We study effects of strong impurities on the heat transfer in a coupled electron-phonon system in disordered graphene. A detailed analysis of the electron-phonon heat exchange assisted by such an impurity through the “resonant supercollision” mechanism is presented. We further explore the local modification of heat transfer in a weakly disordered graphene due to a resonant scatterer and determine spatial profiles of the phonon and electron temperature around the scatterer under electrical driving. Our results are consistent with recent experimental findings on imaging resonant dissipation from individual atomic defects.

I. INTRODUCTION

Dissipation of energy in electron transport in nanosstructures is of fundamental interest and of importance for applications. At low temperatures, the electric resistance is usually governed by elastic scattering off impurities. This resistance determines, in particular, the amount of Joule heat (for a given applied voltage or current). However, the heat dissipation requires an energy transfer from the electronic system to the “environment” — usually, to phonons. Thus, understanding the character of heat dissipation is a complex problem which requires an analysis of the electron-phonon scattering and, more generally, of the heat transfer in a system of electrons and phonons. Remarkably, the heat dissipation (i.e., the delivery of the energy gained by electrons in the electric field to phonons) may be even spatially separated from the region which dominates the resistance, as is the case for a ballistic point contact [11]. Recent work [2] has developed a highly sensitive experimental technique of thermal nanoimaging which utilises a superconducting quantum interference device (SQUID) located on a tip. This technique allows one to obtain a spatial temperature distribution with a resolution of order of micro-Kelvin in temperature and of order of nanometer in space.

The character of dissipation is of special interest in the case of graphene which represents an ultimate two-dimensional (2D) material. It was shown that at sufficiently high temperatures, the dominant electron-phonon relaxation processes are “supercollisions” assisted by impurities [3, 4], as has been also confirmed experimentally [5]. Related studies of the electron-phonon cooling rates were reported in Refs. [6] and [7].

A very recent experiment has reported remarkable results of thermal imaging of dissipation on graphene [8]. Specifically, the authors of Ref. [8] observed dissipation “hot spots” and provided strong evidence that they are associated with individual resonant impurities. It is indeed known that in graphene strong impurities induce resonances near the Dirac point and may crucially affect transport properties [9, 12]. The technique of Ref. [8] has permitted to observe “dissipation rings” in the thermal image which correspond to positions of the tip [2] at which the individual defect is at resonance (at given values of the back-gate voltage and the tip voltage).

The goal of this work is to study the effect of resonant impurities on the heat transfer in a coupled electron-phonon system in graphene. In general, the effect of a strong impurity on the energy dissipation around it may be twofold. First, the impurity modifies locally the electron-phonon collision rate, leading to “resonant supercollisions” that we explore in Sec. II. Remarkably, this effect is drastically enhanced in graphene due to the relativistic character of its spectrum, which leads to a strong singularity of the impurity-scattering waves: \( \Psi_{\text{scat}} \propto 1/r \) as compared to \( \Psi_{\text{scat}} \propto \ln r \) for conventional 2D semiconductors with a parabolic spectrum. As a result, the intensity of energy exchange between electrons and phonons is enhanced, the excessive momenta being transferred to the impurity. The effect shows up already within the Born approximation (with respect to the impurity potential), leading to “weak” supercollisions [3]. The corresponding phonon matrix element \( M(q) \propto \int d^2 r |\Psi_{\text{scat}}(iqr)|^2 \) slowly decays with \( q \) at \( q \gg k_F \): \( M(q) \propto 1/q \) and the electron-phonon heat flux scales as \( T^3 \delta^2 \) (here \( |\mathbf{k}| \) is the plane wave and \( \delta \ll 1 \) is the scattering phase). In this paper, we demonstrate that beyond the Born approximation, the matrix element decays much slower: \( M(q) \propto \int d^2 r |\Psi_{\text{scat}}(iqr)|^2 \Psi_{\text{scat}}(iqr) |^2 \ln(1/qR) \) (here \( R \) is the impurity size) and the heat flux dramatically increases with increasing temperature, scaling as \( T^5 \sin^4 \delta \) (up to logarithmic factors). For weak impurities, \( \delta \ll 1 \), this effect overrides the impact of Born-approximation supercollisions [3] at sufficiently large temperatures. For strong impurities with \( \delta \sim 1 \) the resonant contribution dominates the impurity-mediated heat flux at all temperatures.

The second effect of an individual impurity on the energy dissipation is a local modification of the electric field and current profiles and thus of the associated Joule...
heat. Such a modification of field by a scatterer is associated in the literature with the notion of “Landauer residual-resistivity dipoles” \[13\] [17]. Imaging techniques permit a direct observation of such dipoles by measurement of the spatial distribution of current and voltage on nanoscale \[18\] [19]. In Sec. III we formulate a heat-transfer model that takes into account both kinds of effects induced by an impurity and determine a local profile of electronic and phonon temperatures around a scatterer under electrical driving. As we show in Appendix A the effect of additional Joule heating due to “Landauer dipoles” is relatively small in 2D systems, so that the modification of heating near the impurity is predominantly due to the effect of the impurity on the electron-phonon scattering. The estimates of a characteristic magnitude of the effect for realistic experimental parameters, as well as a comparison to the experiment of Ref. \[8\] is presented in Sec. III B In Sec. IV we summarize our results. Throughout the paper, we set \( h = k_B = 1 \) in some intermediate formulas and restore these constants in final expressions.

II. SUPERCOLLISIONS ON RESONANT IMPURITIES

A. Impurities in graphene

We start with the \( 4 \times 4 \) Dirac Hamiltonian for graphene

\[
\hat{H} = v\hat{r}_3\hat{\sigma}k, \tag{1}
\]

where \( v \) is the Dirac velocity, \( \hat{r}_3 \) is the Pauli matrix acting in the valley space \((K, K')\) and \( \hat{\sigma} \) is the vector of Pauli matrices in the sublattice space \((A, B)\). Electronic states are given by vectors of amplitudes

\[
\psi = (\psi_{AK}, \psi_{BK}, \psi_{BK'}, \psi_{AK'})^T. \tag{2}
\]

Scattering of an electron with energy \( \epsilon = v|k| \) (wavevector \( k \) of the incident wave is counted from the Dirac point \( \alpha = K, K' \)) on a single impurity centered at position \( r = 0 \) is described by the wavefunction

\[
\psi_k(r) = [e^{ikr} + \hat{t}(\epsilon, r)] |k\alpha\rangle. \tag{3}
\]

Here \( \hat{t}(\epsilon, r) \) is the transfer matrix and the spinors \( |k\alpha\rangle \) depend on the direction \( \delta_k \) of the electron momentum:

\[
|kK\rangle = \frac{1}{\sqrt{2}} \left( 1, e^{i\delta_k}, 0, 0 \right)^T, \tag{4}
\]

\[
|kK'\rangle = \frac{1}{\sqrt{2}} \left( 0, 0, 1, -e^{i\delta_k} \right)^T. \tag{5}
\]

We consider the two types of impurity potential with the spatial extension smaller than the Fermi wavelength: “atomically sharp” (short-range) and “atomically smooth” (long-range on the scale of the lattice constant). The transfer matrix takes the form

\[
\hat{t}(\epsilon, r) = \frac{\hat{G}(\epsilon, r)\hat{U}}{1 - \hat{G}(\epsilon, 0)\hat{U}} \tag{6}
\]

and describes the s-wave scattering off impurity. For a short-range (long-range) impurity centered at the site of sublattice \( A \), the potential has the following matrix structure:

\[
\hat{U}_{sr} = 2U_0\hat{\Lambda}_{sr}, \quad \hat{U}_{tr} = U_0\hat{\Lambda}_{tr} \tag{7}
\]

with the amplitude \( U_0 \) and

\[
\hat{\Lambda}_{sr} = \begin{pmatrix} 1/2 & 0 & 0 & 1/2 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 1/2 & 0 & 0 & 1/2 \end{pmatrix}, \quad \hat{\Lambda}_{tr} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{pmatrix}. \tag{8}
\]

The Green function \( \hat{G} \) at energy \( \epsilon \) reads

\[
\hat{G}(\epsilon, r) = \int \frac{d^2k}{(2\pi)^2} e^{i\frac{\epsilon}{v}\hat{r}_3,\hat{\sigma}k} e^{ikr} = \frac{1}{4\epsilon v^2} \left[ \epsilon + v\hat{r}_3\hat{\sigma}(-i\partial_r) \right] H_0^{(1)}(\epsilon r/v), \tag{9}
\]

where \( H_0^{(1)}(z) \) is the Hankel function of the first kind. For finding the transfer matrix, we make use of the small-\( r \) expansion:

\[
\hat{G}(\epsilon, r \to 0) \simeq -\frac{1}{2\pi v} \left[ \frac{i\hat{r}_3 \hat{\sigma}r}{r^2} + \frac{\epsilon}{v} \left( \ln \frac{v}{\epsilon R} + \frac{i\pi}{2} \right) \right]. \tag{10}
\]

The limit \( \hat{G}(\epsilon, r \to 0) \) in the denominator of Eq. \( \[9\] \) is taken after the integration over the spatial region where the impurity potential is nonzero. For an isotropic impurity of small radius, the first term in Eq. \( \[10\] \) does not contribute to Eq. \( \[6\] \) because of the angular integration,

\[
\hat{G}(\epsilon, 0) \to -\frac{\epsilon}{2\pi v^2} \left( \ln \frac{v}{\epsilon R} + \frac{i\pi}{2} \right), \tag{11}
\]

where \( R \) is the ultraviolet scale (the radius of the scattering potential or the lattice constant, whichever is larger). Performing matrix operations, we obtain

\[
\hat{t}(\epsilon, r) \to \frac{4v^2 \sin \delta e^{-i\delta}}{\epsilon} \hat{G}(\epsilon, r)\hat{\Lambda}, \tag{12}
\]

where \( \hat{\Lambda} \) equals either \( \hat{\Lambda}_{tr} \) or \( \hat{\Lambda}_{sr} \) and the scattering phase \( \delta \) is governed by the strength of the impurity,

\[
\cot \delta = \frac{v}{cL} + \frac{2}{\pi} \ln \frac{v}{\epsilon |R|}, \tag{13}
\]

with the scattering length \( L \) given by

\[
L_{tr} = \frac{U_0}{4v}, \quad L_{sr} = \frac{U_0}{2v}. \tag{14}
\]
for the long-range or short-range case, respectively. For a
strong impurity, \( L \gg R \), the transfer matrix (13) acquires
a resonant energy dependence

\[
\sin^2 \delta \simeq \frac{\Gamma^2}{(\epsilon - \epsilon_{\text{res}})^2 + \Gamma^2} \tag{16}
\]

with the resonant energy

\[
\epsilon_{\text{res}} \simeq -\frac{\pi v}{2L \ln(L/R)} \tag{17}
\]

and the width

\[
\Gamma \simeq \frac{\pi^2 v}{4L \ln^2(L/R)} \ll |\epsilon_{\text{res}}|. \tag{18}
\]

In what follows, we refer to such impurities as resonant
ones; note that the stronger the impurity, the closer the
resonant energy to the Dirac point \( \epsilon_{\text{res}} \rightarrow 0 \) for \( U_0 \rightarrow \infty \)
and the sharper the resonance. Below, we will analyze
the electron-phonon interaction in the presence of impu-
rities and show that scattering off a resonant impurity
may strongly enhance the heat exchange between elec-
trons and phonons.

B. Impurity-assisted electron-phonon scattering

Let us now consider the matrix element of electron-
phonon scattering in graphene in the presence of an iso-
lated impurity. Since, by assumption, the impurity poten-
tial is strong, it cannot be treated perturbatively. In-
stead, we calculate phonon-induced scattering between
exact impurity-scattering states (3). Assuming two-
dimensional phonons with the phonon wavevector \( q \)
in the graphene plane, the matrix element of \( \exp(iqr) \) reads:

\[
M_{\alpha}^{k'}(q) = \langle k| \left[ e^{-ikr} + \hat{\ell} \right] (\epsilon, r) \rangle e^{i\hat{q}r} \left[ e^{ik're} + \hat{\ell}' \right] (\epsilon', r) \langle k' | \beta \rangle \tag{19}
\]

where \( \alpha, \beta \) denote the valleys.

We will focus on the case of large phonon momenta
\( q \gg k, k' \), when the spatial structure of the electronic
wavefunctions is irrelevant. The effect of impurity (a
supercollision [3]) can be represented as a sum of the two
terms:

\[
M^{(1)} = \frac{4v^2 \sin \delta}{\epsilon} \langle k| \left[ e^{i\hat{q}r} \hat{G}^\dagger (\epsilon, r) + e^{-i\hat{q}r} \hat{G} (\epsilon', r) \right] |k' \beta \rangle \tag{20}
\]

and

\[
M^{(2)} = \frac{16v^4 \sin^2 \delta}{\epsilon^2} \langle k| e^{i\hat{q}r} \hat{G}^\dagger (\epsilon, r) \hat{G} (\epsilon', r) \hat{\Lambda} |k' \beta \rangle. \tag{21}
\]

As we will see below, only the short-distance asymptotics
of the Green function should be kept, as the supercollis-
ion matrix element at large \( q \) is dominated by the most
singular (at \( r \rightarrow 0 \)) terms in \( G(\epsilon, r) \). In what follows, we
assume \( T \ll E_F \), so that \( |k| \approx |k'| \). For \( M^{(1)} \) we then obtain

\[
M^{(1)} = \frac{4v^2 \sin \delta}{\epsilon} \langle k| \hat{\Lambda} \rangle \left( \hat{G}^\dagger |k' \beta \rangle \right) \tag{22}
\]

in terms of the commutator and anticommutator of ma-
trix \( \hat{\Lambda} \) with the Fourier-transformed Green function \( \hat{G}_q \).

Using the asymptotics of \( \hat{G}_q \) at large \( q \)

\[
\hat{G}_q \simeq -\frac{\langle \hat{\sigma} q \rangle}{vq^2} \hat{\tau}_3, \tag{23}
\]

we obtain

\[
M^{(1)} \simeq -\frac{4v^2 \sin \delta}{\epsilon q} \langle k| \hat{\Lambda} \hat{\sigma} \hat{q} \langle \hat{\tau}_3 |k' \beta \rangle \tag{24}
\]

where \( \hat{q} = q \hat{q} / q \). For \( M^{(2)} \), we notice that the most singular
(at \( r \rightarrow 0 \)) term in the product \( \hat{G}^\dagger \hat{G} \) reads as follows:

\[
\hat{G}_q^\dagger (\epsilon, r) \hat{G} (\epsilon', r) \approx \frac{1}{4\pi^2 v^2 r^2}. \tag{25}
\]

As a result, using \( \hat{\Lambda}^2 = \hat{\Lambda} \), we obtain

\[
M^{(2)} \simeq \frac{8v^2 \sin^2 \delta}{\epsilon q} \ln \frac{1}{qR} \langle k| \hat{\Lambda} |k' \beta \rangle. \tag{26}
\]

In the Born approximation (to the lowest order in \( \delta \ll 1 \), only the first line of Eq. (24) is present. This
contribution was calculated in Ref. [3]. Remarkably, the
contribution of Eq. (24), absent in the Born approxima-
tion, decreases with \( q \) much slower. As a result, it domi-
nates the electron-phonon heat exchange at sufficiently
high temperatures even for weak impurities (the second
line of Eq. (24) is always small). Indeed, the ratio of the
respective contributions to the matrix element at thermal
phonon wavevectors \( q_{T} = T / s \) is given by (omitting
coefficients of order unity)

\[
\frac{M^{(2)}}{M^{(1)}} \sim \tan \delta \frac{T}{T_{BG}} \ln \frac{1}{q_T R}, \tag{27}
\]

where

\[
T_{BG} = \hbar k_F / k_B \simeq 27K \sqrt{n / 10^{12} \text{cm}^{-2}} \tag{28}
\]

is the Bloch-Grüneisen temperature (\( s \) is the sound ve-
cocity, \( k_F \) the Fermi momentum, and \( n \) the electron con-
dcentration).

The condition \( q \gg k, k' \) for typical phonons is real-
ized at sufficiently high temperatures \( T \gg T_{BG} \). When
this condition is not fulfilled, the supercollision matrix
elements can be estimated as (dropping the numerical coefficients)

\[ M^{(1)}(q \ll k, k') \sim \frac{\sin \delta \cos \delta}{k_F^2}, \quad (29) \]

\[ M^{(2)}(q \ll k, k') \sim \frac{\sin^2 \delta}{k_F^2} \ln \frac{1}{k_FR}, \quad (30) \]

and hence their ratio at \( T \ll T_{BG} \) is given by Eq. (27) with \( T \sim T_{BG} \). For a strong impurity \( \tan \delta \gtrsim 1 \). Since the argument of logarithm in Eq. (27) is always large, for resonant impurities one has \( M^{(2)} \gg M^{(1)} \) in the whole temperature range.

C. Heat flux between electrons and phonons

Let us now evaluate the impurity-assisted heat flux \( J \) from electrons to phonons. The Fermi golden rule yields (cf. Ref. [2])

\[ J = \frac{2\pi}{\hbar} n_{imp} v_F^2 g^2 \]

\[ \times 2 \sum_{\alpha\beta} \int \frac{d^2q}{(2\pi)^2} \omega_q^3 \left(N_{\omega_q}^e - N_{\omega_q}^p\right) \left|\langle k, k' | q \rangle_{FS}^\beta \right|^2, \quad (31) \]

where \( n_{imp} \) is the impurity concentration, \( g = D/\sqrt{2\rho s^2} \) the electron-phonon coupling constant (with \( D \) being the deformation-potential constant and \( \rho \) the graphene mass density), \( v_F = k_F/(2\pi \hbar v_F) \) the electronic density of states per spin per valley at the Fermi level, \( \omega_q = sq \) the phonon dispersion, and \( |k| = |k'| = k_F \). Further, \( \langle \ldots \rangle_{FS} \) stands for the Fermi-surface averaging over angles of \( k, k' \), and \( N_{\omega_q}^e, N_{\omega_q}^p \) are the Bose distribution functions with electron and phonon temperatures, \( T_e \) and \( T_p \), respectively.

Performing the integration over \( q \) with Eqs. (24) and (25), the matrix element, we arrive at

\[ J = I(T_e) - I(T_p), \]

where

\[ I(T) = I_0(T) + I_{\text{Born}}(T) + I_{\text{res}}(T). \quad (33) \]

In this expression, \( I_0(T) \) is the contribution that does not involve the impurity scattering, the term \( I_{\text{Born}}(T) \) stems from the matrix element \( M^{(1)} \) and survives in the Born approximation (hence the notation), whereas \( I_{\text{res}}(T) \) corresponds to the matrix element \( M^{(2)} \) that is dominant for resonant impurities. For \( T > T_{BG} \) the term \( I_0(T) \) scales linearly with temperature [20 21]:

\[ I_0(T > T_{BG}) = 4\pi W T^2_{BG} T, \quad (34) \]

\[ W = \frac{g^2 v_F^2 k_F^3}{\hbar} \approx 0.05 \frac{n}{10^{12}\text{cm}^{-2}} \frac{W}{m^2K^3}, \quad (35) \]

and we have used \( D = 20\text{eV} \).

For the impurity-assisted terms in \( I(T) \), we find:

\[ I_{\text{Born}}(T > T_{BG}) \sim n_{\text{imp}} W A_{\text{Born}} \cos^2 \delta \sin^2 \delta T^3, \quad (36) \]

\[ I_{\text{res}}(T > T_{BG}) \sim n_{\text{imp}} W A_{\text{res}} \sin^4 \delta \frac{T^5}{T_{BG}} \ln^2 \frac{1}{k_FR}. \quad (37) \]

Here, \( A_{\text{res}} \) and \( A_{\text{Born}} \) are the numerical coefficients:

\[ A_{\text{Born}} = 64 \zeta(3) \sum_{\alpha\beta} \left|\langle k, \alpha | \hat{A} | k', \beta \rangle\right|, \quad (38) \]

\[ A_{\text{res}} = \frac{3072 \zeta(5)}{\pi^2} \sum_{\alpha\beta} \left|\langle k, \alpha | \hat{A} | k', \beta \rangle\right|^2, \quad (39) \]

For the short-range potential both the inter- and intra-valley transitions contribute equally, whereas for the long-range potential only the inter-valley transitions are allowed. As a result, the coefficients in these two models take different values:

\[ A_{\text{Born}} = 32 \zeta(3), \quad A_{\text{res}} = \frac{768 \zeta(5)}{\pi^2} \quad \text{(short-range)} \]

\[ A_{\text{Born}} = 0, \quad A_{\text{res}} = \frac{6144 \zeta(5)}{\pi^2} \quad \text{(long-range)} \]

with \( \zeta(x) \) the Riemann zeta-function. As seen from Eqs. (26) and (27), for \( T > T_{BG} \), the resonant contribution to the energy flux has a \( T^5 \) temperature dependence, which should be contrasted with the \( T^3 \) dependence of the Born term (the latter was calculated for weak impurities in Ref. [3]).

For the estimate of \( I(T) \) at \( T < T_{BG} \), we use matrix elements (29) and (30) for supercollisions, which yields

\[ I_{\text{Born}}(T < T_{BG}) \sim W N_{\text{imp}} \sin^2 \delta \cos^2 \delta \frac{T^5}{T_{BG}}, \quad (42) \]

\[ I_{\text{res}}(T < T_{BG}) \sim W N_{\text{imp}} \sin^4 \delta \frac{T^5}{T_{BG}} \ln^2 \frac{1}{k_FR}. \quad (43) \]

We thus see that at low temperatures, both contributions to the impurity-assisted heat flux have a \( T^5 \) dependence. For a strong impurity, \( \tan \delta \gtrsim 1 \), the second contribution to \( I(T) \) always wins. The term \( I_0(T) \) at \( T < T_{BG} \) behaves as [22]

\[ I_0(T < T_{BG}) = \frac{8W^4}{15} \frac{T^4}{T_{BG}}. \quad (44) \]

Thus, at low temperatures, \( T < T_{BG} \), the term \( I_0(T) \) scales as \( T^4 \), while both the supercollision terms scale as \( T^5 \) (see Table 1).

In what follows, we assume that the system contains two types of impurities: weak ones with the concentration \( n_{\text{imp}} = n_0 \) and phase shift \( \delta_0 \ll 1 \) and a single resonant impurity at position \( r = 0 \). In the resonant term, we
substitute \( n_{\text{imp}} \rightarrow \delta (r) \). As a result, the function describing energy flux between electrons and phonons becomes r-dependent,

\[
I (r, T) = I_0(T) + I_{\text{Born}} (T) + I_{\text{res}} (r, T). \tag{45}
\]

We summarize the above results for the contributions to the heat flux between electrons and phonons at low \( (T \ll T_{BG}) \) and high \( (T \gg T_{BG}) \) temperatures in Table I. These results will be used below for the analysis of the heat transfer in a weakly disordered graphene with a resonant impurity.

### III. IMPURITY-INDUCED TEMPERATURE DISTRIBUTION

#### A. Heat-transfer equations in graphene

We now turn to the effect of a single resonant impurity at \( r = 0 \) on the distribution of local temperature in graphene, as measured in recent experiments. We assume electrons and phonons to be at the local thermodynamic equilibrium characterized by temperatures \( T_e \) and \( T_{ph} \). As we have shown in the previous Section, in the presence of a resonant impurity on top of the background of weak impurities, there exist two contributions to the heat flux between the electron and phonon systems: the homogeneous one, governed by weak disorder, and the local one, induced by the strong scatterer. The electronic subsystem is electrically driven leading to the Joule heating. The overall heat balance in the steady state is maintained by the coupling of the phonons to the thermal reservoir characterized by the base (substrate) temperature \( T_0 \).

We assume for simplicity that the driving is weak, hence \( T_e \approx T_{ph} \approx T \), and linearize all the non-linear dependencies in the vicinity of \( T \). The spatial dependence of local temperatures in a macroscopic system is governed by the following diffusion-type heat transfer equations:

\[
(C_e \partial_t - \kappa_e \nabla^2) T_e = - \gamma (T_e - T_{ph}) - a \delta (r) (T_e - T_{ph}) + E^2 \sigma_0 [1 + b \delta (r)], \tag{46}
\]

\[
(C_{ph} \partial_t - \kappa_{ph} \nabla^2) T_{ph} = \gamma (T_e - T_{ph}) + a \delta (r) (T_e - T_{ph}) - \gamma_0 (T_{ph} - T_0). \tag{47}
\]

Here \( C_{e, ph} \) are the heat capacities of electronic and phononic subsystems and \( \kappa_{e, ph} \) are the corresponding heat conductivities, and \( \gamma_0 \) quantifies the coupling to the bath. Further, the parameters \( \gamma \) and \( a \) control the homogeneous and the local (induced by the resonant impurity) parts of the energy exchange between the electron and phonon systems, respectively. If the homogeneous exchange is controlled by supercollisions assisted by weak impurities, the heat exchange rate \( \gamma \) is given by

\[
\gamma = \partial I_{\text{Born}} (T)/\partial T, \quad T > T_1, \tag{48}
\]

with \( I_{\text{Born}} (T) \) given by Eq. (36), and thus scales with temperature as \( T^2 \). The temperature \( T_1 \) where this regime is realized is given by

\[
T_1 = \sqrt{k_F T_{BG}}. \tag{49}
\]

For lower temperatures, the background electron-phonon scattering will be determined by processes that do not involve impurities:

\[
\gamma = \partial I_0 (T)/\partial T, \quad T < T_1 \tag{50}
\]

(see Table I). This will not make any change in the theory developed in this Section, apart from a different scaling of \( \gamma \). The parameter \( a \) is obtained from \( I_{\text{res}} \) in Eq. (45) in a similar way:

\[
a \delta (r) = \partial I_{\text{res}} (r, T)/\partial T. \tag{51}
\]

where we use Eq. (37) and Eq. (43) at \( T > T_{BG} \) and \( T < T_{BG} \), respectively (where \( n_{\text{imp}} \) is replaced with \( \delta (r) \)).

The last term in Eq. (46) accounts for the Joule heat (with \( \sigma_0 \) being the conductivity outside the region of the strong scatterer and \( E_{\infty} \) the electric field at \( r \to \infty \), modified by the presence of resonant impurity. Here, we describe the effect of the strong scatterer by introducing phenomenologically a local term \( b \delta (r) \). We will discuss microscopic origin and the characteristic magnitude of this term in connection with the physics of Landauer dipoles in Appendix A.

Let us now analyze the stationary solutions of Eqs. (46) and (47) perturbatively in the local heat-flux and Joule-heat terms induced by the resonant impurity. In the absence of the resonant impurity \( (a = b = 0) \), one obtains a homogeneous heating of the two subsystems:

\[
T_{ph}^{(0)} = T_0 + \gamma_0^{-1} \sigma_0 E^2_{\infty} \tag{52}
\]
and
\[ T_e^{(0)} = T_0 + (\gamma^{-1} + \gamma^{-1}_0) \sigma_0 E^2_{\infty}. \]  
\(53\)

It is worth noticing that at this level, the phonon temperature \(T_e^{(0)}\) is not sensitive to the rate of the electron-phonon heat exchange.

Next, we linearize Eqs. \(46\) and \(47\) around the homogeneous solutions, \(T_{ph}(r) = T_{ph}^{(0)} + \delta T_{ph}(r)\) and \(T_e(r) = T_e^{(0)} + \delta T_e(r)\), and find corrections to the phonon and electron temperatures induced by a single resonant impurity:

\[ \delta T_{ph}(r) = T_\ast \left[ F_1(r) + \frac{\gamma \eta}{\eta} F_2(r) \right] \]  
\(54\)

and

\[ \delta T_e(r) = T_\ast \left[ \frac{\kappa_{ph}(\eta - 1)}{\kappa_e} F_1(r) + \frac{(\gamma_0 + \gamma) \eta - \gamma_0}{\gamma} F_2(r) \right]. \]  
\(55\)

Here, the characteristic temperature scale \(T_\ast\) is given by

\[ T_\ast = \frac{\sigma_0 E^2_{\infty} a}{2\pi \kappa_{ph} \gamma}. \]  
\(56\)

the parameter

\[ \eta = \frac{\gamma b}{a} \]  
\(57\)

controls the relative importance of the local Joule heat at the scatterer, and we have introduced

\[ \tilde{\gamma} = \gamma + (\gamma_0 + \gamma) \frac{\kappa_e}{\kappa_{ph}}. \]  
\(58\)

To simplify the further analysis, we will assume below that the parameter \(\eta\) is small, \(|\eta| \ll 1\); the validity of this assumption is supported by the microscopic analysis, see Appendix A. The spatial temperature distributions in Eqs. \(54\) and \(55\) is governed by the functions

\[ F_1(r) = \frac{q_1^2 K_0(q_1 r) - q_2^2 K_0(q_2 r)}{q_1^2 - q_2^2}, \]  
\(59\)

\[ F_2(r) = \frac{(q_1^2 + q_2^2) K_0(q_2 r) - K_0(q_1 r)}{q_1^2 - q_2^2}, \]  
\(60\)

with \(K_0(z)\) the modified Bessel function and

\[ q_{1,2}^2 = \frac{\gamma}{2\kappa_e} + \sqrt{\left( \frac{\gamma}{2\kappa_e} \right)^2 - \frac{\gamma \gamma_0}{\kappa_e \kappa_{ph}}}. \]  
\(61\)

Equation \(61\) defines the two spatial scales, \(q_2^{-1} < q_1^{-1}\). In the immediate vicinity of the impurity \((r \ll q_2^{-1})\), the functions \(F_1\) and \(F_2\) produce a logarithmic singularity of the local temperatures which is cut off by the ultraviolet scale \(R\). Further simplification is possible due to separation of scales in two limiting cases. First, when

\[ \delta T_{ph}(r) \]  
\[ \ln \frac{1}{q_2 a} \]  
\[ \sim e^{-q_1 r} \]  
\(\text{FIG. 1. Spatial dependence of the phonon temperature } \delta T_{ph}(r) \text{ generated by supercollisions at a resonant impurity located at } r = 0.\)

\[ \delta T_e(r)/T_\ast \]  
\[ \frac{q_1^2}{q_2^2} \]  
\[ \gamma \rightarrow 0 \]  
\[ \gamma_0 \rightarrow 0 \]  
\[ \sim e^{-q_1 r} \]  
\(\text{FIG. 2. Spatial dependence of the electron temperature } \delta T_e(r) \text{ generated by supercollisions at a resonant impurity located at } r = 0.\)

the electron-phonon heat exchange is relatively weak in comparison to heat leakage to the substrate,

\[ \gamma < \frac{\gamma_0}{1 + \kappa_{ph}/\kappa_e}, \]  
\(62\)

we have

\[ q_1 = \sqrt{\gamma/\kappa_e}, \quad q_2 = \sqrt{\gamma_0/\kappa_{ph}}, \]  
\(63\)

with \(q_1 \ll q_2\). In the opposite limit of a sufficiently strong homogeneous electron-phonon heat exchange,

\[ \gamma \gg \frac{\gamma_0}{1 + \kappa_{ph}/\kappa_e}, \]  
\(64\)

we obtain

\[ q_1 = \sqrt{\gamma_0/\kappa_{ph} + \kappa_e}, \quad q_2 = \sqrt{\gamma_0/\kappa_{ph} + \kappa_e}, \]  
\(65\)

and again \(q_1 \ll q_2\).
In any of these limits, we then find for the temperature profiles near the strong impurity:

\[ \delta T_{\text{ph}} (r \ll q_2^{-1}) \sim T_* \ln \frac{1}{q_2 r}, \]

(66)

\[ \delta T_e (r \ll q_2^{-1}) \sim -T_* \frac{\kappa_{\text{ph}}}{\kappa_e} \ln \frac{1}{q_2 r}. \]

(67)

Away from the impurity, the correction to the phonon temperature changes its sign:

\[ \delta T_{\text{ph}} (q_2^{-1} \ll r \ll q_1^{-1}) = -T_* \frac{q^2}{q_2^2} K_0 (q_1 r), \]

(68)

as illustrated in Fig. 1.

For the electron temperature (Fig. 2), the sign of the correction away from the impurity differs in the two limiting cases of small \( \gamma \) and small \( \gamma_0 \):

\[ \delta T_e (q_2^{-1} \ll r \ll q_1^{-1}) = T_* K_0 (q_1 r) \times \left\{ \begin{array}{ll}
\left( -\frac{\kappa_{\text{ph}}}{\kappa_e} \right), & \gamma \to 0, \\
\left( \frac{\kappa_{\text{ph}}}{\kappa_e + \kappa_p} \right), & \gamma_0 \to 0.
\end{array} \right. \]

(69)

We have thus found that the presence of a single strong scatterer in a weakly disordered graphene leads to the local heating (cooling) of the phonon (electron) subsystem in the vicinity of the scatterer, mediated by the “resonant supercollisions”. Away from the resonant scatterer, the correction to the phonon temperature changes its sign. The reason for this is essentially the energy conservation. Indeed, the resonant supercollision leads to a local enhancement of release of the Joule heat accumulated by the electron system. This should be compensated by some reduction of the energy released to phonons further away from the scatterer. Below, we will estimate the magnitude of the effect and discuss its experimental implications.

B. Estimates for the characteristic temperature and length scales

In this Section, we present estimates for the magnitude of the effect of resonant supercollision cooling and for the characteristic spatial scales of the temperature distribution around a strong scatterer in graphene.

From Eq. (56), assuming that \( \gamma \) is dominated by processes without supercollisions (clean samples, \( T > T_1 \)) and using expressions for the electron-phonon heat exchange from Table I, we write for the characteristic magnitude of temperature variations:

\[ T_* \sim \sin^4 \delta \frac{j_0^2}{\sigma_0 \kappa_{\text{ph}} k_F} \times \left\{ \begin{array}{ll}
\frac{T}{T_{\text{BG}}} \ln^2 \frac{1}{k_F R}, & T < T_{\text{BG}}, \\
\left( \frac{T}{T_{\text{BG}}} \right)^4 \ln^2 \frac{T_{\text{BG}}}{k_F R T}, & T > T_{\text{BG}},
\end{array} \right. \]

\[ \delta T_{e,\text{el}}^{(0)} = \delta T_{e,\text{el}}^{(0)} - T_0. \]

(70)

\[ \delta T_{e,\text{el}}^{(0)} = 5 \mu K, \quad \delta T_{\text{ph}}^{(0)} = 2 \mu K \]

(77)

where \( j_0 = \sigma_0 E_\infty \) is the current density far away from the scatterer.

Below we will assume that the impurity is near resonance and thus set \( \sin \delta \sim 1 \) for estimates. A naive estimate for the parameter \( b \) for a resonant impurity is \( b \sim l/k_F \). A simple way to obtain this estimate is to assume that the resistivity is determined by a finite concentration of such resonant impurities and dividing the dissipated heat by the number of impurities. If this estimate would be correct, we would have \( \eta \) comparable to unity for temperatures around \( T_{\text{BG}} \). It turns out, however, that this naive estimate is incorrect in the 2D case, as explained in Appendix [23] and \( \eta \) is in fact much smaller. We thus discard it in our estimates below.

For estimates, we use for the parameters entering Eq. (70) representative values suggested by the experiment [8]:

\[ l \approx 1 \mu m, \quad n \approx 10^{12} \text{cm}^{-2}. \]

(71)

With these values, we estimate

\[ k_F = \sqrt{\pi n} \approx 1.8 \cdot 10^6 \text{m}^{-1}, \quad \sigma_0 = \frac{e^2}{\pi \hbar} l \approx 10^{-2} \Omega^{-1}. \]

(72)

Below we perform estimates for two values of temperature, corresponding to different regimes of temperature: \( T = 10K (T < T_{\text{BG}}) \) and \( T = 50K (T > T_{\text{BG}}) \).

Let us estimate the homogeneous electron-phonon exchange rate \( \gamma \) and the phonon-substrate [23][25] \( \gamma_0 \) cooling rate. At \( T \approx 50 K \ll T_1 \), the homogeneous electron-phonon heat exchange is dominated by \( I_0 \) rather than by supercollisions with weak impurities, see Eqs. (49) and (50), and can be estimated according to Eq. (34):

\[ \gamma \approx 2.3 \cdot 10^4 \frac{W}{\text{m}^2 \text{K}^3}, \quad \gamma_0 \approx 5 \cdot 10^7 \frac{W}{\text{m}^2 \text{K}}. \]

(74)

At \( T = 10K \), we have the low-temperature regime (\( T < T_{\text{BG}} \)), so that electron-phonon heat exchange is given by Eq. (44):

\[ \gamma \approx 0.9 \cdot 10^3 \frac{W}{\text{m}^2 \text{K}^3}, \quad \gamma_0 \approx 5 \cdot 10^6 \frac{W}{\text{m}^2 \text{K}}. \]

(75)

Next, we estimate the homogeneous overheating of phonons and electrons from the base temperature \( T_0 \)

\[ \delta T_{e,\text{el}}^{(0)} = T_{e,\text{el}}^{(0)} - T_0. \]

(76)
for $T = 50K$ and
\[
\delta T_{el}^{(0)} = 0.1 K, \quad \delta T_{ph}^{(0)} = 20 \mu K
\] (78)
for $T = 10K$.

For a quantitative estimate of the magnitude of the impurity-induced overheating of phonons and respective spatial scales, we need to estimate the phonon and electron thermal conductivities. For phonons, considering the graphene layer and the boron-nitride substrate (of 40 nm thickness) as a combined 2D system, we use the results for boron nitride from Refs. [26] and [27]. The electronic heat conductivity can be estimated from the Wiedemann-Franz law,
\[
\kappa_e = \frac{\pi^2 k_B^2}{3e^2} \sigma_0 T.
\]
As a result, we get
\[
\kappa_{ph} \approx 4 \cdot 10^{-7} \frac{W}{K}, \quad \kappa_e \approx 1.2 \cdot 10^{-8} \frac{W}{K}
\] (79)
at $T = 50K$ and
\[
\kappa_{ph} \approx 7 \cdot 10^{-9} \frac{W}{K}, \quad \kappa_e \approx 2.4 \cdot 10^{-9} \frac{W}{K}
\] (80)
at $T = 10K$. The characteristic magnitude of the temperature variation induced by the scatterer can be quantified by the following parameter:
\[
\alpha_s = \frac{T_*}{\delta T_{ph}^{(0)}} = \frac{a}{2\pi \kappa_\phi \gamma}.
\] (81)
Above, we have already estimated all relevant quantities apart from $a$, characterizing the impurity-assisted electron-phonon cooling rate. It can be written as follows:
\[
a = \frac{5 A_{res} \gamma}{k_F^2} \frac{T^4}{T_{BG}^2} \ln \frac{T_{BG}}{k_F R_{max}(T, T_{BG})}.
\] (82)
At 50K it becomes (with $A_{res} \approx 600$ for long-range impurities):
\[
a \approx 4 \cdot 10^{-10} \frac{W}{K}
\] (83)
and at 10K:
\[
a \approx 10^{-12} \frac{W}{K}
\] (84)
Combining all the above estimates, we find
\[
\alpha_s \approx \begin{cases} 
0.4, & T = 50 \text{ K}, \\
0.2, & T = 10 \text{ K}.
\end{cases}
\] (85)
The absolute values of the magnitude of the local temperature change read:
\[
T_s(50\text{K}) \approx 1 \mu K, \quad T_s(10\text{K}) \approx 4 \mu K.
\] (86)

We proceed now with the analysis of the characteristic spatial scales. At $T = 50K$ we are in the regime (62), in which the spatial scales are given by Eq. (63). Combining the above values, we estimate the two spatial scales in the temperature profile at 50K as
\[
q_1^{-1} \approx 7 \cdot 10^{-7} \text{m}, \quad q_2^{-1} \approx 10^{-7} \text{m}.
\] (87)
At $T = 10K$, the condition (62) is still fulfilled and we estimate
\[
q_1^{-1} \approx 1.5 \cdot 10^{-6} \text{m}, \quad q_2^{-1} \approx 4 \cdot 10^{-8} \text{m}.
\] (88)
It is worth mentioning that our quasi-2D approximation for the 40nm-thick slab of graphene and boron nitride turns out to be at the border of applicability, since the slab thickness is comparable to the characteristic size $q_2^{-1}$ of the temperature variation. This, in particular, implies that the actual value of $T_*$ may be a few times larger than that given by our estimates (86), while the size of the overheated region as seen at the surface of the quasi-2D slab is expected to be somewhat larger than our 2D value of $q_2^{-1}$.

Finally, let us compare our results with experimental findings of Ref. [8]. First, the overall magnitude and sign of the effect are shown in Fig. S5 of Ref. [8], with $\delta T > 0$ and $\delta T \sim 5 \mu K$, which is in rough agreement with our estimates, see Eq. (86). Next, the dependence of the excess temperature on the electrical current (illustrated in Fig. S9C of Ref. [8]) is quadratic, consistent with our Eq. (70). Finally, according to our Eqs. (87), (88) the size of the overheated region $q_2^{-1}$ is about a few tens nanometers. The distances between the tip and the impurity at which an enhancement of temperature was detected in Ref. [8] were of the order of or smaller than 100 nm, so that the measurement point was indeed located in the “ overheated” part in our Fig. 1.

**IV. SUMMARY**

In this work, we have studied the effect of strong (resonant) impurities on the heat transfer in a coupled electron-phonon system in disordered graphene. Our key results can be summarised as follows.

First, we have investigated in detail how a strong impurity modifies locally the electron-phonon heat exchange through the “resonant-supercollision” mechanism. The result is given by Eqs. (32) and (37) and in Table [1]. For strong impurities, the contribution of supercollisions to the function $I(T)$ describing the energy flow between electrons and phonon scales with temperature as $T^3$, in contrast to the $T^5$ behavior found for weak impurities.

Second, we have explored the local modification of heat transfer induced by a resonant scatterer in a weakly disordered graphene and calculated the spatial temperature profile around the scatterer under electrical driving. The characteristic profiles of the phonon and electron temperature around the scatterer are illustrated in Figs. [1] and
The sign, magnitude, and characteristic spatial scale of the local temperature distribution of phonons are consistent with the recent experimental findings on imaging resonant dissipation from individual atomic defects reported in Ref. [8].

When we were preparing the manuscript for publication, the preprint [9] appeared with theoretical results that partly overlap with our analysis of “resonant supercollisions”.

ACKNOWLEDGMENTS

We thank E. Zeldov for providing us with unpublished experimental results and for insightful discussions that stimulated this work. We are also grateful to V. Khrapai and A. Finkel’stein for interesting discussions. The work was supported by the joint grant of the Russian Science Foundation (Grant No. 16-42-01035) and the Deutsche Forschungsgemeinschaft (Grant No. MI 658-9/1).

Appendix A: Effect of a scatterer on local Joule heat

In this Appendix, we discuss the local effect of a scatterer on the Joule heat. For transparency, we first calculate the distribution of the Joule heat in a model system, where a spherical region with radius \( R \) and conductivity \( \sigma_{out} \) is inserted at the origin of coordinate \( \mathbf{r} = 0 \) into an infinite medium with the conductivity \( \sigma_{in} \) to which a homogeneous electric field \( \mathbf{E}_{\infty} \) is applied in \( x \) direction. Then we extend the result to the case of an arbitrary scatterer inserted in a homogeneous medium. We start with the discussion of a three-dimensional (3D) case and then generalize the results to the 2D case.

1. 3D case

As stated above, we consider first a spherical region with radius \( R \), center \( \mathbf{r} = 0 \), and conductivity \( \sigma_{in} \) inserted into an infinite medium with the conductivity \( \sigma_{out} \). Away from the scatterer, the electric field is \( \mathbf{E}_{\infty} \) and points in \( x \) direction. The distribution of electrical current \( \mathbf{j}(\mathbf{r}) \) obeys the condition

\[
\text{div} \mathbf{j} = 0.
\]

With the local relation between the current density and the electric field \( \mathbf{j}(\mathbf{r}) = \sigma \mathbf{E}(\mathbf{r}) \), this condition is equivalent to \( \text{div} \mathbf{E} = 0 \) both inside and outside the spherical region. This implies that electric charges can appear only at the sphere surface. We search for the distribution of electric field outside the spherical region as a sum of the field \( \mathbf{E}_{\infty} \) at \( r \to \infty \) and the field of dipole emerged at the boundary \( r = R \). We also assume that the field is homogeneous for \( r < R \). The electrical potential is written as

\[
\Phi(\mathbf{r}) = \begin{cases} 
-E_{\infty}r \cos \theta, \quad &\text{for } \quad r < R, \\
-E_{\infty}r \cos \theta - \frac{d_3}{r^2} \cos \theta, \quad &\text{for } \quad r > R,
\end{cases}
\]

where \( \theta \) is the angle between the direction of \( E_{\infty} \) and \( \mathbf{r} \), and \( d_3 \) characterizes the strength of a 3D dipole. The matching conditions for the potentials and currents at the boundary read:

\[
E_{\infty}R = \frac{d_3}{R^2} + E_{\infty} R, \quad (A2)
\]

yielding

\[
E_{\infty} = E_{\infty} - \frac{3\sigma_{out}}{\sigma_{in} + 2\sigma_{out}}, \quad (A3)
\]

\[
d_3 = E_{\infty} R^3 \frac{\sigma_{out} - \sigma_{in}}{\sigma_{in} + 2\sigma_{out}}. \quad (A4)
\]

Next, we calculate the Joule heat dissipated inside and outside the spherical region. The heat dissipated in the region \( r < R \) is given by

\[
\delta P_{in} = \sigma_{in} E_{\infty}^2 \frac{4\pi R^3}{3} = \frac{12\pi E_{\infty}^2 R^3 \sigma_{out}^2 \sigma_{in}}{(\sigma_{in} + 2\sigma_{out})^2}. \quad (A5)
\]

The heat dissipated outside the ball,

\[
\delta P_{out} = \int_{r > R} d^3 r \sigma \mathbf{E}^2,
\]

contains a contribution from homogeneous external field \( \propto E_{\infty}^2 \), a dipole contribution \( \propto d_3 \), and the cross term \( \propto E_{\infty} d_3 \). The first term diverges at large \( r \), so that we introduce a large finite volume \( V \gg R^3 \) of the whole system. The cross-term cancels out after integration over angles. Then, after integration of the dipole contribution, we obtain

\[
\delta P_{out} = \sigma_{out} E_{\infty}^2 \left( V - \frac{4\pi R^3}{3} \right) + \frac{8\pi E_{\infty}^2 R^3 \sigma_{out} (\sigma_{out} - \sigma_{in})^2}{3(\sigma_{in} + 2\sigma_{out})^2}. \quad (A6)
\]

Now, we can find the total change of the dissipated power induced by the insertion of the spherical region with the conductivity \( \sigma_{in} \neq \sigma_{out} \):

\[
\delta P = \delta P_{in} + \delta P_{out} - \sigma_{out} E_{\infty}^2 V = \frac{4\pi R^3}{3} \sigma_{out} E_{\infty}^2 \frac{\sigma_{in} - \sigma_{out}}{\sigma_{in} + 2\sigma_{out}}. \quad (A7)
\]

We thus see that the total correction to the Joule heat is proportional to the product of the current density at infinity, \( j_0 = \sigma_{out} E_{\infty} \), and the “Landauer dipole” strength \( d_3 \):

\[
\delta P = c_3 j_0 d_3, \quad (A8)
\]
with
\[ c_3 = -\frac{4\pi}{3}. \]  
(A9)

When the local inhomogeneity is created by an individual impurity (not characterized by the conductivity \( \sigma_{\text{in}} \)), it gives rise to the Landauer dipole of the magnitude \[ d_3 = \frac{3\pi \hbar j_0 s_{\text{tr}}}{4e^2 k_F}. \]  
(A10)

where \( s_{\text{tr}} \) is the transport scattering cross-section of the impurity. The local variation of the Joule heat due to insertion of the scatterer can be still expressed in terms of this dipole moment via Eq. (A8). A transparent derivation of this result is given below in Sec. A3.

2. 2D case

Let us now turn to the explicit calculation of the Joule heat in a 2D electronic system with a disk of radius \( R \) characterized by the conductivity \( \sigma_{\text{in}} \) distinct from the background conductivity. In a 2D case, the electron charge distribution \( n(r) \) around the disk is no longer homogeneous and the electric potential is related to \( n(r) \) by

\[ \Phi(r) = \int \frac{d^2 r' n(r')}{|r - r'|}. \]  
(A11)

For the electrical current one has to take into account the “diffusive contribution” determined by the gradient of the concentration:

\[ j(r) = \sigma(r)E(r) - D(r)\nabla n(r), \]
\[ = \sigma(r)E_{\text{ec}}(r), \]  
(A12)

where \( D(r) \) is the local diffusion coefficient. The second line of Eq. (A12) expresses the current in terms of the “electrochemical field” \( E_{\text{ec}}(r) = -e \nabla \Phi_{\text{ec}}(r) \), where \( \Phi_{\text{ec}}(r) \) is the electrochemical potential (below, we drop the subscript “ec”). In a full analogy with the 3D case, the electrochemical potential has the form

\[ \Phi(r) = \begin{cases} 
-\frac{E_{\text{in}} r \cos \theta}{R}, & \text{for } r < R, \\
-\frac{E_{\text{in}} r \cos \theta}{R} - \frac{d_2}{R} \cos \theta, & \text{for } r > R,
\end{cases} \]  
(A13)

with the correction introduced by the inhomogeneous conductivity having a form of a “2D dipole” characterized by \( d_2 \). The matching conditions at the disk boundary read

\[ E_{\text{in}} R = \frac{d_2}{R} + E_{\text{in}} R, \]  
(A14)
\[ \sigma_{\text{in}} E_{\text{in}} = \sigma_{\text{out}} \left( E_{\infty} - \frac{d_2}{R^2} \right), \]

yielding

\[ E_{\text{in}} = E_{\infty} \frac{2\sigma_{\text{out}}}{\sigma_{\text{in}} + \sigma_{\text{out}}}, \]  
(A15)
\[ d_2 = E_{\infty} R^2 \frac{\sigma_{\text{out}} - \sigma_{\text{in}}}{\sigma_{\text{in}} + \sigma_{\text{out}}}. \]  
(A16)

The heat dissipated inside the disk, \( r < R \), is given by

\[ P_{\text{in}} = \sigma_{\text{in}} E_{\text{in}}^2 \pi R^2 = \frac{4\pi E_{\infty}^2 R^2 \sigma_{\text{out}}^2}{(\sigma_{\text{in}} + \sigma_{\text{out}})^2}. \]  
(A17)

The heat dissipated outside the disk reads

\[ P_{\text{out}} = \int_{r > R} d^2 r \sigma_{\text{out}} E^2 = \sigma_{\text{out}} E_{\infty}^2 (S - \pi R^2) + \frac{\pi \sigma_{\text{out}} d_2^2}{R^2} \]
\[ = \sigma_{\text{out}} E_{\infty}^2 (S - \pi R^2) + \frac{\pi R^2 \sigma_{\text{out}} E_{\infty}^2 (\sigma_{\text{out}} - \sigma_{\text{in}})^2}{(\sigma_{\text{in}} + \sigma_{\text{out}})^2}, \]  
(A18)

where \( S \) is total area of the system. Remarkably, in contrast to the 3D case, the total change of the dissipated power induced by the insertion of the disk equals zero:

\[ \delta P = P_{\text{in}} + P_{\text{out}} - \sigma_{\text{out}} E_{\infty}^2 S \equiv 0. \]  
(A19)

For an individual scatterer, the strength of the 2D dipole was calculated in Refs. [15] and [16]:

\[ d_2 = \frac{2\hbar j_0 s_{\text{tr}}}{e^2 k_F}. \]  
(A20)

Naively, one would expect, in analogy with Eq. (A8),

\[ \delta P = c_2 j_0 d_2. \]  
(A21)

It turns out, however, that in the 2D case the numerical coefficient \( c_2 \) vanishes,

\[ c_2 = 0. \]  
(A22)

A general reason for this result is given below.

3. General analysis of the Joule heat

Below we present a more general derivation of a relation between the strength of the dipole and the local change \( \delta P \) of the dissipated power. This will allow us to see that the difference between 3D and 2D cases that we have observed for a model of a macroscopic spherical obstacle is in fact of general character. To this end, we write the expression for total dissipated power as follows

\[ P = \int d^2 r \ E_{\text{ec}}(r) j(r) = -\int d^2 r \ j \nabla \Phi(r) \]
\[ = \int d^2 r \left[ -\text{div}(\Phi j) + \Phi \text{div} j \right]. \]  
(A23)
Since \( \text{div} \mathbf{j} = 0 \) in the stationary case, we find the total Joule heat as a surface integral

\[
P = \sigma_{\text{out}} \oint dS \Phi(r) \mathbf{n} \cdot \nabla \Phi(r).
\]  
(A24)

Here, \( \mathbf{n} \) is the normal vector to this surface and we took into account that \( \mathbf{j} = -\sigma_{\text{out}} \nabla \Phi \) away from the scatterer. We see that the Joule heat can be fully expressed in terms of the asymptotics of the electric potential at large \( r \). Let us assume that the integration surface in Eq. (A24) is spherical with the radius \( R' \) much larger than the size of the scatterer. Using Eqs. (A1), (A13) and (A24), we get

\[
P = \begin{cases} 
\sigma_{\text{out}} \frac{4\pi R'^3}{3} \left( E_{\infty} - \frac{2d_3}{R'^3} \right) \left( E_{\infty} + \frac{d_3}{R'^3} \right), & \text{3D case} \\
\sigma_{\text{out}} \pi R'^2 \left( E_{\infty} - \frac{2d_2}{R'^2} \right) \left( E_{\infty} + \frac{2d_2}{R'^2} \right), & \text{2D case} 
\end{cases}
\]  
(A25)

Now we send \( R' \) to infinity. The term, proportional to \( E_{\infty}^2 \), yields the Joule heat in the absence of the obstacle. The term proportional to the square of the dipole tends to zero. Hence, only the cross terms (those proportional to \( E_{\infty} \) and to the dipole strength) may give a correction \( \delta P \) to the homogeneous Joule heat in the limit \( R' \to \infty \). For the 3D case, we reproduce Eqs. (A8), (A9). For the 2D case, the cross terms mutually cancel and we find \( \delta P = 0 \), in agreement with Eq. (A22).

Importantly, this derivation is quite general as it only uses the dipole form of the potential at large distances as well as locality of the conductivity and the homogeneity of the system away from the scatterer. One can expect that fluctuations in positions of impurities surrounding a considered scatterer (including associated quantum interference effects) will produce a finite \( \delta P \) also in the 2D case. This effect should be, however, parametrically small in the case of a good metallic system.
