the DDIs becomes asymmetric, breaking the usual type of the solitons’ symmetry.

The aim of the present work is to explore what kind of symmetry may be featured by two-component discrete solitons for oblique orientation of the dipoles. We demonstrate that, unless the dipole moments are oriented strictly perpendicular or parallel to the system’s axis, the solitons’ shapes become uneven (spatially asymmetric), which makes it necessary to modify the definition of the symmetry between the soliton’s components, replacing it by cross-symmetry. Actually, two types of cross-symmetry are found for different sets of the system’s parameters, see Eqs. (9) and (11) below. To the best our knowledge, discrete solitons with such types of the symmetry were not studied before.

The rest of the paper is structured as follows. The two-component discrete model is introduced in Sec. II, and the cross-symmetry of solitons in it, controlled by the orientation of the dipoles, is studied in Sec. III. In Sec. IV, we introduce a further generalization of the system, by lending it the $PT$ symmetry (represented by spatially separated and mutually balanced gain and loss). The paper is concluded by Sec. V.

II. THE MODEL

We consider a chain of two-well systems, into which the dipolar BEC is loaded, as schematically shown in Fig. 1(a). It can be built as the usual quasi-one-dimensional (1D) lattice [50], split into a pair of parallel ones by an additional repulsive (blue-detuned) laser sheet. We consider configurations with different angles $\theta$ of the orientation of the dipoles with respect to the lattice, as shown in Fig. 1(b).

In the tight-binding approximation [51, 52], the mean-field dynamics of the condensate in this system is governed by the two-component discrete Gross-Pitaevskii equation for wave functions $\tilde{\psi}_n$ and $\tilde{\phi}_n$ of particles trapped in local
potential wells:

\[
\frac{id}{dt}\tilde{\psi}_n = -\frac{C}{2}(\tilde{\psi}_{n+1} + \tilde{\psi}_{n-1}) + \left[\sigma|\tilde{\psi}_n|^2 + \sum_{m \neq n} \left(F_{nm}|\tilde{\psi}_m|^2 + G_{nm}|\tilde{\phi}_m|^2\right)\right] \tilde{\psi}_n - J\tilde{\phi}_n,
\]

\[
\frac{id}{dt}\tilde{\phi}_n = -\frac{C}{2}(\tilde{\phi}_{n+1} + \tilde{\phi}_{n-1}) + \left[\sigma|\tilde{\phi}_n|^2 + \sum_{m \neq n} \left(F_{nm}|\tilde{\phi}_m|^2 + G_{nm}|\tilde{\psi}_m|^2\right)\right] \tilde{\phi}_n - J\tilde{\psi}_n. \tag{1}
\]

Here, \(C\) and \(J\) are, respectively, the coupling constants (determined by the respective hopping rates) along the lattice and between the parallel ones, \(\sigma\) is the strength of the contact nonlinearity, while \(F_{nm}\) and \(G_{nm}\) are DDI kernels, which account, severally, for the nonlocal self- and cross-interactions in the coupled Gross-Pitaevskii equations:

\[
F_{nm} = \begin{cases} 0, & (m = n) \\ (1 - 3 \cos^2 \theta)/|m - n|^3 & (m \neq n) \end{cases}, \tag{2}
\]

\[
G_{nm} = \begin{cases} (1 - 3 \sin^2 \theta)/D^3 & (m = n) \\ [1 - 3 \cos^2 \varphi_1]/[D^2 + (m - n)^2]^{3/2} & (m < n) \\ [1 - 3 \cos^2 \varphi_2]/[D^2 + (m - n)^2]^{3/2} & (m > n) \end{cases} \tag{3}
\]

where \(D\) is the scaled separation between the parallel lattices, \(\varphi_1 = \beta - \theta\), and \(\varphi_2 = \pi - (\beta + \theta)\) [see in Fig. 1(c)], with \(\beta \equiv \arccos\left|(m - n)/\sqrt{D^2 + (m - n)^2}\right|\). Recently, a similar configuration was considered as an Ising model with long-range interactions, which does not include the transverse hopping, i.e., with \(C = 0\).

Stationary states are looked for in the usual form,

\[
(\tilde{\psi}_n, \tilde{\phi}_n) = (\psi_n, \phi_n)e^{-i\mu t}, \tag{4}
\]

where \((\psi_n, \phi_n)\) are stationary wave functions, and \(\mu\) is a real chemical potential. Two-component solitons are characterized by their total norm,

\[
P = P_\psi + P_\phi \equiv \sum_{n=-N/2}^{n=N/2} \left(|\tilde{\psi}_n|^2 + |\tilde{\phi}_n|^2\right), \tag{5}
\]

which is a dynamical invariant of Eq. (1).

For \(\theta = 0\) or \(\pi/2\), matrix \(G_{nm}\) given by Eq. (3) is symmetric, with \(G_{nm} = G_{mn}\). When \(0 < \theta < \pi/2\), this property is broken, which makes nonlocal cross-interaction asymmetric, see Fig. 1(c). Obviously, at \(\theta = 0\) vertical (alias inter-lattice) interactions, i.e., the onsite DDI between condensate droplets trapped in the two potential wells belonging to the parallel lattices, is repulsive, while the horizontal DDI along each lattice is attractive. With the increase of \(\theta\), the vertical interaction vanishes at

\[
\theta_1 = \arcsin\left(1/\sqrt{3}\right) \approx 0.196\pi \approx 35.3^\circ, \tag{6}
\]

while the horizontal DDI remains attractive. Another special angle,

\[
\theta_2 = \arccos\left(1/\sqrt{3}\right) \approx 0.304\pi \approx 54.7^\circ, \tag{7}
\]

corresponds to the vanishing of the horizontal interaction, while the vertical DDI is attractive.

Obviously, at \(\theta = 0\) and \(\pi/2\), symmetric discrete solitons obey the spatial-symmetry condition,

\[
\phi_{-n} = \phi_n, \psi_{-n} = \psi_n. \tag{8}
\]

However, when \(\theta\) is different from 0 and \(\pi/2\), shapes of the two components are not spatially even because, as mentioned above, \(G_{nm}\) is not a symmetric matrix anymore. In the following section we introduce another type of symmetry which two-component discrete solitons may feature in this case. To the best of our knowledge, the asymmetric cross-interactions corresponding to asymmetric \(G_{nm}\) were not considered previously.
III. CROSS-SYMMETRIC SOLITONS

To focus on effects induced by the DDIs, we drop the contact nonlinearity in the system, by setting $\sigma = 0$ in Eq. (1), and assume equal horizontal and vertical hopping rates, scaling both to be unity: $C = J = 1$. The remaining control parameters are $P$, $D$, and $\theta$, i.e., the total norm of the solitons [see Eq. (5)], separation between the lattices, and the orientation of the dipoles, respectively. Here, we consider the case of $0 < \theta < \pi/2$, in which $G_{nm}$ is not symmetric, as said above.

The only feasible approach to the study of the present system may be based on numerical methods. Discrete solitons in models with nearest-neighbor interactions can be explored by means of a variational approximation [54]; however, it cannot be developed in an analytically tractable form for lattices with long-range interactions.

Figure 2 displays a typical example of a two-component discrete soliton, with $(P,D,\theta) = (3,0.4,0.196\pi)$, obtained numerically by means of the imaginary-time method [58–60]. The figure corroborates that the two components of the
soliton indeed do not obey symmetry conditions \[^5\]: nevertheless, they satisfy the definition of the cross-symmetry:

\[ \phi_n = \psi_{-n}, \psi_n = \phi_{-n}, \]

which is compatible with Eq. \[^1\] in the case of asymmetric cross-interaction matrix \( G_{nm} \). Note that locations of maxima of both components coincide in Fig. \[^2\].

It is relevant to stress that all the soliton families considered below, which may be characterized by the respective dependences \( \mu(P) \), satisfy the well-known Vakhitov-Kolokolov (VK) criterion \[^55\], \( d\mu/dP < 0 \) [a typical example of dependence \( \mu(P) \) is displayed in Fig. \[^3\](d)], which is a necessary condition for stability of solitons against small perturbations. While this criterion was originally established for solitons in continuum media \[^55\], its generalization for two-component discrete solitons is known too \[^56\]. In fact, the results reported below demonstrate that the VK criterion is sufficient for the stability of discrete solitons in the present system (except for its \( P\bar{T} \)-symmetric extension, which is introduced in Section IV). In this connection, it is relevant to mention that, although configurations with dipoles oriented perpendicular to the system’s direction tends to be the most stable one \[^57\], we here demonstrate that the discrete solitons with oblique orientations are stable too.

It follows from Eq. \[^3\] that cross-symmetric solitons have equal norms of the their components, \( P_\psi = P_\phi \). The cross-symmetry is quantified by the on-site mismatch between the components, defined as

\[ \Delta S = \frac{1}{P} \sum_{n=-N/2}^{N/2} \left| (|\psi_n|^2 - |\phi_n|^2) \right|. \]  

(10)

For usual symmetric solitons Eq. \[^10\] yields \( \Delta S = 0 \), as it follows from Eq. \[^8\]. A larger magnitude of \( \Delta S \) corresponds to a stronger mismatch between the two components.

The cross-symmetry may suffer spontaneous breaking, similar to the above-mentioned SSB phenomena. This effect will be signaled by emergence of soliton solutions with \( P_\psi \neq P_\phi \), and will be considered elsewhere.

To dependence of the cross-symmetry degree \[^10\] on the inter-lattice separation \( D \) and orientation \( \theta \) is displayed in Fig. \[^3\] which shows that \( \Delta S \) attains a maximum at finite values of \( D \) and \( \theta \). According to the figure, the cross-symmetry is well pronounced around the maximum, in parameter intervals \( 0.35 < D < 0.55 \) and \( 0.18\pi < \theta < 0.22\pi \). Further consideration of solitons in this area with the increase of the total norm reveals another variety of the cross-symmetry, different from that defined by Eq. \[^9\]. A typical example of the new variety is displayed in Fig. \[^4\]. Comparing it with the counterpart displayed above in Fig. \[^2\] we find that maxima of the two components are separated in Fig. \[^4\] by one lattice site, with the respectively modified cross-symmetry defined as

\[ \phi_n = \psi_{1-n}, \psi_n = \phi_{1-n}, \]

(11)

cf. Eq. \[^9\]. It is possible to say that cross-symmetry axes, corresponding to definitions \[^9\] and \[^11\], are set, severally, on-site and off-site (at the midpoint between two sites in the latter case), therefore we refer to these two varieties as on- and off-site cross-symmetries, respectively.

Existence areas of the cross-symmetric discrete solitons of these two types in the \( (P,D) \) and \( (P,\theta) \) planes are displayed in Fig. \[^5\] which shows that the off-site cross-symmetric solitons exist in finite areas [their boundaries are vertical in panels \[^5\](b-d) up to the accuracy of the numerical results]. Along the border between these areas, there is a very narrow band, shown as a gray strip, which is filled by discrete solitons of an intermediate type. They do not feature any explicit symmetry, except for the equality between the total norms of the two components, \( P_\psi = P_\phi \), see a typical example in Fig. \[^4\]. The asymmetric intermediate states account for a continuous transition between the cross-symmetric discrete solitons of the on- and off-site types, being as stable as their cross-symmetric counterparts are. The continuum of the transition is made evident in Fig. \[^5\](c) by the dependence of the cross-symmetry degree, \( \Delta S \) [defined by Eq. \[^10\] ], on the total norm, going across areas occupied by these three types of the discrete solitons.

We have also studied interaction between two cross-symmetric solitons, originally separated by distance \( \Delta n \). If \( \Delta n \) is smaller than a certain critical value, \( (\Delta n)_{cr} \), which corresponds to the boundary between green and read areas in Fig. \[^4\](a), the solitons with zero phase shift between them attract each other and merge into a single excited (oscillating) state, as shown in In Fig. \[^4\](b). At \( \Delta n > (\Delta n)_{cr} \), the pinning force from the underlying lattice is stronger than the attraction, and the solitons stay in the initial positions [see Fig. \[^7\](c)]. It is easy to understand why \( (\Delta n)_{cr} \) strongly grows with the decrease of \( P \), as seen in Fig. \[^7\](a): for small \( P \), the broad solitons are quasi-continuum modes, for which the force of pinning to the lattice is exponentially small \[^61\].

IV. TWO-COMPONENT DISCRETE SOLITONS IN THE SYSTEM WITH CROSS-\( \mathcal{P}\mathcal{T} \)-SYMMETRY

Theoretical studies of many linear- and nonlinear-wave systems may be naturally extended by adding the \( \mathcal{P}\mathcal{T} \)-symmetry, i.e., spatially symmetric distributions of globally balanced gain and loss terms \[^62\] \[^63\]. In particular,
FIG. 5: (Color online) Existence regions of stable discrete cross-symmetric discrete solitons of the on- and off-site are shown in parameter planes by red and yellow colors, respectively. In panel (a), orientation $\theta = 0.196\pi$ is fixed, and the off-site (yellow) area exists between $D = 0.1$ and $0.62$. The inset in (a) displays a zoom around $D = 0.4$, with the minuscule gray area representing the intermediate state. In panel (b), $D = 0.4$ is fixed. In the green region, asymmetric solitons are found. The off-site solitons exist in the region between $\theta = 0.177\pi$ and $0.206\pi$, which is displayed at a larger scale in panel (c). Panel (d) is a zoom of a very small gray area, where the intermediate solitons are found at $0.198\pi < \theta < 0.206\pi$.

FIG. 6: (Color online) A typical example of a stable asymmetric discrete soliton, intermediate between cross-symmetric ones of the on- and off-site types, for $(P, D, \theta) = (3.15, 0.4, 0.196\pi)$. Panels have the same meaning as in Figs. 2 and 4.

FIG. 7: (Color online) (a) In the green area of the plane of $(P, \Delta n)$, two in-phase solitons with identical powers $P$, separated by initial distance $\Delta n$, merge into a single excited mode [as shown in (b) for $P = 4, \Delta n = 8$], while in the red area the solitons stay put [see panel (c), for $P = 4, \Delta n = 16$]. Other parameters are $D = 0.4, \theta = 0.196\pi$. 
much interest has been drawn to solitons in $PT$-symmetric systems \cite{64}. In term of matter waves, the gain and loss represent symmetrically placed and mutually balanced sources and sinks of coherent atoms. Although the experimental realization of sources in BEC may not be easy, the theoretical analysis of BEC-$PT$ systems has attracted considerable interest, see, e.g., Refs. \cite{65,66}. In particular, a model applying the $PT$ symmetry to dipolar BEC trapped in a symmetric double potential well was proposed recently \cite{69}. In this section, we aim to develop the $PT$-symmetric version of the system based on Eq. (1), which, in particular, will provide, as far as it is known to us, the first example of a discrete $PT$-symmetric system with long-range interactions.

Thus, Eq. (1) is replaced by

$$i\frac{d}{dt}\tilde{\psi}_n = -\frac{C}{2}(\tilde{\psi}_{n+1} + \tilde{\psi}_{n-1}) + \left[\sigma|\tilde{\psi}_n|^2 + \sum_{m \neq n} \left(F_{nm}|	ilde{\psi}_m|^2 + G_{nm}|	ilde{\phi}_m|^2\right)\right]\tilde{\psi}_n - J\tilde{\phi}_n + i\kappa\tilde{\psi}_n,$$

$$i\frac{d}{dt}\tilde{\phi}_n = -\frac{C}{2}(\tilde{\phi}_{n+1} + \tilde{\phi}_{n-1}) + \left[\sigma|\tilde{\phi}_n|^2 + \sum_{m \neq n} \left(F_{nm}|	ilde{\phi}_m|^2 + G_{nm}|	ilde{\psi}_m|^2\right)\right]\tilde{\phi}_n - J\tilde{\psi}_n - i\kappa\tilde{\phi}_n. \quad (12)$$

where $\kappa > 0$ is the coefficient accounting for the gain and loss of atoms in the first and second components, respectively.

The continuum limit of Eq. (12), with dominant local nonlinearity, resembles known models of nonlinear $PT$-symmetric couplers, in which the $P$ transformation amounts to swapping the two coupled cores, one carrying gain and the other being lossy \cite{70,72}. In the general case of $0 < \theta < \pi/2$ considered in this work, which corresponds to the asymmetric interaction matrix $G_{nm}$, Eq. (12) realizes the cross-$PT$ symmetry, in the sense of the cross symmetry defined as Eq. (10) below. Because the latter definition is actually tantamount to the $P$ transformation along discrete coordinates $n$, Eq. (12) effectively defines a 2D $PT$-symmetric system (cf. the definition of $CPT$ symmetry proposed in Ref. \cite{64}).

In the continuous model of the $PT$-symmetric coupler with cubic intra-core nonlinearity, stationary symmetric solutions take the general form of \cite{71,72}

$$\tilde{\psi}(x) = e^{-i\mu t}f(x)\exp[(i/2)\arcsin\kappa],$$

$$\tilde{\phi}(x) = e^{-i\mu t}f(x)\exp[-(i/2)\arcsin\kappa], \quad (13)$$

where $\mu$ is a real chemical potential of the solutions, and real $f(x)$ is a solution of the single continuous equation without the $PT$ terms, for the same $\mu$. Accordingly, a $PT$-symmetric solution of the discrete system is looked for as

$$\tilde{\psi}_n = e^{-i\mu t}f_n\exp[(i/2)\arcsin\kappa] \equiv e^{-i\mu t}\tilde{\psi}_n,$$

$$\tilde{\phi}_n = e^{-i\mu t}f_n\exp[-(i/2)\arcsin\kappa] \equiv e^{-i\mu t}\tilde{\phi}_n. \quad (14)$$

Equation (14) suggests that $PT$-symmetric states exist when $\kappa < 1$, satisfying the following relations:

$$\text{Re}[\psi_n] = \text{Re}[\tilde{\psi}_n] = \text{Re}[\tilde{\phi}_n] = \text{Re}[\phi_n],$$

$$\text{Im}[\phi_n] = \text{Im}[\tilde{\psi}_n] = -\text{Im}[\tilde{\phi}_n] = -\text{Im}[\phi_n],$$

$$|\psi_n|^2 = |\tilde{\psi}_n|^2 = |\tilde{\phi}_n|^2 = |\phi_n|^2, \quad (15)$$

cf. Eq. (8). In our system, Eq. (15) holds when the nonlocal cross-interaction is symmetric, i.e., with a symmetric matrix $G_{nm}$, which is correct for the orientation angles $\theta = 0$ or $\pi/2$. As said above, in the case of asymmetric $G_{nm}$, i.e., for $0 < \theta < \pi/2$, the spatial symmetry is replaced by the on-site or off-site cross-symmetry, i.e., discrete cross-$PT$ symmetric solution should be subject to constraints

$$\text{Re}[\psi_n] = \text{Re}[\phi_{-n}],$$

$$\text{Im}[\phi_n] = -\text{Im}[\phi_{-n}],$$

$$|\psi_n|^2 = |\phi_{-n}|^2, \quad (16)$$

or

$$\text{Re}[\psi_n] = \text{Re}[\phi_{1-n}],$$

$$\text{Im}[\phi_n] = -\text{Im}[\phi_{1-n}],$$

$$|\psi_n|^2 = |\phi_{1-n}|^2. \quad (17)$$

Figures 8 and 9 display, severally, typical examples of cross-$PT$-symmetric solitons of the of the on- and off-site types. Similar to their counterpart in the conservative system, the off-site cross-$PT$-symmetric solitons exist, as stable
FIG. 8: (Color online) A typical example of stable cross-$\mathcal{PT}$-symmetric solitons of the on-site type, for $(P, D, \theta, \kappa) = (2, 0.4, 0.196\pi, 0.2)$. Panel (a) displays the real and imaginary parts of both field components. Panels (b),(c) and (d) have the same meaning as in Figs. 2, 4 and 8.

FIG. 9: (Color online) A typical example of stable cross-$\mathcal{PT}$-symmetric solitons of the off-site type, for $(P, D, \theta, \kappa) = (5, 0.4, 0.196\pi, 0.1)$. Panels have the same meaning as in Fig. 8.

states, only in a narrow area in a vicinity of $\theta = 0.196\pi$ and $D = 0.4$. Further, Fig. 11(a) displays a stability area of these two types of solitons in the $(\kappa, P)$ plane for $\theta = 0.196\pi$ and $D = 0.4$. Sandwiched between the two stability areas is a narrow (gray) stripe, where asymmetric solitons of the intermediate type are found in the cross-$\mathcal{PT}$-symmetric system, see a typical example in Fig. 11. Unlike their counterparts in the conservative system, the asymmetric solitons are unstable. However, on the contrary to unstable solitons in the usual $\mathcal{PT}$-symmetric systems [64], they do not suffer a blowup, as a result of the instability development. Instead, the instability turns these soliton into robust moving breathers, as shown in Fig. 11(c).

The influence of the strength of the gain-loss coefficient on the degree of the cross-symmetry, $\Delta S$ [defined by the same expression (10) as above] was studied too, as shown in Fig. 10(b), which displays $\Delta S(D)$ dependences for different fixed values of $\kappa$, at fixed $\theta = 0.196\pi$ and $P = 1.5$. It is seen that the increase of $\kappa$ slightly enhances the cross-$\mathcal{PT}$-symmetry, by making $\Delta S$ somewhat larger than in the case of $\kappa = 0$.

Stable cross-$\mathcal{PT}$-symmetric solitons feature robust oscillations under the action of random perturbations, see an example displayed in Fig. 10(a). As shown in Fig. 10(b), the peak frequency of the power spectrum of the intrinsic oscillations of stable solitons of both the on-site and off-site centered types increases with the growth of the soliton’s total power. Actually, it identifies the frequency of a dominant internal mode of the stable cross-$\mathcal{PT}$-symmetric solitons.

V. CONCLUSION

We have introduced the model of the chain of double-well potential traps for dipolar BEC. In the tight-binding approximation, it amounts to a system of two coupled discrete Gross-Pitaevskii equations with the long-range DDIs (dipole-dipole interactions) determined by angle $\theta$ of the orientation of the dipoles with respect to the system’s axis. Except for the limit cases of $\theta = 0$ and $\theta = \pi/2$, the system, with the spatially asymmetric DDI between the two parallel lattices, gives rise to the cross-symmetric discrete two-component solitons of two different types, on-site or off-site centered. These two families are stable, being separated by a very narrow region populated by intermediate asymmetric discrete solitons, which are stable too. Finally, we have extended the analysis by adding the $\mathcal{PT}$-symmetry to the system. In this case, stability areas for the cross-$\mathcal{PT}$-symmetric solitons of the on- and off-site-centered solitons have been identified. The corresponding intermediate asymmetric solitons are unstable, evolving into robust breathers.
FIG. 10: (Color online) (a) The stability map for discrete solitons in the cross-PT-symmetric system for \((D, \theta) = (0.4, 0.196\pi)\). The red and yellow areas represent stability regions for the cross-PT-symmetric solitons of the on- and off-site types, respectively. The intermediate gray stripe, \(3 < P < 3.3\), is populated by unstable asymmetric solitons. All solutions are unstable in the white area. (b) The cross-symmetry measure \(10\) vs. \(D\), for the solitons of the on-site cross-PT-symmetric type with \((P, \theta) = (1.5, 0.196\pi)\), cf. Fig. 8(a) for the conservative system.

FIG. 11: (Color online) A typical example of an unstable asymmetric soliton found in the cross-PT-symmetric system for \((P, D, \theta, \kappa) = (3.15, 0.4, 0.196\pi, 0.05)\). Panels have the same meaning as in Figs. 8 and 9. Panel (c) clearly demonstrates that the instability turns the stationary solitons into an effectively stable moving breather.

It may be interesting to extend the work to the consideration of higher-order solitons, such as twisted (spatially antisymmetric \([52]\) ones. A challenging possibility is to introduce a two-dimensional version of the present discrete system.

FIG. 12: (Color online) (a) An example of robust oscillations of a stable cross-PT-symmetric soliton of the on-site-centered type, excited by adding a white-noise perturbation to the initial conditions, with a 2% relative amplitude. Parameters of this soliton are \((P, D, \theta, \kappa) = (2, 0.4, 0.196\pi, 0.1)\). (b) The frequency of the intrinsic oscillations of the randomly-perturbed solitons of both on-site and off-site-centered types, which corresponds to the maximum of the respective power spectrum, versus the total power of the soliton. The other parameters are \((D, \theta, \kappa) = (0.4, 0.196\pi, 0.1)\).
Acknowledgments

We are indebted to Prof. L. Santos for valuable discussions. Z.W.F. appreciates technical assistance provided by Ms. Jiaying Zou (Wuhan Institute of Technology). This work was supported by the National Natural Science Foundation of China through Grants 11575063, 61575041, and 11204089. The work of B.A.M. is supported, in a part, by grant No. 2015616 from the joint program in physics between Natural Science Foundation (US) and Binational (US-Isreal) Science Foundation. This author appreciates hospitality of the Department of Applied Physics at the South China Agricultural University (Guangzhou).
