Minimal dark energy models, described by the same number of free parameters of the standard cosmological model with cold dark matter plus a cosmological constant to parameterize the dark energy component, constitute very appealing scenarios which may solve long-standing, pending tensions. On the one hand, they alleviate significantly the tension between cosmological observations and the presence of one sterile neutrino motivated by the short-baseline anomalies: we obtain a 95% CL cosmological bound on the mass of a fully thermalized fourth sterile neutrino \( M_{\nu_4} \) equal to \( m_{\nu_4} < 0.65 \) (1.3) eV within the PEDE (VM) scenarios under consideration. Interestingly, these limits are in agreement with the observations at short-baseline experiments, and the PEDE scenario is favored with respect to the ΛCDM case when the full data combination is considered. On the other hand, the Hubble tension is satisfactorily solved in almost all the minimal dark energy schemes explored here. These phenomenological scenarios may therefore shed light on differences arising from near and far universe probes, and also on discrepancies between cosmological and laboratory sterile neutrino searches.

I. INTRODUCTION

The standard cosmological model describes surprisingly well the present universe, which contains mostly dark matter (the ingredient responsible for the growth of the structures we observe today) and dark energy (the largely unknown engine for the current cosmic acceleration). The most economical nature of the dark energy component relies on the introduction of a Cosmological Constant (CC) in Einstein’s equations, which has a constant equation of state \( w \) with a value \( w = -1 \). This assumption leads to the so-called ΛCDM model [1], which is the basis of most cosmological analyses. Nevertheless, when computing the vacuum energy density of dark energy from a quantum field theory approach, the expected value for the CC exceeds the measured one by more than 120 orders of magnitude, leading to the so-called Cosmological Constant Problem [2]. In the absence of a fundamental symmetry which sets the vacuum energy to very small values, it is appropriate to look for alternative physical mechanisms, such as quintessence [3–10], modified gravity [11–34], and other exotic scenarios [35–51]. On the other hand, any extension of the Λ-cosmology in terms of extra degrees of freedom may increase the reduced \( \chi^2 \) of the best fit in the extended cosmological scenario compared to the minimal Λ-cosmology, and thereby, a question mark is still left in terms of the observational fittings. Therefore, the construction of a different minimal cosmological model, alternative to the standard one with a CC, is very important. Keeping in mind the idea of a minimal cosmology, the authors of Ref. [52] proposed a possible alternative framework based on phenomenological grounds, namely, the Phenomenologically Emergent Dark Energy (PEDE) model. On the other hand, the Vacuum Metamorphosis (VM) model, relying on a late-time gravitational phase transition, is also a possible minimal alternative based on the first principles [53–55]. These scenarios have exactly the same number of free parameters as the spatially flat ΛCDM cosmology and they have been shown to provide an excellent solution to the well-known \( H_0 \) tension; see recent reviews in this direction in Refs. [56–59].

On another note, in the Standard Model (SM) of elementary particles, from the invisible Z-boson width at the Large Electron Positron collider (LEP) at CERN [60], we know that there are three active neutrinos (and antineutrinos) sensitive to weak interactions: \( \nu_e (\bar{\nu}_e), \nu_\mu (\bar{\nu}_\mu) \) and \( \nu_\tau (\bar{\nu}_\tau) \). However, as in the cosmological constant case aforementioned, in which there is no known fundamental symmetry imposing a very small vacuum energy, there is also no known fundamental reason in nature establishing the number of sterile neutrino species, i.e. right-handed fermions which do no participate in weak interactions.

Short Baseline (SBL) oscillation experiments [61–63], corresponding to a small ratio of the propagation distance between source and detector and the neutrino energy (e.g. distances of \( \sim 0(10) \) m for energies of a
few MeV), have led to observational anomalies \[64\] that can be explained in a satisfactory way in terms of neutrino oscillations with \(\Delta m^2 \gtrsim 1 \text{ eV}^2\). This mass splitting is much larger than the solar and atmospheric ones that emerge from three-neutrino oscillation observations (the atmospheric squared-mass difference being \(\Delta m^2_{\odot} \approx 2.55 \times 10^{-3} \text{ eV}^2\) and the solar one being \(\Delta m^2_{\odot} \approx 7.5 \times 10^{-5} \text{ eV}^2\) \[73\]), which require at least two massive neutrino eigenstates. Since the sign of the largest mass splitting remains unknown, two mass orderings are possible, called normal \((m_1 < m_2)\) and inverted \((m_3 < m_1)\). In the normal ordering, the sum of the neutrino masses must satisfy \(\sum m_\nu \gtrsim 0.06 \text{ eV}\), while in the inverted ordering, \(\sum m_\nu \gtrsim 0.10 \text{ eV}\), with \(\sum m_\nu\) representing the sum of the three light neutrino masses.

In order to explain SBL neutrino oscillation data, one possibility is to invoke the existence of a fourth sterile neutrino state with a mass \(m_s \sim 1 \text{ eV} \) \[74\] \[76\], therefore heavier than the active neutrino states. Short-baseline data hint towards eV sterile neutrino masses and relatively large mixing angles with the active neutrinos \[61\] \[62\] \[75\] \[76\] \[85\] \[93\]. These large mixing angles would ensure the thermalization of sterile neutrinos in the early universe, and since they where relativistic before CMB decoupling, sterile neutrinos contribute to dark radiation, parameterized by \(N_{\text{eff}}\), which encodes the number of relativistic degrees of freedom in the early universe. Within the standard models of both particle physics and cosmology, \(N_{\text{eff}} = 3.044\); see the recent Refs. \[94\] \[96\] and references therein. If the light sterile neutrino needed to explain the short baseline anomalies existed in nature, it would be copiously produced in the very early universe via mixing with the active neutrinos, leading to a value of \(N_{\text{eff}} \approx 4 \) \[97\] \[98\]. Cosmology can therefore provide an independent test to weigh and bound the sterile neutrino masses and abundances, respectively. Current cosmological bounds on sterile massive species provide \(N_{\text{eff}} < 3.29\) and \(m_{\text{eff, sterile}} < 0.65 \text{ eV}\) (assuming \(m_s < 10 \text{ eV}\), from Planck TT,TE,EE+lowE+lensing+BAO at 95% CL) \[11\] \[12\] \[13\] \[14\] \(\text{(see also Refs.} \[85\] \[88\] \[92\] \[99\] \[105\])\), leaving a little room for the interpretation of the SBL results in terms of a fourth sterile neutrino. While this tension can be reduced in extensions of the minimal ΛCDM model including extra interactions and other exotic physics, it is mandatory to test if minimal dark energy models can alleviate this controversy.

The question we would like to address here is whether these minimal cosmological scenarios, containing the very same number of degrees of freedom of the canonical ΛCDM, can alleviate the SBL–cosmology sterile neutrino tension along with a resolution to the Hubble constant tension at the same time. We shall explore two possible minimal schemes, the Phenomenologically Emergent Dark Energy (PEDE) and the Vacuum Metamorphosis (VM) models, that modify only late time physics, leaving unchanged the standard cosmological history at the inflationary, radiation domination, recombination, CMB decoupling and structure formation periods. We recall that the aforementioned minimal cosmological scenarios have provided an excellent solution to the Hubble constant tension even in presence of the active neutrinos, see Refs. \[52\] \[107\] \[108\] for PEDE alone and its extension with neutrinos and Refs. \[109\] \[111\] for VM and its various extensions with neutrinos. The inclusion of the sterile neutrino into these minimal cosmological scenarios, however, is a new ingredient in this article, which significantly differs from their earlier investigations. To constrain these cosmological scenarios, we have made use of a series of observational probes such as Cosmic Microwave Background (CMB) temperature and polarization angular power spectra \[112\] \[113\] and CMB lensing \[114\] from Planck 2018, Baryon acoustic oscillations (BAOs) from different astronomical surveys, namely from 6dFGS \[115\], SDSS-MGS \[116\], and BOSS DR12 \[117\], Pantheon sample \[118\] of the Supernovae Type Ia, a measurement of the Hubble constant from the SH0ES (Supernovae, \(H_0\), for the Equation of State) collaboration \[119\] and finally SBL neutrino oscillations data, see Section III for details.

The structure of the paper is as follows. Section II contains a brief description of the two minimal dark energy scenarios considered here. Section III is devoted to explain the cosmological and neutrino oscillation measurements exploited to obtain the results presented and discussed in Section IV. We summarize the main findings in Section V.

### II. MINIMAL DARK ENERGY MODELS

According to the observational evidence, our universe is almost homogeneous and isotropic at the largest scales. This geometric configuration is well described by the...
Friedmann-Lemaître-Robertson-Walker metric:

\[
ds^2 = -dt^2 + a^2(t) \left[ \frac{dr^2}{1 - kr^2} + r^2(d\theta^2 + \sin^2 \theta d\phi^2) \right]
\]

expressed in terms of the comoving coordinates \((t, r, \theta, \phi)\), where \(a(t)\) (hereafter we shall use \(a\)) is the expansion scale factor of the universe. Here, \(k\) is a constant representing the curvature of the universe. For \(k = +1, 0, -1\), we respectively have a closed, flat and open universe. We assume that the gravitational interaction follows Einstein’s general relativity and the matter distribution within the universe is minimally coupled to gravity. Along with the normal baryons and relativistic radiation, pressureless dark matter, a dark energy component, we also assume that sterile neutrinos are also present. Furthermore, we restrict ourselves to the simplest cosmological scenario in which none of the components in the matter sector interacts with any other component. Under these assumptions, and considering a flat universe \((i.e. \ k = 0)\), one can write down the Friedmann equations as follows:

\[
H^2 = \frac{8\pi G}{3} \sum \rho_i;
\]

\[
2\dot{H} + 3H^2 = -8\pi G \sum p_i,
\]

where \(\rho_i, p_i\) are respectively the energy density and pressure of the \(i\)-th fluid component. Under the assumption of no interactions between any two fluids, all the components enjoy the usual conservation equation, \(\dot{\rho}_i + 3H(1 + w_i)\rho_i = 0\), where \(w_i = p_i/\rho_i\). For the dark energy fluid, the conservation equation takes the form \(\dot{\rho}_{DE} + 3H(1 + w_{DE})\rho_{DE} = 0\), where \(w_{DE} = p_{DE}/\rho_{DE}\) is the equation-of-state parameter of dark energy. Solving the conservation equation for dark energy, one gets

\[
\rho_{DE} = \rho_{DE,0} \exp \left[ 3 \int_0^z \frac{1 + w_{DE}(z')} {1 + z'} dz' \right],
\]

where \(\rho_{DE,0}\) is the present value of the dark energy density. In the following subsections we describe two minimal dark energy models, which both are described by the same number of free parameters as the ΛCDM framework.

A. Phenomenologically Emergent Dark Energy (PEDE)

The PEDE model was originally introduced in Ref. [52] as an alternative to the standard ΛCDM model. Although it has exactly the same number of free parameters as the ΛCDM model, interestingly, in this scenario the DE equation of state has a dynamical character, contrary to the ΛCDM scenario in which the cosmological constant acting as the DE candidate has a constant equation of state. Within this model, the Hubble constant value can be increased without any extra degrees of freedom with respect to the cosmological constant case (see also [107]). In this new cosmological model, the dark energy density with respect to the current critical energy density is parametrized as

\[
\frac{\rho_{DE}}{\rho_{crit,0}} = \tilde{\Omega}_{DE}(z) = \Omega_{DE,0} \left[ 1 - \tanh(\log_{10}(1 + z)) \right],
\]

where \(\Omega_{DE,0}\) is the present value of the dark energy density parameter \(\Omega_{DE}\). By construction, this dark energy model has a dynamical evolution, contrary to the time-independent cosmological constant \(\Lambda\) in the context of the ΛCDM model. Consequently, the cosmological scenario described by this PEDE model has exactly the same number of free parameters than the standard ΛCDM model, but a different phenomenology. Making use of the conservation equation for the dark energy component, one could derive the dark energy equation-of-state as

\[
w_{DE}(z) = -1 + \frac{1}{1 + z} \times \frac{d \ln \tilde{\Omega}_{DE}(z)} {dz},
\]

which, for the model in Eq. (5), takes the form:

\[
w_{DE}(z) = -1 - \frac{1}{3 \ln 10} \times \left[ 1 + \tanh(\log_{10}(1 + z)) \right].
\]

Notice that \(w_{DE}\) asymptotically converges to \(-1\) in the far future, while it currently has a phantom nature: \(w_{DE}(z = 0) = -1 - 1/(3 \ln 10)\).

B. The Vacuum Metamorphosis model

The Vacuum Metamorphosis (VM) model, inspired on quantum gravitational effects, is based on a late-time gravitational phase transition [53–55]. This phase transition will take place when the Ricci scalar curvature \(R\) is of the order of the squared mass of the scalar field, \(m^2\), which determines the matter density today, \(\Omega_m\). As a consequence, the VM model should be regarded as minimal, since it has the same number of free parameters as the flat ΛCDM scenario. A further motivation in favor of this model is that it provides a possible solution to the \(H_0\) tension [109,111].

The expansion rate before and after the phase transition reads as [110]:

\[
\frac{H^2}{H_0^2} = \begin{cases} 
\Omega_m(1 + z)^3 + \Omega_r(1 + z)^4 + \Omega_k(1 + z)^2 - M \left\{ 1 - \left[ 3 \left(\frac{4\pi}{3\Omega_m}\right)^4 M(1 - M - \Omega_k - \Omega_r) \right]^{-1} \right\}, & \text{for } z > z_{ph}^t; \\
(1 - M - \Omega_k)(1 + z)^4 + \Omega_k(1 + z)^2 + M, & \text{for } z \leq z_{ph}^t,
\end{cases}
\]
where \( M = m^2/(12H_0^2) \) and \( \Omega_k = -k/H_0^2 \). The phase transition occurs at the redshift
\[
z_{t}^{ph} = -1 + \frac{3\Omega_m}{4(1 - M - \Omega_k - \Omega_r)}.
\]

Notice that in the original Vacuum Metamorphosis scenario described above, the mass \( M \) of the field, and consequently \( M \), are not completely free parameters, but they are related to the matter energy density as follows:
\[
\Omega_m = \frac{4}{3} \left[3M(1 - M - \Omega_k - \Omega_r)^3\right]^{1/4},
\]

obtained assuming that there is not a cosmological constant at high redshifts. In other words, before the phase transition, the universe behaves as one with matter, radiation, and spatial curvature, while after the phase transition it effectively has a radiation component, that rapidly redshifts away leaving the universe in a de Sitter phase. This first principles is therefore not nested with the \( \Lambda \)CDM scenario.

It is also possible to extend this VM scheme into a more general one, in which \( M \) is not further constrained by any relationship and a cosmological constant appears at high redshifts, as the vacuum expectation value of the massive scalar field. This model is dubbed as Elaborated Vacuum Metamorphosis (EMV) \cite{[119],[110]} and it is not minimal anymore. In this case we have to impose the additional conditions \( z_t^{ph} \geq 0 \) and \( \Omega_{DE}(z > z_t^{ph}) \geq 0 \). In this EVM case the effective equation of state of DE is \cite{[110]}:
\[
\begin{align*}
\Omega_{DE}(z) = -1 + \frac{1}{3} \frac{3\Omega_m(1 + z)^3 - 4(1 - M - \Omega_k - \Omega_r)(1 + z)^4}{3M + (1 - M - \Omega_k - \Omega_r)(1 + z)^4 - \Omega_m(1 + z)^3},
\end{align*}
\]

III. OBSERVATIONAL DATASETS AND METHODOLOGY

In this section we describe the cosmological probes and the statistical methodology used to extract the constraints from present cosmological observations, starting from the cosmological and neutrino oscillation datasets considered in our analyses.

1. Cosmic Microwave Background (CMB): The latest Cosmic microwave background (CMB) temperature and polarization angular power spectra \( plikTTTTEEE+lowl+lowE \) from Planck 2018 have been used \cite{[113],[112]}.  

2. Lensing: The CMB lensing reconstruction likelihood from Planck 2018 \cite{[113]} has also been used.  

3. Baryon acoustic oscillation (BAO) distance measurements: We include Baryon acoustic oscillations (BAOs) from different astronomical surveys, namely from 6dFGS \cite{[115]}, SDSS-MGS \cite{[116]}, and BOSS DR12 \cite{[117]}.  

4. Pantheon sample: The Pantheon \cite{[118]} sample of the Supernovae Type Ia has been included in the analyses.

5. Hubble constant, \( H_0 \) (R20): A Gaussian prior on the Hubble constant from the Supernovae, \( H_0 \), for the Equation of State (SHOES) collaboration yielding \( H_0 = 73.2 \pm 1.3 \) km/sec/Mpc at 68% CL \cite{[119]} has also been incorporated.  

6. SBL neutrino oscillations: We consider the posterior probability on \( m_\nu \) obtained with a combined Bayesian analysis of the data of the \( \nu_\mu \rightarrow \nu_e \) appearance experiments LSND \cite{[64]}, MiniBooNE \cite{[120]}, BNL-E776 \cite{[121]}, KARMEN \cite{[122]}, NOMAD \cite{[123]}, ICARUS \cite{[124]} and OPERA \cite{[125]}. We consider only SBL \( \nu_\mu \rightarrow \nu_e \) appearance data because the positive indication in favor of light sterile neutrinos given by the LSND and MiniBooNE \cite{[120]} data is currently the strongest one and has not been directly excluded by other experiments. The data of the other SBL \( \nu_\mu \rightarrow \nu_e \) appearance experiments constrain the mass and mixings of the sterile neutrino, leaving an allowed interval of masses around 1 eV (see Fig. 4a of Ref. \cite{[62]}).

Cosmological observables are computed with a modified version of CAMB \cite{[130]}. To derive bounds on the proposed scenarios, we modify the efficient and well-known  

\footnote{The current global fit of SBL neutrino oscillation data does not give reliable results because of a strong tension between the neutrino oscillation interpretations of appearance and disappearance data (see the reviews in Refs. \cite{[62],[63],[64],[120]}.}

\footnote{The recent results of the MicroBooNE experiment \cite{[127]} disfavor the interpretation of the MiniBooNE low-energy excess \cite{[120]} as a photon background \cite{[128],[129]} and strengthen the neutrino oscillation interpretation.}
TABLE I. Flat priors on various free parameters of the different cosmological scenarios explored here.

| Parameter          | Prior            |
|--------------------|------------------|
| $\Omega_b h^2$    | [0.005, 0.1]     |
| $\Omega_c h^2$    | [0.001, 0.99]    |
| $\tau$            | [0.01, 0.8]      |
| $n_s$             | [0.8, 1.2]       |
| $\log[10^{10} A_s]$ | [1.61, 3.91]  |
| $100\theta_{MC}$ | [0.5, 10]        |
| $N_{\text{eff}}$  | [0.05, 10]       |
| $m_{\text{light}}$ [eV] | [0.5]          |
| $m_s$ [eV]        | [0.1, 10]        |
| $M_{\text{vacuum}}$ | [0.5, 1]       |

We start here discussing the results within the PEDE scenario, and comparing them to those in other possible cosmologies. In Tables I and II we have summarized the constraints obtained from all possible datasets and their combinations. From the results depicted in Tab. II, we note that the limits on the sterile neutrino mass and also on the lightest active neutrino mass are mildly relaxed compared to the $\Lambda$CDM constraints shown in Tab. IV. This is a consequence of the negative value adopted by the dark energy equation of state within the PEDE framework, which is $w_{\text{DE}} < -1$ at very low redshifts (see Eq. (11)), and of the well-known strong degeneracy between the dark energy equation of state and the neutrino mass [134]. If $w_{\text{DE}}$ is allowed to vary, $\Omega_m$ can take very high values, as required when either the active or the sterile neutrino masses are increased. For all the data combinations shown in Tab. II, the sterile neutrino mass is unconstrained at 95% CL; therefore, the strong existing tension between cosmological bounds and the SBL fits is robustly alleviated. From the results shown in Tab. II one notes that not only the cosmological sterile neutrino mass bounds are weakened in the context of minimal dark energy models such as the PEDE one, but also the bounds on the active neutrino masses are considerably relaxed with respect to the ones obtained in the $\Lambda$CDM scheme. The combination of CMB and BAO observations provides a 95% CL limit of $m_{\text{light}} < 0.077$ eV, while within the standard cosmological picture the corresponding bound is $m_{\text{light}} < 0.041$ eV for the very same data combination. Interestingly, in one case, there is a (very) mild indication of a non-zero value for the lightest neutrino mass ($m_{\text{light}} = 0.090^{+0.043}_{-0.064}$ eV at 68% CL when combining CMB plus SNIa Pantheon data). These findings agree with previous results in the literature; see e.g. [108], where an indication for a non-zero neutrino mass with a significance of $2\sigma$ ($\sum m_\nu = 0.21^{+0.15}_{-0.14}$ eV) was found, always in the context of the PEDE scenario.

Within the PEDE model, the values of $N_{\text{eff}}$ are not shifted to larger values, as the 95% CL upper bounds on the effective number of relativistic degrees of freedom are very close to those computed within the canonical $\Lambda$CDM picture. For instance, $N_{\text{eff}} < 3.24$ eV at 95% CL for the CMB plus BAO data analyses. Therefore, one should still advocate some mechanism to suppress the thermalization of the sterile neutrino state in the early universe and its contribution to $N_{\text{eff}}$; see e.g. [102]. Among the large number of possible scenarios proposed in the literature, an incomplete list of possibilities includes exotic sterile neutrino interactions [100] [133] [140], a dark energy model with a redshift dependent equation of state [141], low reheating temperature scenarios [142] and lepton asymmetries [133] [145].

---

6 This bound results from the combination of CMB+BAO+Pantheon+Lensing data plus a prior on the Hubble constant plus Dark Energy Survey (DES) measurements.
In addition to the relief provided on the sterile neutrino tension, the PEDE scenario also offers a dark energy solution that alleviates the H0 tension [20]. Notice that within the PEDE minimal cosmology the value of H0 for Planck 2018 CMB + Lensing (H0 = 73.33 ± 1.44 km s⁻¹ Mpc⁻¹) is much larger than the one obtained within the ACDM framework (H0 = 66.51 ± 1.0 km s⁻¹ Mpc⁻¹) at also 68% CL; see previous findings in Refs. [52] [107] [108] [136]. It is crucial to stress that the larger value of the Hubble constant obtained in PEDE models is robust against different data combinations.

Still referring to the results obtained within the PEDE framework, Tab. III reports the constraints for the combined datasets, namely CMB+Lensing+BAO+Pantheon and CMB+Lensing+BAO+Pantheon+SBL for both a free value of N_eff and for the N_eff = 4 case. The latter case (i.e. N_eff = 4) refers to a fourth, fully thermalized, sterile neutrino state. These bounds can be compared to those resulting within the ACDM picture, shown in Tab. IV. Notice that the results we obtain for the case of a freely varying N_eff are almost similar to those discussed above, being the sterile neutrino mass unconstrained at 95% CL for the dataset CMB+Lensing+BAO+Pantheon. When combining this set of cosmological measurements with appearance SBL data, the limit on the sterile neutrino mass becomes tighter (m_s = 0.75 ± 0.06 eV at 68% CL for CMB+Lensing+BAO+Pantheon+SBL) and coincides with the region favoured by appearance SBL neutrino oscillation experiments, i.e. close to $\Delta m^2_{31} \sim 0.6 eV^2$ [77] [93], see the blue solid curve in Fig. 3. In such a case, the tension between SBL and cosmological estimates of the sterile neutrino mass is significantly alleviated.

Furthermore, we also notice that the value of

### TABLE II. Constraints on various free and derived parameters within the PEDE scenario. We report 68% and 95% CL limits. When the upper limit coincides with the upper prior range (see Tab. I), as in the case of m_s, we mark the parameter as “unconstrained”.

### Parameters

| Parameter | CMB | CMB + BAO | CMB + Lensing | CMB + Pantheon | CMB + Pantheon + SBL |
|-----------|-----|----------|--------------|---------------|----------------------|

| $r_{\text{drag}}$ [Mpc] | 104.7 ± 2.4 | 104.7 ± 2.4 | 104.5 ± 2.4 | 101.2 ± 2.4 | 105.9 ± 2.4 |

### TABLE III. Constraints on various free and derived parameters within the PEDE scenario, considering the combined datasets CMB+Lensing+BAO+Pantheon and CMB+Lensing+BAO+Pantheon+SBL. We present the cases where $N_{\text{eff}}$ is either freely varying (second and third columns), or fixed to $N_{\text{eff}} = 4$ (fourth and fifth columns).

In addition to the relief provided on the sterile neutrino tension, the PEDE scenario also offers a dark energy solution that alleviates the $H_0$ tension [20]. Notice that within the PEDE minimal cosmology the value of $H_0$ for Planck 2018 CMB + Lensing ($H_0 = 73.33 \pm 1.44$ km s⁻¹ Mpc⁻¹) is much larger than the one obtained within the ACDM framework ($H_0 = 66.51 \pm 1.0$ km s⁻¹ Mpc⁻¹) at 68% CL; see previous findings in Refs. [52] [107] [108] [136]. It is crucial to stress that the larger value of the Hubble constant obtained in PEDE models is robust against different data combinations.
the Hubble constant is considerably larger in the PEDE scheme than in the ACDM case: for CMB+Lensing+BAO+Pantheon dataset, we have $H_0 = 70.32^{+0.78}_{-0.69}$ km s$^{-1}$ Mpc$^{-1}$ for PEDE versus $H_0 = 67.60^{+0.51}_{-0.51}$ km s$^{-1}$ Mpc$^{-1}$ for ACDM, both at 68% CL, while for the CMB+Lensing+BAO+SBL dataset, we obtain $H_0 = 70.52^{+0.80}_{-0.60}$ km s$^{-1}$ Mpc$^{-1}$ for PEDE versus $H_0 = 67.69^{+0.45}_{-0.49}$ km s$^{-1}$ Mpc$^{-1}$ for ACDM, both at 68% CL. The large value of the Hubble constant obtained within the PEDE minimal dark energy scenario is depicted in Fig. 1. The upper panel shows in red and blue lines the 68% and 95% CL contours in the $m_s-H_0$ plane arising from the analyses of CMB+Lensing+BAO+Pantheon data in the ACDM and PEDE frameworks, respectively.

When the fourth sterile neutrino is assumed to be fully thermal, we notice significant changes in the constraints with respect to the case of a free $N_{\text{eff}}$. For instance, one can see that for CMB+Lensing+BAO+Pantheon, we have a 95% CL bound on $m_s$ in the PEDE scenario ($m_s < 0.65$ eV while it is unconstrained with free $N_{\text{eff}}$) which is still less tight than within the ACDM case ($m_s < 0.255$ eV). For CMB+Lensing+BAO+Pantheon+SBL, we get a tight constraint on $m_s$ leading to $m_s = 0.678^{+0.066}_{-0.067}$ eV (at 68% CL), slightly higher than the ACDM prediction $m_s = 0.621^{+0.057}_{-0.056}$ eV (68% CL). Such results are shown in Fig. 3. When SBL data are added into the analyses, the limit barely changes. Interestingly, the cosmological limit of $m_s < 0.65$ eV lies very close to the best fit from SBL appearance data, which points to $\Delta m_{12} \approx 0.55$ eV [78, 93]. As in the case of a freely varying $N_{\text{eff}}$, the addition of SBL measurements fixes a lower bound for $m_s$ of ~0.5 eV. In this $N_{\text{eff}} = 4$ scenario, the $H_0$ tension is strongly lifted, as the value obtained for the Hubble constant within the PEDE cosmology is $H_0 = 74.29^{+0.79}_{-0.85}$ km s$^{-1}$ Mpc$^{-1}$ at 68% CL (for CMB+Lensing+BAO+Pantheon) and $H_0 = 73.30^{+0.56}_{-0.54}$ km s$^{-1}$ Mpc$^{-1}$ at 68% CL (for CMB+Lensing+BAO+Pantheon+SBL). The effect of both a larger value of $m_s$ and $H_0$ obtained within the

The red (green) solid contours show the 68% and 95% CL constraints from CMB + Lensing + BAO + Pantheon + SBL data in the $\Lambda$CDM (PEDE) scenario. In this case, $N_{\text{eff}} = 4$.

The PEDE cosmology with respect to the canonical $\Lambda$CDM picture in the fully thermalized case is depicted in the lower panel of Fig. [1] where one can clearly notice that the green contours, corresponding to the PEDE minimal dark energy scenario, are shifted towards larger values of both $m_s$ and $H_0$.

Table [VI] shows the constraints for the Vacuum Metamorphism (VM) model described in the previous section for several data combinations. Notice that, as in the case of the PEDE scenario, the bounds on both the sterile neutrino and the active neutrino masses are significantly relaxed. Again, this is due to the large negative value adopted by the effective dark energy equation of state within the VM framework, $w_{\text{VMDE}}$, especially at low redshifts; see Eq. [11] and Refs. [109,111]. These findings agree with previous results in the literature; see e.g.

Ref. [11], in which the authors found a $3 \sigma$ evidence for a non-zero neutrino mass for the Planck+BAO+Pantheon dataset combination, always in the context of the VM scenario. Similarly also to the PEDE model, the values of $N_{\text{eff}}$ are barely changed with respect to the LCDM scheme, so that also in this case a suppression mechanism to avoid a complete sterile neutrino thermalization in the early universe would be required. As an example, $N_{\text{eff}} < 3.36$ eV at 95% CL for the CMB plus BAO data analyses. The tension on the Hubble constant is notably reduced for almost all the data combinations shown in Tab. [VI] for Planck 2018 CMB+Lens, $H_0 = 79.3^{+3.3}_{-3.2}$ km s$^{-1}$ Mpc$^{-1}$ at 68% CL. This resolution of the Hubble constant was also present in the PEDE model. However, the error bars now are much larger, due to the strong degeneracy between $H_0$ and the parameter $M$, which also depends on the $H_0$ value, as we discussed in Section [11B].

Instead, for the CMB+Pantheon data combination, we find a very low value of $H_0$ and a relatively low, non-zero preferred value for the sterile neutrino mass ($m_\nu = 1.09^{+0.29}_{-0.29}$ eV at 68% CL). These results agree with those of Ref. [11] and are due to the fact that the addition of SNIa no longer allows $\nu_{\mu,\tau}$ to adopt very large negative values at low redshifts. The overall effect is translated into both a smaller Hubble constant and a smaller sterile neutrino mass.

Table [VII] shows the results within the VM minimal cosmology for the combined datasets, i.e. CMB+Lens+BAO+Pantheon and CMB+Lens+BAO+Pantheon+SBL, considering the two possible scenarios, i.e. when $N_{\text{eff}}$ is treated as a free parameter and when $N_{\text{eff}} = 4$, referring to the case with a fourth, fully thermalized, sterile neutrino state. For both the choices of $N_{\text{eff}}$, the results on $m_\nu$ for cosmological data only and for the combined cosmological plus SBL data analyses are depicted in Fig. [V] see the dotted and solid green lines, respectively. The results for the case of a freely varying $N_{\text{eff}}$ are almost identical to the PEDE case, except for the active neutrino mass and the
Hubble constant, whose bounds and mean values are less constraining and higher than within the PEDE scheme, respectively. Notice again that the sterile neutrino mass is unconstrained at 95% CL when $N_{\text{eff}}$ is free and considering the case CMB+Lensing+BAO+Pantheon. For CMB+Lensing+BAO+Pantheon+SBL, $m_s$ is constrained to $m_s = 0.79^{+0.07}_{-0.01}$ eV (at 68% CL). The case of $N_{\text{eff}} = 4$, instead, has the 95% CL upper cosmological bound on $m_s$ equal to 1.3 eV. This value is in perfect agreement with the bounds obtained from SBL appearance experiments, see the dotted cyan line in Fig. 3 and compare them with the dashed black line. Notice that within the VM dark energy framework with $N_{\text{eff}} = 4$, the combination with SBL data tightens the cosmological upper limit; see the solid cyan line in Fig. 3.

The value of the Hubble constant for the VM scenario with $N_{\text{eff}} = 4$ is $H_0 = 77.18 \pm 0.80$ km s$^{-1}$ Mpc$^{-1}$ at 68% CL.

Even if it is not among the main focus of this study, as it is not a minimal dark energy scenario, however, we shall briefly comment on the constraints within the extended VM model, i.e. within the Elaborated Vacuum Metamorphosis (EVM), where a cosmological constant at high redshifts is included as the vacuum expectation value of the massive scalar field. Table VIII shows the equivalent to Tab. VII but within this EVM model. While the results concerning the sterile neutrino parameters and the Hubble constant are very similar to those previously shown in the original VM case, the CMB+Pantheon data analyses are very different, as in this case they offer the same relief to both the SBL-cosmological sterile neutrino and $H_0$ tensions, which is also visible in the remaining data combinations explored here. This is due to the fact that the dark energy equation of state after the phase transition is now effectively a free parameter and therefore the addition of the Pantheon sample of the SNIa data no longer fixes this parameter. Finally, Tab. X shows the constraints for the full data combination for both a freely varying value of $N_{\text{eff}}$ and for $N_{\text{eff}} = 4$. For the latter case, $m_s < 0.467$ eV and $m_{\text{light}} < 0.0647$ both at 95% CL and $H_0 = 76.27^{+0.56}_{-0.51}$ km s$^{-1}$ Mpc$^{-1}$ at 68% CL.

We close this section by reporting the results of a Bayesian model comparison analysis on the minimal dark energy scenarios considered here versus the $\Lambda$CDM case, considering both the freely varying $N_{\text{eff}}$ and the $N_{\text{eff}} = 4$ cases, for the complete dataset, namely, CMB+Lensing+BAO+Pantheon+SBL. This is shown in Table X (see the last column), where we present the Bayes factors $\ln B_{ij}$ to estimate the strength of the preference for any cosmological model $M_i$ (PEDE, VM, EVM) with respect to the base $\Lambda$CDM model. Notice that positive values favor the considered model, while negative ones prefer the $\Lambda$CDM case. For the scenarios with $N_{\text{eff}} = 4$, only PEDE offers an improvement with respect to the $\Lambda$CDM case when SBL appearance data are included together with the CMB+Lensing+BAO+Pantheon cosmological data. This is a consequence of the very similar results on $m_s$ between the PEDE fit without SBL data and the SBL constraints alone. In all the other cases, the $\Lambda$CDM model is favored with respect to the non-standard case. Notice that, according to Table X both the VM and EVM models are decisively disfavored by the considered data combinations, for both with free or fixed $N_{\text{eff}}$. Therefore, the PEDE phenomenological dark energy model may provide a better description of a number of cosmological, astrophysical, and, eventually, particle physics observations than the standard $\Lambda$CDM model.

V. CONCLUDING REMARKS

Tensions in the cosmological and neutrino oscillation measurements may have a common explanation. On the one hand, there is the well-known Hubble constant tension, a $4 - 6\sigma$ discrepancy between high and low redshift measurements of the Hubble constant. On the other hand, Short Baseline (SBL) neutrino oscillation experiments require the existence of a fourth sterile neutrino with a $\sim$ eV mass. However, this preferred value for the sterile neutrino mass is at odds with cosmological bounds, unless some unknown mechanism suppresses the thermalization of the new neutrino in the early universe and consequently reduce its contribution to $N_{\text{eff}}$. A sterile neutrino mass at the eV scale is indeed allowed when the thermalization leads to values of $N_{\text{eff}}$ very close to the standard value with three neutrinos, 3.044.

The assumption of an underlying cosmological scenario may bias the results on the different parameters, even if

| \( r_{\text{drag}} \) [Mpc] | 106.43 ± 1.8 | 106.43 ± 1.8 | 106.43 ± 1.8 | 106.43 ± 1.8 | 106.43 ± 1.8 |

The scenario is the canonical and minimal ADMCD picture, which nevertheless provides an excellent fit to almost all available current cosmological observations. It is therefore timely to investigate if there are alternative cosmological scenarios, as minimal as the ADMCD one, which not only provide a very good fit to observations, but also alleviate current tensions. In this regard, we have explored here two possible minimal dark energy models, that do not involve additional parameters with respect to the simple ADMCD scenario. One of them is constructed from a phenomenological ground while the other one emerges from first principles. We focused on the Phenomenologically Emergent Dark Energy (PEDE) and the Vacuum Metamorphosis (VM) models, which both modify only late time physics, and we have shown that such models can alleviate the current existing tensions in a significant way. After dedicated analyses and fits to cosmological and SBL appearance measurements, we have found that in the two scenarios when we assume \( N_{\text{eff}} \approx 4 \), the sterile neutrino mass bound is significantly relaxed, due to the large negative value that the effective dark energy equation of state is allowed to adopt in these minimal cosmologies. We have found that \( m_s < 0.65 (1.3) \) eV at 95% CL for the PEDE (VM) minimal dark energy scenario with \( N_{\text{eff}} = 4 \), respectively, when considering the most complete dataset combination. Notice, moreover, that the PEDE minimal scenario with \( N_{\text{eff}} = 4 \) is the only case that is favored with respect to the ADMCD model when the CMB + Lensing + BAO + Pantheon + SBL dataset is considered, while the VM and EVM models are strongly disfavored by data. When \( N_{\text{eff}} \) is free to vary, the sterile neutrino mass is basically unconstrained. In such case, however, the low value of \( N_{\text{eff}} \) close to 3 cannot be explained by the preferred active-sterile neutrino oscillation parameters, and some new mechanism or extra interaction is required to avoid the complete thermalization of the sterile neutrino state in the early universe. Last, but not least, the Hubble constant tension is strongly
Table X. Natural logarithm of the Bayes factors between the PEDE, VM, EVM minimal dark energy cosmologies and the $\Lambda$CDM case, considering the CMB+Lensing+BAO+Pantheon+SBL and either a free $N_{\text{eff}}$ or fixed $N_{\text{eff}} = 4$. Negative values prefer the $\Lambda$CDM scenario.

| Models                              | CMB+Lensing+BAO | CMB+Lensing+BAO |
|-------------------------------------|-----------------|-----------------|
|                                     | $+\text{Pantheon+SBL (}N_{\text{eff}} \text{ free)}$ | $+\text{Pantheon+SBL (}N_{\text{eff}} = 4)$ |
| PEDE                                | $-3.7$          | $+5.2$          |
| VM                                  | $-99.2$         | $-92.0$         |
| EVM                                 | $-38.1$         | $-19.3$         |

Table X shows the natural logarithm of the Bayes factors between different dark energy cosmologies and the $\Lambda$CDM case, considering various combinations of observations including CMB, lensing, BAO, Pantheon, and SBL. The Bayes factors are given for scenarios where $N_{\text{eff}}$ is either free or fixed at 4. Negative values indicate a preference for the $\Lambda$CDM scenario.

relieved also in both minimal dark energy scenarios.

With the growing sensitivity of the observational surveys that we witnessed over the past years, we are quite hopeful that future terrestrial searches for sterile neutrinos via oscillation experiments, and cosmological probes, testing the dark energy/radiation components and improving the current uncertainties on the Hubble parameter, will shed light on these tensions and also on the most favoured description of our universe.
