Compact formulas for trapped-particle and passing-particle guiding-center orbits in axisymmetric tokamak geometry are given in terms of the Jacobi elliptic functions and complete elliptic integrals. These formulas can find applications in bounce-center kinetic theory as well as neoclassical transport theory.

I. INTRODUCTION

The presence of trapped-particle and passing-particle guiding-center orbits in axisymmetric tokamak geometry has had a significant impact on magnetic fusion research (see Refs. [1, 2] for a brief historical survey). Because of their fundamental importance in understanding neoclassical and anomalous transport in tokamak plasmas [3], it is desirable to find compact analytic representations for the trapped-particle and passing-particle guiding-center orbits in axisymmetric tokamak geometry. In particular, compact expressions might allow explicit calculations of bounce-angle averages in bounce-center kinetic theory beyond the deeply-trapped limit. In addition, a bounce-center Fokker-Planck collision operator might be constructed from the guiding-center Fokker-Planck collision operator [4], which would enable a kinetic description of neoclassical transport beyond the zero-banana-width limit [8].

Previous analytic representations have used a simplified tokamak geometry [5] in which the magnetic surfaces are unshifted concentric circular toroidal surfaces centered on the magnetic axis (located at a major radius R for the axis of symmetry). In this simplified tokamak geometry, trapped-particle and passing-particle guiding-center orbits [8] are represented in terms of complete and incomplete elliptic integrals [11]. The purpose of this work is to present compact analytic formulas for these trapped and passing guiding-center orbits expressed in terms of the Jacobi elliptic functions [11, 12]. These compact formulas are readily amenable to explicit calculations that do not require using simplifying limits such as the deeply-trapped limit (in which case the Jacobi elliptic functions become simple trigonometric functions).

The remainder of the paper is organized as follows. In Sec. I we introduce the simple axisymmetric tokamak geometry used here and in previous works [8]. In Sec. II we introduce the bounce and transit actions J_b = (J_b, J_t) associated with the trapped-particle (ℓ = b) and passing-particle (ℓ = t) guiding-center orbits and their associated orbital frequencies ω_b ≡ (∂J_b/∂E)−1, which are given in terms of complete elliptic integrals [9]. In Sec. III we present compact expressions for the poloidal angle θ in terms of Jacobi elliptic functions depending on the bounce angle ζ_b (for trapped-particle orbits) and the transit angle ζ_t (for passing-particle orbits). In Sec. IV we introduce the canonical parallel coordinates s(ζ_b, J_b) and p_b(ζ_b, J_b) for trapped-particle and passing-particle guiding-center orbits, which satisfy a canonical condition {s, p_b} ≡ 1. This canonical conditions forms the basis of the bounce-center phase-space transformation [13] in general magnetic geometry. The fact that the parallel coordinates explicitly satisfy the canonical conditions is a major result of the present work. Lastly, in Sec. V the slow toroidal-drift guiding-center dynamics is described in terms of compact expressions involving the Jacobi elliptic functions and our work is summarized in Sec. VII.

II. SIMPLE TOKAMAK GEOMETRY

In circular, large-aspect-ratio tokamak geometry [9], the magnetic-field strength is approximated as

\[ B(ψ, θ) \approx B_0 \left(1 - \frac{r}{R} \cos θ\right) = B_e + 2B_0\epsilon \sin^2 \frac{θ}{2}, \]

(1)

where the small inverse aspect ratio

\[ \epsilon(ψ) \equiv \frac{r(ψ)}{R} < 1 \]

(2)

is defined in terms of the minor radius r(ψ) of a circular magnetic surface (labeled by ψ), and the poloidal angle θ is measured from the outside equatorial plane. In Eq. (1), B_0 denotes the magnetic-field strength on the magnetic axis (at r = 0) and B_e ≡ B_0(1-\epsilon) denotes the magnetic-field strength on the (outside) equatorial plane. Lastly, we note that the magnitude of the toroidal magnetic is B_\text{tor} ≈ B while the magnitude of the poloidal magnetic field at the minor radius r is B_\text{pol} \approx \epsilon(ψ)B_0/q(ψ), where q(ψ) is the safety factor [9]. In all expressions presented here, terms of order \epsilon^2 are systematically omitted (the symbol \approx is used whenever this approximation is first introduced).

On a single magnetic surface (at fixed \epsilon), the magnitude of the parallel momentum \( |p_p|/(θ) \equiv \sqrt{2m(E - μB)} \) of a guiding-center of mass m (at fixed total energy E,
magnetic moment $\mu$, and magnetic flux $\psi$ is

$$|p_\parallel| (\vartheta) \simeq \sqrt{2m (E - \mu B_\parallel)} \left(1 - \frac{2\epsilon \mu B_0}{E - \mu B_e} \right) \sin^2 \frac{\vartheta}{2} \equiv p_{\parallel e} \sqrt{1 - \kappa^{-1} \sin^2 \frac{\vartheta}{2}} \equiv m R_\parallel |\vartheta|, \quad (3)$$

Here, the equatorial parallel momentum (on the low-field side at $\vartheta = 0$) of the guiding-center orbit is defined as

$$p_{\parallel e} = \sqrt{2m (E - \mu B_e)} = 2\sqrt{\kappa} m R_\parallel \omega_\parallel, \quad (4)$$

where the bounce-transit parameter $\xi_e$ is defined as

$$\kappa (E, \mu, \psi) = \frac{E - \mu B_e}{2 \epsilon \mu B_0} = \frac{\xi_e^2 (1 - \epsilon)}{2 \epsilon (1 - \xi_e^2)}, \quad (5)$$

and $\xi_e \equiv p_{\parallel e} / p$ denotes the equatorial pitch-angle coordinate. In Eq. (4), we also defined the characteristic parallel frequency

$$\omega_\parallel = \frac{1}{R_\parallel} \sqrt{\frac{\mu B_0}{m}} \equiv \sqrt{\epsilon \frac{\rho_0}{R_\parallel}} \ll 1, \quad (6)$$

and the connection length $R_\parallel \equiv q(\psi) R$. Using these definitions and Eq. (4), the equatorial poloidal angular velocity is defined as

$$\vartheta_e \equiv 2 \sqrt{\kappa} \omega_\parallel. \quad (7)$$

Note that the parallel frequency (6) is small compared to the gyrofrequency $\Omega_0$ (evaluated at the magnetic axis):

$$\frac{\omega_\parallel}{\Omega_0} = \frac{1}{R_\parallel} \sqrt{\frac{\mu B_0}{m \Omega_0^2}} \equiv \frac{\sqrt{\epsilon \rho_0}}{2 R_\parallel} \ll 1, \quad (8)$$

where $\rho_0 \equiv \sqrt{2 \mu B_0 / (m \Omega_0^2)}$ denotes the gyroradius of a guiding-center (with magnetic moment $\mu$) evaluated at the magnetic axis.

The condition $\kappa < 1$ in Eq. (3) implies that a trapped particle bounces back and forth between the bounce poloidal angles $\vartheta_b$, where

$$\vartheta_b \equiv 2 \arcsin \sqrt{\kappa}, \quad (9)$$

while a passing particle is in transit for $\kappa > 1$ in Eq. (3), with the minimum parallel momentum $p_{\parallel \text{min}} = p_{\parallel e} \sqrt{1 - \kappa^{-1}} < p_{\parallel e}$ attained at $\vartheta = \pi$. Using the definition (5), the bounce-transit boundary $\kappa = 1$ yields the trapping condition

$$\xi_e^2 \lesssim 2 \epsilon (1 + \epsilon) \simeq 2 \epsilon \quad (10)$$

in the simple tokamak magnetic field [1].

III. BOUNCE AND TRANSIT ACTIONS

At the lowest order on the bounce-transit time scale, the magnetic flux $\psi$ is frozen and thus the minor radius $r = \epsilon R$ and the connection length $R_\parallel$ are constant. Hence, the parallel momentum (3) depends only on the poloidal angle $\vartheta$ as a guiding-center moves along a magnetic-field line $s(\vartheta)$ (projected onto the poloidal plane at fixed toroidal angle $\phi$).

A. Bounce action and bounce frequency for trapped particles

By using the infinitesimal parallel-length element $ds \simeq R_\parallel d\vartheta$, we easily obtain the following expression for the bounce action for trapped particles ($\kappa < 1$):

$$J_b \equiv \frac{1}{2\pi} \int p_{\parallel e} ds \simeq p_{\parallel e} R_\parallel \int_{-\vartheta_b}^{\vartheta_b} \sqrt{1 - \kappa^{-1} \sin^2 \frac{\vartheta}{2}} \frac{d\vartheta}{2 \pi}. \quad (11)$$

After making the substitution $\sin \vartheta / 2 = \sqrt{\kappa} \sin \varphi$ in Eq. (11), we obtain [6]

$$J_b = p_{\parallel e} R_\parallel \frac{4\sqrt{\kappa}}{\pi} \int_0^{\pi/2} \frac{\cos^2 \varphi}{\sqrt{1 - \kappa \sin^2 \varphi}} d\varphi \equiv m R_\parallel^2 \omega_\parallel \left\{ \frac{8}{\pi} \left[ E(\kappa) - (1 - \kappa) K(\kappa) \right] \right\}, \quad (12)$$

where we wrote $\cos^2 \varphi = \kappa^{-1} \left[ (1 - \kappa \sin^2 \varphi) - (1 - \kappa) \right]$ while $K(\kappa)$ and $E(\kappa)$ denote the complete elliptic integrals of the first and second kind, respectively [11, 12].

By using standard properties of these complete elliptic integrals [11], the bounce frequency for trapped particles $\omega_b \equiv (\partial J_b / \partial \mathcal{E})^{-1}$ is expressed as

$$\omega_b = \frac{\pi \omega_\parallel}{2 K(\kappa)}, \quad (13)$$

where we used $\partial \kappa / \partial \mathcal{E} = \kappa / (E - \mu B_e)$ and the relation [11]

$$\frac{d}{d\kappa} \left[ E(\kappa) - (1 - \kappa) K(\kappa) \right] = \frac{1}{2} K(\kappa). \quad (14)$$

In the deeply-trapped approximation, where the equatorial pitch-angle coordinate is $\xi_e^2 \ll 2 \epsilon$ (so that $\kappa \ll 1$), we use $K(\kappa) \simeq \pi / 2$ and $E(\kappa) - (1 - \kappa) K(\kappa) \simeq \pi \kappa / 4$, and Eqs. (12)-(13) become $J_b \simeq \mathcal{E} \xi_e^2 / \omega_\parallel$ and $\omega_b \simeq \omega_\parallel$, where $\omega_\parallel = R_\parallel^{-1} \sqrt{\epsilon E/m}$. 

action (21) is shown for \( \kappa > 1 \) while the transit action (20) is shown for \( \kappa < 1 \). The bounce action (12) and the transit action (15) can both be combined into a single expression for the normalized action \( \mathcal{J}(\kappa) = J/(m R_{\parallel}^2 \omega_{\parallel}) \) for arbitrary bounce-transit parameter \( \kappa \):

\[
\mathcal{J}(\kappa) = \frac{8}{\pi} \alpha(\kappa) \int_0^{\mathcal{K}(\kappa)} \text{cn}^2(u | \kappa) \, du,
\]

(17)

B. Transit action and transit frequency for passing particles

For a passing particle (\( \kappa > 1 \)), the transit action is

\[
J_t = \frac{p_{\parallel} R_{\parallel}}{\omega_{\parallel}} \int_{-\pi}^{\pi} \sqrt{1 - \kappa^{-1} \sin^2 \vartheta} \, d\vartheta = m R_{\parallel}^2 \omega_{\parallel} \left[ \frac{4\sqrt{\kappa}}{\pi} \mathcal{E}(\kappa^{-1}) \right].
\]

(15)

The corresponding transit frequency \( \omega_t = (\partial J_t / \partial \mathcal{E})^{-1} \) is expressed as

\[
\omega_t = \omega_{\parallel} \frac{\pi \sqrt{\kappa}}{K(\kappa^{-1})} = \frac{\pi \omega_{\parallel}}{K(\kappa)},
\]

(16)

where we used the relation [11]

\[
\frac{d}{d\kappa} \left[ \sqrt{\kappa} \mathcal{E}(\kappa^{-1}) \right] = \frac{K(\kappa^{-1})}{2 \sqrt{\kappa}} = \frac{1}{2} K(\kappa).
\]

In the large-\( \kappa \) (energetic-passing) limit, we recover \( J_t \approx p_{\parallel} R_{\parallel} \) and \( \omega_t \approx p_{\parallel} \omega_{\parallel} / (m R_{\parallel}) \) from Eqs. [15-16], which both scale as \( \sqrt{\kappa} \) for \( \kappa \gg 1 \).

C. Unified representation for action integrals

We note that the bounce action (12) and the transit action (15) can both be combined into a single expression for the normalized action \( \mathcal{J}(\kappa) = J/(m R_{\parallel}^2 \omega_{\parallel}) \) for arbitrary bounce-transit parameter \( \kappa \):

\[
\mathcal{J}(\kappa) = \frac{8}{\pi} \alpha(\kappa) \int_0^{\mathcal{K}(\kappa)} \text{cn}^2(u | \kappa) \, du,
\]

(17)

where \( \alpha(\kappa) = 1 \) (\( \kappa < 1 \)) or \( \alpha(\kappa) = 1/2 \) (\( \kappa > 1 \)). Note that the factor \( \alpha = 1/2 \) yields a consistent relation between the poloidal angle \( \vartheta \) and the transit angle \( \zeta_t \) for passing particles [see Eq. (25)].

For \( \kappa < 1 \), we use the definition [11] for the elliptic integral

\[
\mathcal{E}(\kappa) = \int_0^{\mathcal{K}(\kappa)} \text{dn}^2(u | \kappa) \, du
\]

and the identities

\[
\text{cn}^2(u|\kappa) + \text{sn}^2(u|\kappa) = 1 \equiv \text{dn}^2(u|\kappa) + \kappa \text{sn}^2(u|\kappa),
\]

(19)

to obtain

\[
\mathcal{J}_b(\kappa) \equiv \frac{8}{\pi} \int_0^{\mathcal{K}(\kappa)} \left[ \kappa - 1 + \text{dn}^2(u | \kappa) \right] \, du
\]

(20)

so that \( \mathcal{J}_b(\kappa = 1) = 8/\pi \). For \( \kappa > 1 \), we use the conversion relation [11][11] \( \text{cu}(u|\kappa) \equiv \text{dn}(\sqrt{\kappa} u | \kappa^{-1}) \) associated with \( \kappa > 1 \) \( \rightarrow \kappa^{-1} \) \( \rightarrow 1 \). By using the change of variable \( v = \sqrt{\kappa} u \), Eq. (17) becomes

\[
\mathcal{J}_t(\kappa) \equiv \frac{8}{2\pi} \int_0^{\mathcal{K}(\kappa^{-1})} \text{dn}^2(v | \kappa^{-1}) \, dv
\]

(21)

so that \( \mathcal{J}_t(\kappa = 1) = 4/\pi \).

Figures 1 and 2 show the normalized action \( \mathcal{J} = J/(m R_{\parallel}^2 \omega_{\parallel}) \), defined by Eq. (17), and the normalized frequency \( \mathcal{\Omega} = \omega/\omega_{\parallel} \) versus the bounce-transit parameter \( \kappa \). Figure 1 shows the discontinuity of the bounce and transit actions at \( \kappa = 1 \). This discontinuity is related to the fact the transit period for a marginally-passing particle is associated with the motion from \( \vartheta = -\pi \) to \( +\pi \), while the bounce period for a marginally-trapped particle is associated with the motion from \( \vartheta = -\pi \rightarrow \pi \) (i.e., doubling the path taken to complete a bounce period). The bounce frequency (13) and
the transit frequency \( [16] \) both vanish (i.e., the corresponding periods become infinite) at the bounce-transit boundary \( \kappa = 1 \) since \( K(x) \to \infty \) as \( x \to 1 \).

## IV. BOUNCE AND TRANSIT ANGLES

The angles canonically conjugate to the bounce action \( J_b \) and the transit action \( J_t \) are the bounce angle \( 0 \leq \zeta_b \leq 2\pi \) and the transit angle \( -\pi \leq \zeta_t \leq \pi \), respectively. These angles have been expressed previously in terms of the incomplete elliptic integrals, which often prevented immediate analytical applications. In the present Section, we use the Jacobi elliptic functions to give compact expressions of the poloidal angle \( \vartheta \) in terms of the bounce or transit angles.

### A. Bounce angle for trapped particles

The bounce angle \( \zeta_b \) for trapped particles \( (\kappa < 1) \) is defined as

\[
\zeta_b \equiv \pi + \frac{\omega_b}{2\sqrt{\kappa}} \int_{-\vartheta_b}^{\vartheta} \frac{d\vartheta'}{\sqrt{1 - \kappa^{-1} \sin^2 \vartheta'/2}}
\]

\[
= \pi + \frac{\pi}{2K(\kappa)} \int_{-\Theta}^{\vartheta/2} \frac{d\varphi}{\sqrt{1 - \kappa^{-1} \sin^2 \varphi}}
\]

\[
= \frac{3\pi}{2} + \frac{\pi}{2K(\kappa)} \sin^{-1} \left( \sin \Theta \mid \kappa \right),
\]

(22)

where \( \sin \Theta \equiv \sin(\vartheta/2)/\sqrt{\kappa} \) and we defined \( \zeta_b \equiv \pi \) at \( \vartheta = -\vartheta_b \) (i.e., at \( \Theta = -\pi/2 \)). Equation (22) can be inverted to give

\[
\sin \frac{\vartheta}{2} = \sqrt{\kappa} \sin \left( \frac{2K(\kappa)}{\pi} \zeta_b - 3K(\kappa) \mid \kappa \right)
\]

\[
\equiv \sqrt{\kappa} \cos \left( \frac{2K(\kappa)\zeta_b}{\pi} \mid \kappa \right),
\]

(23)

where we used the standard notation \( \text{pq} \equiv \text{pn}/\text{qn} \) (with \( p \) and \( q \) either \( c, s, \) or \( d \)) and the identities \([11] \) \( \sin(u - 3K) \equiv \sin(u + K) \equiv \text{cd}(u) \), with \( u \equiv 2K(\kappa)\zeta_b/\pi \) and we used the 4K-periodicity of \( \sin \).

Equation (23) yields the poloidal angular velocity

\[
\dot{\vartheta} = -\dot{\vartheta}_c \sqrt{1 - \kappa \sin^2 \left( \frac{2K(\kappa)\zeta_b/\pi}{\kappa} \right)}
\]

\[
\equiv -\dot{\vartheta}_c \sqrt{1 - \kappa^{-1} \sin^2 \frac{\vartheta}{2}},
\]

(24)

where \( \dot{\vartheta}_c \) is defined in Eq. [19] and we used the relations \([19] \). Figure 3 shows the normalized poloidal angle \( \vartheta/\pi \) versus the normalized bounce angle \( \zeta_b/\pi \) for various values of \( \kappa < 1 \). In the standard deeply-trapped approximation \( (\kappa \ll 1) \) \( \vartheta \approx \vartheta_b \cos \zeta_b \) is shown by the solid curve.

### B. Transit angle for passing particles

Next, the transit angle \( \zeta_t \) for passing particles \( (\kappa > 1) \) is defined as

\[
\zeta_t \equiv \frac{\omega_t}{2\sqrt{\kappa}} \int_0^{\vartheta} \frac{d\vartheta'}{\sqrt{1 - \kappa^{-1} \sin^2 \vartheta'/2}}
\]

\[
= \frac{\pi}{K(\kappa)} \int_0^{\vartheta/2} \frac{d\varphi}{\sqrt{1 - \kappa^{-1} \sin^2 \varphi}}
\]

\[
= \frac{\pi}{K(\kappa)} \sin^{-1} \left( \sin \frac{\vartheta}{2} \mid \kappa^{-1} \right),
\]

(25)

which can be easily inverted to give

\[
\sin \frac{\vartheta}{2} = \sin \left( \frac{K(\kappa^{-1})\zeta_t}{\pi} \mid \kappa^{-1} \right)
\]

\[
\equiv \sqrt{\kappa} \sin \left( \frac{K(\kappa)\zeta_t}{\pi} \mid \kappa \right),
\]

(26)

with \( \vartheta = \pi \) when \( \zeta_t = \pi \) (for all values of \( \kappa > 1 \)) and we used \( \sin(\sqrt{\kappa} u|\kappa^{-1}) = \sqrt{\kappa} \sin(u|\kappa) \) and \( K(\kappa^{-1}) = \sqrt{\kappa}K(\kappa) \). We note that the definition (25) yields the correct poloidal angular velocity

\[
\dot{\vartheta} = \dot{\vartheta}_c \cos \left( \frac{K(\kappa)\zeta_t/\pi}{\kappa} \right)
\]

\[
\equiv \dot{\vartheta}_c \sqrt{1 - \kappa^{-1} \sin^2 \frac{\vartheta}{2}},
\]

(27)

which is consistent with the definition of the transit action \([13] \). Figure 4 shows the normalized poloidal angle \( \vartheta/\pi \) versus normalized transit angle \( \zeta_t/\pi \) for various values of \( \kappa^{-1} < 1 \). Note that in the energetic-passing limit \( \kappa^{-1} \ll 1 \), we find \( \dot{\vartheta} \approx \dot{\vartheta}_t \) (shown by a solid line in Fig. 4).
FIG. 4: Normalized poloidal angle $\vartheta/\pi$ versus normalized transit angle $\zeta_1/\pi$ for $\kappa = 5$ (solid curve), 1.05 (dashed curve), and 1.0001 (dotted curve). In the energetic-passing limit ($\kappa^{-1} \ll 1$), we find $\vartheta \simeq \zeta_1$ (solid curve).

V. CANONICAL PARALLEL COORDINATES

In this Section, we derive suitable expressions for the canonical parallel coordinates $(s, p_\parallel)$, which are required to satisfy (with $ds \simeq R_\parallel \, d\vartheta$) the canonical condition

$$\{s, p_\parallel\} \equiv \frac{\partial s}{\partial \zeta} \frac{\partial p_\parallel}{\partial J} - \frac{\partial s}{\partial J} \frac{\partial p_\parallel}{\partial \zeta} \equiv \frac{(E - \mu B_c)}{p|e\sqrt{K}} \left( \frac{\partial p_\parallel}{\partial \chi} \frac{\partial E}{\partial \vartheta} - \frac{\partial \vartheta}{\partial \chi} \frac{\partial p_\parallel}{\partial E} \right) = 1 \tag{28}$$

for both trapped and transit particles, where $\zeta \equiv 2\pi \chi [\alpha(\kappa)/|K(\kappa)|]$ for trapped-particle ($\alpha = 1$) and passing-particle ($\alpha = 1/2$) orbits. In Eq. (28), we also made use of the identity $R_\parallel|\omega_\parallel| \equiv (E - \mu B_c)/(p|e\sqrt{K})$, which follows from the definitions (3)-(6).

A. Parallel coordinates for trapped particles

For a trapped particle, using Eq. (23), the parallel momentum $p_\parallel$ is defined as

$$p_\parallel = -p_{\parallel|e} \sqrt{1 - \kappa^{-1}} \sin^2 \vartheta/2 \equiv -p_{\parallel|e} \sqrt{1 - \kappa} \, \vartheta_b \left( \frac{\vartheta_b}{\kappa} \right). \tag{29}$$

Figure 5 shows the normalized parallel momentum $p_\parallel/(m R_\parallel \omega_\parallel)$ versus the normalized bounce angle $\zeta_b/\pi$ for $\kappa = 0.1$ (solid curve), 0.8 (dashed curve), and 0.999 (dotted curve). In the deeply-trapped limit ($\kappa \ll 1$), $p_\parallel \simeq -p_{\parallel|e} \sin \zeta_b$ (solid curve).

and

$$\frac{\partial \vartheta}{\partial \chi_b} = -2 \sqrt{\kappa(1 - \kappa)} \, \vartheta_b \left( \frac{\vartheta_b}{\kappa} \right). \tag{30}$$

Next, we verify that the parallel coordinates $\vartheta(E, \chi_b)$ and $p_\parallel(E, \chi_b)$, defined by Eqs. (29) and (30), satisfy the canonical condition (28). First, using Eq. (29), we obtain

$$\frac{\partial \vartheta}{\partial \chi_b} = -2 \sqrt{\kappa(1 - \kappa)} \, \vartheta_b \left( \frac{\vartheta_b}{\kappa} \right). \tag{31}$$

By combining Eqs. (30)-33 into Eq. (28), we obtain

$$\{s, p_\parallel\}_b = \frac{\partial}{\partial \kappa} \left[ \kappa \left( (1 - \kappa) \, \vartheta_b \left( \frac{\vartheta_b}{\kappa} \right) \right) \right] = 1, \tag{34}$$

where we used the identity $(1 - \kappa) \, \vartheta_b \left( \frac{\vartheta_b}{\kappa} \right) = 1$ obtained from Eq. (19).

B. Parallel coordinates for passing particles

For a passing particle, using Eq. (26), the parallel momentum $p_\parallel$ is

$$p_\parallel = p_{\parallel|e} \, d\vartheta \left( \frac{K(\kappa^{-1}) \, \frac{\vartheta}{\kappa}}{\kappa^{-1}} \right) \equiv p_{\parallel|e} \, d\vartheta \left( \frac{K(\kappa)}{\kappa} \right), \tag{35}$$

where $p_{\parallel|\text{min}} \equiv p_{\parallel|e} \sqrt{1 - \kappa^{-1}}$ when $\vartheta = \pi$. The modulation in parallel momentum

$$\Delta p_\parallel = p_{\parallel|e} \left( 1 - \sqrt{1 - \kappa^{-1}} \right) = 2 \, m \, R_\parallel|\omega_\parallel | \left( \sqrt{\kappa - \sqrt{\kappa^{-1}}} \right) \tag{36}$$

decreases with increasing values of \( \kappa \). Figure 6 shows the normalized parallel momentum \( p_\parallel / (m R_\parallel \omega_\parallel) \) versus the normalized transit angle \( \zeta_\text{t}/\pi \) for various values of \( \kappa > 1 \).

We now verify that the parallel coordinates \( \vartheta(E, \chi_\text{t}) \) and \( \rho_\parallel E, \rho_\parallel \), defined by Eqs. (26) and (35), satisfy the canonical condition (28). First, using Eq. (26), we obtain

\[
\frac{\partial \vartheta}{\partial \chi_\text{t}} = 2 \sqrt{\kappa} \text{cn},
\]

and

\[
\frac{\partial \vartheta}{\partial E} = \frac{\sqrt{\kappa}}{(E - \mu B_\varphi)} \left[ \text{sd} + \text{nd} \left( 2 \kappa \frac{\partial \text{sn}}{\partial \kappa} \right) \right].
\]

Next, using Eq. (35), we obtain

\[
\frac{\partial \rho_\parallel}{\partial \chi_\text{t}} = - \rho_\parallel E \text{dn sn},
\]

and

\[
\frac{\partial \rho_\parallel}{\partial E} = \frac{\rho_\parallel E}{2 (E - \mu B_\varphi)} \left( \text{cn} + 2 \kappa \frac{\partial \text{cn}}{\partial \kappa} \right).
\]

By combining Eqs. (37)-(40) into Eq. (28), we obtain

\[
\{s, \rho_\parallel\}_\text{t} = \frac{\partial}{\partial \kappa} \left[ \kappa \left( \text{sn}^2 + \text{cn}^2 \right) \right] = 1,
\]

which follows from Eq. (19).

C. Phase portrait

We have demonstrated in Eqs. (34) and (41) that the parallel coordinates \( (s, \rho_\parallel) \), expressed in terms of Jacobi elliptic functions, are valid canonical coordinates for the trapped-particle and passing-particle guiding-center orbits.

VI. TOROIDAL GUIDING-CENTER DYNAMICS

In this Section, we discuss the guiding-center dynamics in the toroidal direction (i.e., the direction of axisymmetry) and its implications on the canonically-conjugate drift action. So far, the toroidal angle \( \phi \) was considered fixed, which enabled a study of the trapped and passing guiding-center orbits projected onto the poloidal plane, and the magnetic flux \( \psi \) was assumed to be frozen on the bounce-transit time scale.

The axisymmetry of the tokamak magnetic geometry implies that the toroidal canonical momentum (or drift action)

\[
P_\phi = - \frac{e}{c} \psi + p_\parallel B_\phi \equiv - \frac{e}{c} \psi_\star
\]

is conserved, where \( B_\phi \approx B_0 R \) is approximately constant.

A. Trapped-particle guiding-center orbits

For a trapped-particle guiding-center orbit, this conservation law is expressed as \( \psi_\star \equiv \psi_0 \) in terms of the magnetic flux \( \psi_0 \) at the bounce points, so that Eq. (42) becomes

\[
\psi - \rho_\parallel B_\phi \equiv \psi_0,
\]
where \( \rho_{||} \equiv p_{||}/(m\Omega) \). By substituting the Taylor approximation \( \psi \simeq \psi_0 + \Delta r \ (\epsilon_0 B_0/q_0) \), the normalized radial deviation \( \Delta \epsilon_b \equiv \epsilon - \epsilon_0 \) (from the magnetic surface \( \psi \equiv \psi_0 \)) is expressed as

\[
\Delta \epsilon_b \simeq \frac{q_0 \rho_{||}}{\epsilon_0} = -2 \delta \sqrt{\kappa (1 - \kappa)} \text{sd} \left( 2K(\kappa) \frac{\zeta_b}{\pi} \bigg| \kappa \right),
\]

where, using Eq. (8), we have defined the trapped-orbit parameter

\[
\delta \equiv \frac{q_0^2 \omega_{||}}{\epsilon_0 \Omega_0} = \frac{q_0}{\sqrt{2\epsilon_0}} \frac{\rho_0}{R}.
\]

The maximum radial deviation (44) is \( (\Delta \epsilon_b)_{\text{max}} = 2\delta \sqrt{\kappa} \leq 2\delta \).

A trapped-particle guiding-center orbit can be projected onto the normalized poloidal plane \( (\tau \equiv x/R, \varsigma \equiv z/R) \) and represented as

\[
\begin{align*}
\tau(\zeta_b, \kappa) &= 1 + \left( \epsilon_0 + \Delta \epsilon_b \right) \cos \vartheta(\zeta_b, \kappa) \\
\varsigma(\zeta_b, \kappa) &= \left( \epsilon_0 + \Delta \epsilon_b \right) \sin \vartheta(\zeta_b, \kappa)
\end{align*}
\]

Figure 8 shows the trapped (banana) guiding-center orbits for \( (\epsilon_0, \delta) = (0.5, 0.1) \) for various values of \( \kappa < 1 \), with the magnetic surface \( \psi = \psi_0 \) shown as a dashed circle. We note that, in the simple orbit topology considered here, a trapped-particle orbit does not enclose the magnetic axis [13].

**B. Passing-particle guiding-center orbits**

For a passing-particle guiding-center orbit, the conservation law (43) may be expressed in terms of the magnetic flux \( \psi \equiv \psi_t \) at the inside equatorial midplane (at \( \vartheta = \pi \)). By using the Taylor approximation \( \psi \simeq \psi_t + \Delta r \ (\epsilon_t B_0/q_t) \), the normalized radial deviation \( \Delta \epsilon_t \equiv \epsilon - \epsilon_t \) (from the magnetic surface \( \psi \equiv \psi_t \)) is expressed as

\[
\Delta \epsilon_t \equiv 2\delta \left[ \sqrt{\kappa} \text{dn} \left( K(\kappa^{-1}) \frac{\zeta_t}{\kappa^{-1}} \bigg| \kappa^{-1} \right) - \sqrt{\kappa - 1} \right],
\]

where orbit parameter (45) is now evaluated at \( \psi_t \) (note that \( \Delta \epsilon_t \) vanishes on the inside equatorial plane where \( p_{||} = p_{||\text{min}} = p_{||c} \sqrt{1 - \kappa^{-1}} \)). The maximum radial deviation (47) is \( (\Delta \epsilon_t)_{\text{max}} = 2\delta \sqrt{\kappa - 1} \), i.e., the largest radial deviation for a passing-particle orbit occurs for marginally-passing particles \( (\kappa - 1) \ll 1 \).

A passing-particle guiding-center orbit can be projected onto the normalized poloidal plane and represented as

\[
\begin{align*}
\tau(\zeta_t, \kappa) &= 1 + \left( \epsilon_t + \Delta \epsilon_t \right) \cos \vartheta(\zeta_t, \kappa) \\
\varsigma(\zeta_t, \kappa) &= \left( \epsilon_t + \Delta \epsilon_t \right) \sin \vartheta(\zeta_t, \kappa)
\end{align*}
\]

Figure 9 shows the passing guiding-center orbits for \( (\epsilon_t, \delta) = (0.5, 0.1) \) for various values of \( \kappa > 1 \), with the magnetic surface \( \psi = \psi_t \) shown as a dashed circle.

**C. Bounce-averaged toroidal drift frequency**

The bounce-averaged toroidal drift frequency [9]

\[
\omega_d \simeq \left\langle \phi - q \dot{\varphi} \right\rangle \equiv - \frac{c\mu}{e} \left\langle \frac{\partial B}{\partial \psi} \right\rangle
\]

(49)
is approximated (ignoring magnetic shear) as

\[
\omega_d \simeq \frac{2\mu B_0}{m\Omega_0} \frac{q}{\epsilon R^2} \left( \frac{E(\kappa)}{K(\kappa)} - \frac{1}{2} \right),
\] (50)

where we used \( \partial B/\partial \psi \) and \( \partial \kappa/\partial \epsilon \). The toroidal drift frequency (50) can thus be approximately expressed as

\[
\omega_d \simeq \frac{q_\ast \omega_b}{\epsilon \Omega_0} \frac{\partial}{\partial \epsilon} \left( \frac{J_b}{m R^2} \right). \tag{52}
\]

Hence, the toroidal drift reversal occurs when the radial derivative of the bounce action (12) changes sign.

VII. SUMMARY

The analytical formulas presented in this paper provide compact expressions in terms of the Jacobi elliptic functions \((cn, sn, dn)\) that describe trapped-particle \((\kappa < 0)\) and passing-particle \((\kappa > 0)\) guiding-center orbits in simple axisymmetric tokamak geometry for arbitrary bounce-transit parameter \(\kappa\). The parallel coordinates \((s, p_s)\) derived in Sec. VII which satisfy the canonical condition \(54\) for trapped particles and \(44\) for passing particles, guarantee that the bounce-center transformation \(\bar{E}\) in axisymmetric tokamak geometry can be explicitly carried out beyond the deeply-trapped and energetic-passing limits \(\overline{E}\).

Applications of the compact Jacobi-elliptic representations of trapped-particle and passing-particle guiding-center orbits include the derivation of bounce-center-averaged fluctuating potentials in bounce-kinetic theory \(\overline{E}\) and the derivation of a bounce-center Fokker-Planck collision operator \(\overline{E}\) beyond the zero-banana-width approximation.
