Abstract. Salinity responses and salinity-related suppression of budbreak of drip-irrigated pecan [Carya illinoinensis (Wangenh.) K. Koch] seedlings under different irrigation water salinity (ECIRR) levels were investigated in the pot-in-pot system. The 1-year-old pecan seedlings of rootstock ‘Riverside’ grafted with ‘Western Schley’ scions were transplanted in pots filled with sandy loam soil and grown for 2 years under the same amount of irrigation water but four irrigation ECIRR treatment levels consisting of 1.4 dS m\(^{-1}\) (control), and three qualities of irrigation water obtained by using a solution of calcium chloride (CaCl\(_2\)) and sodium chloride (NaCl) in a ratio of 2:1 (by weight) to reach the ECIRR levels of 3.5, 5.5, and 7.5 dS m\(^{-1}\), respectively. The leachate electrical conductivity (EC\(_d\)) was highly correlated with soil salinity (EC\(_{1:1}\)) and was significantly higher when the irrigation ECIRR treatment levels increased from 1.4 (control) to 7.5 dS m\(^{-1}\). However, both EC\(_d\) and ECIRR remained nearly constant within the same irrigation ECIRR treatment level during both years. Increasing salinity in irrigation water, particularly the ECIRR levels of 5.5 and 7.5 dS m\(^{-1}\), showed significantly low seedling height and stem diameter growth and delayed or even inhibited budbreak in the seedlings. The EC\(_{1:1}\) that inhibited seedling heights, stem diameters, and budbreak was somewhere between 0.89 and 2.71 dS m\(^{-1}\) (or EC\(_{IRR}\) between 1.4 and 3.5 dS m\(^{-1}\) and EC\(_d\) between 2.10 and 4.86 dS m\(^{-1}\)), providing that soil water content was not a limiting factor in the root zone and irrigation water was uniformly distributed in the confined root zone to obtain uniform salt leaching. The visual symptoms of leaf scorch for irrigation ECIRR levels of 3.5, 5.5, and 7.5 dS m\(^{-1}\) also indicated that somewhere between 0.89 and 2.71 dS m\(^{-1}\) of the EC\(_{1:1}\) salt injury started to occur. Increasing salinity in irrigation water significantly increased chloride (Cl\(^-\)) accumulation but reduced nitrogen (N) content in the scorched leaves, particularly under the irrigation ECIRR levels of 5.5 and 7.5 dS m\(^{-1}\). Leaf scorch symptoms in pecan seedlings were likely associated with Cl\(^-\) toxicity. No pecan seedling bud under the irrigation EC\(_{IRR}\) treatment levels of 5.5 and 7.5 dS m\(^{-1}\) survived to the end of the 2-year growing period. Thus, threshold EC\(_{1:1}\) was somewhere between 0.89 and 2.71 dS m\(^{-1}\) beyond which plant injury increases with increasing EC\(_{1:1}\) threatening the survival of pecan seedlings.

Salinity stress is an ever-present environmental constraint to crop productivity in arid and semiarid regions. The quality of irrigation water remains a primary factor influencing soil salinity. In the arid and semiarid southwestern United States, the occurrence of salt-affected soils in pecan orchards is common in upland soils irrigated with moderately saline water (1 to 2 dS m\(^{-1}\)) and in alluvial soils with poor drainage or inadequate permeability (Miyamoto and Storey, 1995). High evapotranspiration rates exceeding rainfall as well as poor-quality irrigation water containing considerable amounts of salts have accentuated salt problems across pecan-producing areas of this region. Salts present in the soil and irrigation water are expected to increase as the competition for freshwater uses among domestic, agriculture, and industrial sectors intensifies; the expectation of optimized consumptive water use of pecans and enhanced irrigation efficiency grows; and the increased emphasis on conservation of water resources in conflict with the necessity of large amounts of good-quality irrigation water for pecan production continues.

Irrigation water in pecan-producing areas of the southwestern United States, a leading pecan-producing region in the nation, is considerably saline and less sodic (Miyamoto and Storey, 1995). The supply of good-quality water from river irrigation projects has become increasingly limited in many areas. The shortfall is commonly supplemented with groundwater that may have elevated salinity. Most irrigation water from groundwater sources in the pecan-producing areas of the southwestern region contains 500 to 1500 ppm of dissolved salts, resulting in 5 to 15 tons of salts per hectare carried into the orchard annually (Miyamoto et al., 1995). Picchiioni et al. (2000) surveyed 15 commercial pecan orchards along a 120-km stretch of the middle Rio Grande basin in southern New Mexico to evaluate whether pecan cultivation in this region was threatened by high soil salinity. Ten of the 15 sites were found to be on soils considered too saline for pecan trees with the soil saturated paste electrical conductivity (EC) values between 2 and 3 dS m\(^{-1}\) at the upper 0 to 60 cm of soil depth. Water availability is considered one of the major constraints to pecan productivity in the southwestern United States (Deb et al., 2011, 2013), but the decline in irrigation water quality, particularly salinity, continues to be a major challenge to pecan production in this region.

Pecans are among the most salt-sensitive tree crops, yet there is a paucity of research concerning the effects of soil and irrigation water salinity on the growth of pecans. Miyamoto and Gobran (1983) reported that symptoms of salt damage to mature pecan trees ranged from marginal leaf tip burn to mortality of trees. The threshold soil salinity of the saturation extract in the main root zone for tree growth appears to be ≈2.0 dS m\(^{-1}\) when sodium (Na\(^+\)) is the dominant cation (Miyamoto et al., 1986; Miyamoto and Nesbitt, 2011). Tree growth decreases when soil salinity of the saturation extract reaches 2 to 3 dS m\(^{-1}\) and ceases at soil salinity of 4 to 5 dS m\(^{-1}\), and branch dieback begins at soil salinity of ≈5 to 6 dS m\(^{-1}\) in the soil saturation extract (Miyamoto et al., 1986; Miyamoto and Nesbitt, 2011). High soil salinity also causes reduction in nut size and yield (Miyamoto et al., 1986).

The responses of pecans to high salinity may be expected to vary with growth stage. There have been only a few studies that have examined the responses of pecan seedlings to irrigation water salinity levels. In particular, it is difficult to assess the effects of increased salinity of irrigation water or quality of irrigation water on budbreak or growth of pecan seedlings. In a greenhouse experiment where healthy seedlings were subjected to short-term exposure to saline solutions, Faruque (1968) reported that leaf injury of pecan seedlings (cv. Riverside) was related to chloride (Cl\(^-\)) but not Na\(^+\) or SO\(_4^{2-}\) ions. Miyamoto et al. (1985) studied the effects of Na\(^+\) and Cl\(^-\) on growth and ion uptake of three rootstock cultivars, Apache, Burkett, and Riverside, which were grown in outdoor lysimeters and irrigated with eight different qualities. Seedling growth, evaluated in terms of leaf, stem,
and root weights, was inversely related to Na+ concentrations in both soil solutions and seedling leaves. Because the Riverside cultivar absorbed substantially less Na+, Miyamoto et al. (1985) recommended that ‘Riverside’ was a better suited rootstock for saline areas. However, no studies have examined whether increased salinity of irrigation water suppresses budbreak of grafted seedlings or whether salt-affected buds adjust to salt stress under higher irrigation water salinity treatment levels. The objective of this study was to compare salinity responses and salinity-related suppression of budbreak of drip-irrigated pecan seedlings of rootstock ‘Riverside’ grafted with ‘Western Schley’ scions under different irrigation water salinity treatment levels.

Materials and Methods

An in-ground, pot-in-pot experiment was conducted from Feb. 2009 to Oct. 2010 at New Mexico State University’s Fabian Garcia Science Center (FGSC) in Las Cruces, NM (lat. 32°16’ 51.76” N, long. 106°46’ 30.76” N; elevation 1186 m). The 34-L (upper external diameter = 36 cm; height = 36 cm) plastic holder or socket pots (Eco-Lip-Econo-Grip GL/EG 4000; Nursery Supplies, Orange, CA) were placed in the ground with the top rim remaining above ground level. The cultivation pots (hereafter referred to as the pot) containing pecan seedlings were then placed within the holder pots. In this study, we used a total of 24 holder pots. Holder pots were placed in four rows 65 cm apart, and each treatment row had six pots. The area within and between rows was bare sandy loam soil.

Each pot contained small drainage holes at the bottom and a plastic permeable mulch cover was placed on the base of pot. This allowed for drainage within the holder pot and thus collection of leachate. Each pot was filled with sandy loam soil. The soil particle size distribution was determined (sand 63.60% ± 0.86%, silt 27.50% ± 0.96%, and clay 8.90% ± 0.18%) using the hydrometer method (Gee and Bauder, 1986). Other physical properties of the sandy loam soil included soil bulk density (ranged from 1.37 ± 0.04 to 1.44 ± 0.02 Mg-m⁻³), saturated hydraulic conductivity (ranged from 17.3 ± 1.44 to 92.2 ± 4.46 cm·h⁻¹), field capacity water content at 30 kPa (ranged from 0.17 ± 0.03 to 0.27 ± 0.0 cm³·cm⁻³), and wilting point water content at 1500 kPa (0.10 ± 0.04 cm³·cm⁻³) were reported in Deb et al. (2011, 2013).

Pecan seedlings, one seedling per pot, were transplanted on 25 Feb. 2009. One-year-old seedlings of rootstock ‘Riverside’ grafted with ‘Western Schley’ scions were selected from a local nursery (Peñas Pecan Nursery, Mesilla Park, NM). Before transplantation, roots of all the seedlings were trimmed to 30.5-cm length. A drip irrigation system was installed to irrigate the seedlings at a rate of 3.8 L·h⁻¹. The drip irrigation system consisted of one drip tubing supply line at each pot-in-pot row, one drip emitter per pot to distribute water over the surface of the pot to develop a uniform root system in the pot, and a series of four water storage tanks to apply groundwater and saline irrigation. All the pots were irrigated to saturation with groundwater (EC_IRR = 1.4 dS·m⁻¹) before being subjected to irrigation water salinity (EC_IRR) level treatments from Mar. 2009 to Oct. 2010. Four irrigation water salinity (EC_IRR) treatment levels were applied to the pecan seedlings: irrigation with groundwater (EC_IRR = 1.4 dS·m⁻¹) available in the FGSC (considered as a control) and three higher salinity treatment levels (EC_IRR = 3.5, 5.5, and 7.5 dS·m⁻¹). Concentrations of Na+, Ca²⁺, Mg²⁺, K⁺, NO₃⁻, and Cl⁻ in the control irrigation water were 56.6 ± 0.5, 75.3 ± 0.7, 12.8 ± 0.2, 5.0 ± 0.2, 0.05 ± 0.02, and 70.0 ± 1.95 mg·L⁻¹, respectively. Each of the three EC_IRR treatment levels (3.5, 5.5, and 7.5 dS·m⁻¹), respectively, was obtained by gradually adding amounts of calcium chloride (CaCl₂) and sodium chloride (NaCl) in a ratio of 2:1 (by weight) to the irrigation solution and by determining the incremental EC of the solution with a portable EC meter (ECTestr 11; Oakton Instruments, Vernon Hills, IL) until it reached the desired level of EC_IRR. Treatments were replicated six times with one pecan seedling per replication.

Interactive effects of salinity and water stress were not considered in this study, and therefore, pecan seedlings under all treatments were well watered to prevent soil water stress. The amount of water added to each pot was adjusted every 1 to 2 weeks according to the average amount of gravimetric moisture loss (e.g., Catlin et al., 1993; St. Hilaire et al., 2006). Therefore, in this study, Ψ (kPa) was estimated from the voltage measured by the watermark sensors using the non-linear equation of Shock et al. (1998):

$$\psi = \frac{4.093 + 3.213 \times \left(\frac{10^V}{(2.5 - V)}\right)}{1 - 0.009733 \times \left(\frac{10^V}{(2.5 - V)}\right)} - (0.01205 \times T_s)$$  (1)

where the term \(10^V/(2.5-V)\) is the resistance of the sensor (kΩ), V is the measured voltage from the sensor and recorded by the data logger (volts), and T_s is the measured soil temperature (°C) near the watermark sensor. Two pots under the irrigation EC_IRR treatment levels of 3.5 and 5.5 dS·m⁻¹ were also instrumented with temperature sensors (TM6C-HD; Onset Computer Corp., Bourne, MA). These sensors were installed at 10- and 20-cm depths and connected to Hobo H8 data loggers (Onset Computer Corp.). Soil temperatures were recorded every 30 min. The soil water retention model of van Genuchten (1980) was used to convert Ψ to volumetric soil water content \(\theta(\psi)\):

$$\theta(\psi) = \begin{cases} 
\theta_0 + \frac{(\theta_s - \theta_0)}{[1 + (\alpha \psi)^n]} & \psi < 0 \\
\theta_s & \psi \geq 0 
\end{cases}$$  (2)

where \(\theta_0\) is the residual θ (cm³·cm⁻³); \(\theta_s\) is the saturated θ (cm³·cm⁻³); and \(\alpha\) (air entry parameter, cm⁻¹), n (pore size distribution parameter, unitless), and \(m\) (= 1-n/3) are empirical parameters. The soil water retention curve for sandy loam soil was determined using the pressure chamber method at \(\psi\) of 0, 30, 50, 100, 300, 500, 1000, and 1500 kPa (Deb et al., 2011). The parameters \(\theta_0\) (= 0.08 cm³·cm⁻³), \(\theta_s\) (= 0.46 cm³·cm⁻³), \(\alpha\) (= 0.003 cm⁻¹), and \(m\) (= 2.0) were estimated by fitting the van Genuchten (1980) soil water retention model [Eq. (2)] to the measured drainage curve data (Deb et al., 2011).
Regression analysis was used to evaluate correlations between volumetric soil water contents at 3.5-dS·m⁻¹ and 5.5-dS·m⁻¹ treatment pots for 7- and 15-cm depths, respectively.

All the pecan seedlings were fertilized with Hoagland's solution (containing 0.815 g·L⁻¹ of soluble fertilizer) on 30 Mar., 29 May, 26 June, 20 July, and 12 Aug. during 2009 and on 4 Apr., 17 May, 15 June, 21 July, and 17 Aug. during 2010. Drainage water or leachate was collected from the holder pots every week starting from May to September during both years. The volume of leachate collected from each pot was measured using a graduated cylinder. The leaching fraction, the volume of solution leached divided by the volume of solution applied to the seedling, was estimated for each pot at 2-week intervals. The leachate ECs (ECₜ) were measured at 2-week intervals in the field using a portable EC meter (ECtest 11; Oakton Instruments, Vernon Hills, IL) and also in the laboratory using a Fisher Accumet Meter (Denver Instrument Company, Denver, CO).

Soil samples at depths of 0 to 20 cm were collected from all treatment pots using a push probe to determine soil EC on a monthly basis at the time of leachate volume sampling. Gravimetric water contents at 7- and 15-cm depths were also determined once per month and compared with soil water contents obtained using Eq. (2) for two pots under the irrigation ECIRR treatment levels of 3.5 and 5.5 dS·m⁻¹. Soil samples that were removed from each pot during the sampling were replaced by the same soil type. Soil samples were air-dried, passed through a 2-mm sieve, and analyzed for the EC in 1:1 ratio of soil:water (EC₁:₁) using the Fisher Accumet Meter (Denver Instrument Company). Although the saturated paste extract method is generally accepted, we determined soil EC (ECₛₚₐₚ) by the 1:1 soil:water method on all soil samples because of reduced time investments. Simplicity makes 1:1 soil to water extract a method potentially useful in salinity characterization (Zhang et al., 2005). As a result of the consistency in the amount of water used, the 1:1 soil:water method reduces the difficulties in sample preparation and increases reproducibility, which are often encountered with the saturation paste extractions (e.g., Fowler and Hamm, 1980; Sonneveld and Van Den Ende, 1971; Zhang et al., 2005). Moreover, in this study, the 1:1 soil:water method was likely to be appropriate because the soil water content always remained high in all the treatment pots throughout the growing season (described in "Results and Discussion" section). Below 10-cm depth, soil water content remained slightly below saturation but always above field capacity. The EC of sandy loam soil used in this pot-in-pot experiment was also determined on soil samples using the saturated paste extract method and in 1:1, 1:2, 1:3, 1:4, 1:5, and 1:10 soil:water methods to obtain the empirical relationship between soil EC levels determined using the saturated paste extract and soil to water extract methods.

The growth of seedlings in all treatment pots were monitored visually on a weekly basis as well as continuously using garden watch cameras (PlantCam; Wingscapes, Inc., Alabaster, AL). To determine annual changes in seedling height and stem diameter growth during each year, measurements of seedling heights and stem diameters were made on 2 Mar. and 5 Oct. during 2009 and 22 Mar. and 9 Oct. during 2010. Seedling height from the top of the pot to the top of the canopy was measured with a ruler. Stem diameter below the graft union was measured at 2 cm above the soil surface of the pot using a digital caliper. Leaf evaluations were recorded weekly starting from April to October during each year. Visual quality rating scales for evaluating salt damage on the leaves have been widely used to assist the plants (e.g., Niu et al., 2007a, 2007b; Worley, 1990; Zollinger et al., 2007). Salt damages on seedling leaves on the entire seedling were evaluated visually on a scale of 0 to 5, where 0 = no scorching or no visual damage; 1 = insignificant scorching; 2 = 25% of leaf area scorched; 3 = 50% of leaf area scorched; 4 = 75% of leaf area scorched; and 5 = all the leaf area scorched or dead leaf.

Weather conditions including solar radiation, minimum and maximum relative humidity, wind velocity, and minimum and maximum air temperature were measured continuously at 1-h intervals in the FGSC meteorological station. During March to October of the each year, leaf temperatures were measured once per month using an infrared thermometer (Fluke thermometer 54H; Fluke Corporation, Everett, WA). Leaves from all the treatment pots were harvested on 5 Oct. in 2009 and 9 Oct. in 2010. Leaf samples from each treatment were dried at 60 °C for 24 h. Dried samples were then ground and sieved with a 2-mm mesh screen and analyzed for total N and chloride (Cl⁻) contents in the AgSource Harris Laboratory (Lincoln, NE).

Data obtained from measurements were analyzed for variance using SAS for Windows Version 9.2 (SAS Institute Inc., Cary, NC). All comparisons among the four treatment means were carried out using Tukey’s test (P ≤ 0.05).

Results and Discussion

The EC of the leachate (ECₜ) collected from each holder pot under the irrigation water salinity (ECIRR) treatment levels of 1.4 (control), 3.5, 5.5 and 7.5 dS·m⁻¹ are presented in Tables 1 and 2 for 2009 and 2010, respectively. The effect of salinity level treatments was significant on the ECₜ. The leachate samples had significantly higher ECₜ when the irrigation ECIRR treatment levels increased from 1.4 (control) to 7.5 dS·m⁻¹. The ECₜ within the same irrigation ECIRR treatment level remained nearly constant during both years (Tables 1 and 2). The leachate volumes within the same irrigation ECIRR treatment level remained similar at each sampling date during both years. The leachate volumes within the 2-week period usually ranged from

5.5-dS with average values of 0.33 and 0.41 cm$^3$ at 7 and 15 cm, respectively. For both 3.5-dS$^{-1}$ and 5.5-dS$^{-1}$ treatment pots, throughout the growing season, the gradual decrease in daily soil water contents at 15-cm depth was slower and water content remained higher compared with soil water contents at 7 cm. The water content fluctuations between irrigation events were greater at 7 cm depth likely as a result of the evaporation from the pot surface as well as water uptake by roots.

In addition to stable soil water content within the root zone in all the treatment pots, daily average soil temperature, a crucial factor in root development and function in the pot-in-pot system (e.g., Martin et al., 1999; Miralles et al., 2012), was similar in all the treatments during the experimental period (data not shown). This also suggested that daily average soil temperature in all the treatments was unaffected by the irrigation water or rainfall. For example, as shown in Fig. 2, temporal variations in daily average soil temperatures at 10-cm depth during both 2009 and 2010 were similar in pots under the irrigation EC$_{IRR}$ treatment levels of 3.5 dS$^{-1}$ and 5.5 dS$^{-1}$. The variations in daily average air temperatures were slightly lower or similar to soil temperatures observed in all the treatments during the experimental period (Fig. 2). The benefit of the pot-in-pot system was that soil temperature in cultivation pots remained similar to air temperature, which, in contrast to traditional cultivation in above-ground pots, might reduce root zone temperature stress (Miralles et al., 2012; Neal, 2010; Young and Bachman, 1996).

Soil salinity (EC$_{1:1}$) within the 0- to 20-cm depths was significantly higher when the irrigation EC$_{IRR}$ treatment levels increased from 1.4 to 7.5 dS$^{-1}$. The EC$_{1:1}$ data under the irrigation EC$_{IRR}$ levels of 1.4 (control), 3.5, 5.5, and 7.5 dS$^{-1}$ were highly correlated with the EC$_{d}$ data (Fig. 3). As expected, the EC$_{d}$ was always greater than the EC$_{1:1}$. Both EC values were similar when the EC$_{1:1}$ data were converted to the equivalent saturated paste (data not shown) using the relationship shown in Fig. 4. As shown in Fig. 4, the EC of 1:1, 1:2, 1:3, 1:4, 1:5, and 1:10 soil to water extracts are typically lower than those of the saturation paste as a result of increased dilution effect, which has been reported in other studies (e.g., Reitemeier, 1946; Sonneveld and Van Den Ende, 1971; Zhang et al., 2005). In particular, the EC in the saturated paste extract is 2-fold ($\approx 1.905$ times) greater than that (EC$_{1:1}$) in the 1:1 soil/water extract (Fig. 4).

Although soil water content was not measured in all the treatment pots, magnitudes and variations in soil water contents were likely to differ only slightly among treatments. For example, as shown in Fig. 1, magnitudes and variations in daily average volumetric soil water contents during 2009 were similar under the irrigation EC$_{IRR}$ treatment levels of 3.5 dS$^{-1}$ and 5.5 dS$^{-1}$. The coefficients of determination ($R^2$) between soil water contents at 3.5-dS$^{-1}$ and 5.5-dS$^{-1}$ treatment pots were 0.95 and 0.96 ($P \leq 0.05$) for 7- and 15-cm depths, respectively. Soil water content was not a limiting factor for different salinity treatment pots. During Mar. to Dec. 2009, measured daily average soil water contents remained higher and similar in 3.5-dS$^{-1}$ and 5.5-dS$^{-1}$ treatment pots, which varied between 0.28 and 0.40 cm$^3$·cm$^{-1}$ at 7-cm and 0.38 and 0.44 cm$^3$·cm$^{-1}$ at 15-cm soil depths with average values of 0.33 and 0.41 cm$^3$·cm$^{-1}$.
Reduced significantly when the soil salinity of loamy sand during a 2-year period was re-observed that pecan seedlings growth in fine lysimeter experiments. Miyamoto et al. (1985) for seedlings of pecan rootstock cultivars in salinity reported by Miyamoto et al. (1985) that the threshold soil salinity falls between 1.4- and 7.5 dS m⁻¹ (equivalent EC in the saturated paste extract somewhere between 1.70 and 5.16 dS m⁻¹ or EC₃₀ somewhere between 2.10 and 4.86 dS m⁻¹). During 2010, leaf scorch symptoms were again noticed on 25 July, 5 Aug., and 22 Aug. in all the seedlings under the irrigation ECIRR treatment levels of 7.5, 5.5, and 3.5 dS m⁻¹, respectively (Table 4). Leaf scorch rated visually ranged from 0 to 1.2, 2.0 to 3.2, and 3.0 to 3.3 on a scale of 0 to 5 in pecan seedlings grown for 2 years under the irrigation ECIRR treatment levels of 3.5, 5.5, and 7.5 dS m⁻¹, respectively (Tables 3 and 4). No leaf scorch symptoms were seen in pecan seedlings under the control treatment (ECIRR = 1.4 dS m⁻¹) during both years. It was determined that the leaf scorch symptoms were abiotic, i.e., were not pecan bacterial leaf scorch caused by Xylella fastidiosa (Sanderlin and Heyderich-Alger, 2000), but only as a result of the salt stress imposed on pecan seedlings under irrigation ECIRR treatment levels of 7.5, 5.5, and 3.5 dS m⁻¹. A laboratory test at New Mexico State University’s Plant Diagnostic Clinic could not detect the presence of Xylella fastidiosa in scorched leaves by polymerase chain reaction (Randall et al., 2009).

In pecan seedlings with scorched leaves resulting from salt injury, it appeared that leaf chloride (Cl⁻) was significantly higher compared with the control treatment, indicating that Cl⁻ ions were readily translocated to the leaves (Fig. 6B). Even at the control treatment (1.4 dS m⁻¹), no pecan seedlings had the ability to exclude Cl⁻ accumulation from its leaves. During both years, increasing salinity levels of irrigation water, particularly the irrigation ECIRR treatment levels of 5.5 and 7.5 dS m⁻¹ tended to increase leaf Cl⁻ significantly (Fig. 6B). In contrast, increasing irrigation salinity (ECIRR) levels reduced N accumulation in leaves (Fig. 6A). These results also suggested the disturbance of the mechanism controlling the translocation of N to the leaves by increasing irrigation salinity treatments. In short-term greenhouse experiments, Faruque (1968) and Hanna (1972) reported that Cl⁻ was exclusively responsible for leaf injury of pecan seedlings grown in gravel-nutrient solution. On the contrary, in a 2-year lysimeter experiment, Miyamoto et al. (1985) reported the poor correlation between pecan seedling growth and Cl⁻ in leaves or in soil solutions. The reduction in pecan seedling growth was attributed more to Na⁺ than to Cl⁻ accumulation in leaves and primarily in soil solutions when Na⁺ was the main cation and soil water depletion did not exceed 50% of the available water (Miyamoto et al., 1985). However, pecan seedlings subjected to short-term exposure to saline solution are susceptible to acute effects of Cl⁻ ions, whereas the
Table 3. Evolution of budbreak and leaf scorch symptoms in pecan (Carya illinoinensis) seedlings of rootstock ‘Riverside’ grafted with ‘Western Schley’ scions grown in the pot-in-pot system under the irrigation water salinity (electrical conductivity, ECIRR) treatment levels of 1.4, 3.5, 5.5, and 7.5 dS m⁻¹ during the 2009 growing season.

*Date recorded when the bud scales split and the leaf began to expand.

*Evaluated visually on a scale of 0 to 5, where 0 = no scorching, 1 = insignificant scorching, 2 = 25% of leaf area scorched, 3 = 50% of leaf area scorched, 4 = 75% of leaf area scorched, and 5 = all leaf area scorched or dead leaf.

As mentioned earlier, the annual changes in seedling heights and stem diameters were not significantly different (Fig. 5) and the timing of budbreak was similar (Tables 3 and 4) under irrigation ECIRR treatment levels of 1.4 and 3.5 dS m⁻¹. Nevertheless, the annual mean soil salinity (EC1:1) value of 2.71 dS m⁻¹ (equivalent to EC of 5.16 dS m⁻¹ in the saturated paste extract or EC₆ of 4.86 dS m⁻¹) under the irrigation ECIRR treatment level of 3.5 dS m⁻¹ displayed clear visual symptoms of salt injury or scorch in the leaves (Fig. 3; Tables 3 and 4). As presented in Table 4, no pecan seedlings under the irrigation ECIRR treatment levels of 1.4 and 5.5 dS m⁻¹ survived to the end of the 2-year growing period. For these ECIRR treatment levels, the respective annual mean values of EC1:1 and EC₆ ranged from 4.01 to 5.44 dS m⁻¹ and 9.70 to 9.98 dS m⁻¹ during 2009 and from 4.16 to 5.94 dS m⁻¹ and 7.65 to 10.2 dS m⁻¹ during 2010 (Tables 1 and 2; Fig. 3). Therefore, the soil salinity range observed between the 1.4- and 3.5-dS m⁻¹ ECIRR treatments, i.e., the EC1:1 and EC₆ values somewhere between 0.89 and 2.71 dS m⁻¹ (equivalent EC in the saturated paste extract somewhere between 1.70 and 5.16 dS m⁻¹ or EC₆ somewhere between 2.10 and 4.86 dS m⁻¹) could be hazardous for the survival of pecan seedlings. These EC1:1 values under the 1.4 and 3.5 dS m⁻¹ ECIRR treatments were within the threshold range that has been observed by Miyamoto et al. (1985) in the lysimeter experiment for pecan rootstock cultivars. Miyamoto et al. (1985) reported that the minimal pecan seedling growth was at soil salinity of 5.2 dS m⁻¹ in the saturation extract and seedling tip dieback was at 8.5 dS m⁻¹.

Responses of pecan seedlings to irrigation water salinity observed in our pot-in-pot experiment may not be directly applicable to nut-producing trees. The concentration of saline irrigation water in the confined root zone systems of cultivation pots might magnify the symptoms. Therefore, salinity effects in pecan seedlings could be more pronounced than those in nut-producing trees grown in the orchard where roots are growing in a much larger volume of soil with lower average salt concentrations. However, our observations provide essential information regarding the salinity response and salinity-related suppression of budbreak of grafted seedlings to irrigation water salinity levels. Note that it was not the intent of our pot-in-pot experiments to improve the irrigation application efficiency, and therefore, a large amount of irrigation water was frequently applied to prevent soil water stress as well as obtain leaching of salts from the soil profile. Further experiments are needed to find an optimum balance between the desired leaching fractions to achieve specific levels of soil salinity and irrigation efficiency to optimize the water needed for the pot-in-pot pecan production.

Conclusions

Salinity responses of drip-irrigated pecan seedlings grown in the pot-in-pot system under irrigation water salinity (ECIRR) treatment...
Table 4. Evolution of budbreak and leaf scorch symptoms in pecan (*Carya illinoinensis*) seedlings of rootstock ‘Riverside’ grafted with ‘Western Schley’ scions grown in the pot-in-pot system under the irrigation water salinity (electrical conductivity, EC _IRR_) treatment levels of 1.4 (control), 3.5, 5.5, and 7.5 dS·m⁻¹ during the 2010 growing season.

¹Date recorded when the bud scales split and the leaf began to expand.

²Evaluated visually on a scale of 0 to 5, where 0 = no scorching, 1 = insignificant scorching, 2 = 25% of leaf area scorched, 3 = 50% of leaf area scorched, 4 = 75% of leaf area scorched, and 5 = all the leaf area scorched or dead leaf.

levels of 1.4 (control), 3.5, 5.5, and 7.5 dS·m⁻¹ were compared. The leachate EC (EC₀) was highly correlated with soil salinity (EC₁:1) under all the treatments and was significantly higher when the irrigation EC _IRR_ treatment levels increased from 1.4 (control) to 7.5 dS·m⁻¹. Compared with the control treatment, increasing irrigation salinity, particularly the irrigation EC _IRR_ treatment levels of 5.5 and 7.5 dS·m⁻¹, significantly decreased the heights and stem diameters of the seedlings and delayed or inhibited budbreak in seedlings. The soil salinity (EC₁:1) that inhibited the heights and stem diameter growth of the seedlings and budbreak was somewhere between 0.89 and 2.71 dS·m⁻¹ (equivalent EC in the saturated paste extract somewhere between 1.70 and 5.16 dS·m⁻¹ or EC₀ somewhere between 2.10 and 4.86 dS·m⁻¹), providing that soil water content was not a limiting factor and irrigation water was uniformly distributed in the root zone to obtain uniform salt leaching. The clear visual symptoms of salt injury or scorch in the leaves for pecan seedlings under high irrigation EC _IRR_ levels of 5.5 and 7.5 dS·m⁻¹ could be hazardous for the survival of pecan seedlings.
