Abstract: Iron(III) is well-known to play a vital role in a variety of metabolic processes in almost all living systems, including the human body. However, the excess or deficiency of Fe\(^{3+}\) from the normal permissible limit can cause serious health problems. Therefore, novel analytical methods are developed for the simple, direct, and cost-effective monitoring of Fe\(^{3+}\) concentration in various environmental and biological samples. Because of the high selectivity and sensitivity, fast response time, and simplicity, the fluorescent-based molecular probes have been developed extensively in the past few decades to detect Fe\(^{3+}\). This review was narrated to summarize the Fe\(^{3+}\)-selective fluorescent probes that show fluorescence enhancement (turn-on) and ratiometric response. The Fe\(^{3+}\) sensing ability, mechanisms along with the analytical novelties of recently reported 77 fluorescent probes are discussed.

Keywords: Fluorescent sensors; Turn-on sensors; Ratiometric sensor; iron(III); Bioimaging

1. Introduction

Iron is well known to play an important role in a variety of physiological processes in the human body, such as oxygen metabolism, muscle contraction, synthesis of DNA and RNA, nerve conduction, proton transfer, enzyme synthesis, and regulation of acid-base balance and osmotic pressure in cells [1]. Despite the biological importance, the excess (hyperferremia) and the deficiency (hypoferremia) of iron can lead to serious health problems. The iron overload in the human body can cause severe diseases like osteoporosis, cancers, dysfunction of organs, hemochromatosis, and Alzheimer’s and Parkinson’s disease [2], whereas the iron deficiency can cause anemia and affect several cellular metabolic processes [3]. During the iron disorder, the labile iron generates destructive oxygen species (such as hydroxyl radical) via the Fenton reaction due to the facile redox process between Fe\(^{2+}\) and Fe\(^{3+}\) in the presence of molecular oxygen. The reactive oxygen species can damage peroxidative tissue and cause serious complications in pathological situations like β-thalassemia [4]. Therefore, there is a need for novel analytical methods for the monitoring of iron concentration in various environmental, industrial, and biological samples.

The optically (chromogenic and fluorogenic) active molecular probes have been widely investigated for the selective detection of Fe\(^{3+}\) in the last few decades. Among the two optical modes, the fluorescence-based molecular probes are extensively developed because of their simplicity, high selectivity and sensitivity, precise and real-time measuring of the target analyte up to a very low concentration without the need of pre-treatment of the sample, and sophisticated instrument [5]. The fluorescent probes are mainly designed by suitably connecting the chelating agent (binding unit) with a light-emitting group (fluorophore unit) (Scheme 1). The selective complexation of target analyte with the binding unit alters the fluorescence property of the photoexcited fluorophore mainly due to the
energy or electron transfer, which allows quantifying the target analyte. The fluorescence signals from the probe upon analyte binding can be observed in the form of enhancement (turn-on), quenching (turn-off), or red/blue-shift in the fluorescence maxima of the probe (ratiometric). The well-known mechanisms like fluorescence resonance energy transfer (FRET), photo-induced electron transfer (PET), intramolecular charge transfer (ICT), C=N isomerization, chelation-induced enhanced fluorescence (CHEF), excimer formation, etc. have been applied to develop fluorescent probes for the selective detection of various analytes, including Fe$^{3+}$, and the mechanisms are well described in the recently published review paper [6].

![Scheme 1. Schematic illustration of the components and signaling of fluorescent turn-on and ratiometric probes.](image)

In 2012, we reviewed the various molecular and supramolecular fluorescent probes developed for the selective detection of Fe$^{3+}$ [7] and observed that most of the fluorescent probes are based on the fluorescent quenching mechanism due to the paramagnetic nature of Fe$^{3+}$ [8,9]. The fluorescent turn-on and ratiometric probes possess several analytical novelties like less probability to give false signals, increased sensitivity over turn-off probes, and, therefore, several Fe$^{3+}$-selective fluorescent turn-on and ratiometric probes are reported in the last few years. This critical review was narrated to summarize the Fe$^{3+}$-selective fluorescent turn-on and ratiometric probes developed after 2012, and discussion has been made on the sensing mechanisms with their potential applications to biological samples for the qualitative and quantitative monitoring of intracellular Fe$^{3+}$ ions in live cells. All the fluorescent probes were presented in three different groups: (i) fluorescent turn-on probes for Fe(III), (ii) fluorescent ratiometric probes for Fe(III), and (iii) fluorescent chemodosimeters for Fe(III) according to their signaling process and sensing mechanisms.

2. Fluorescent Turn-on Probes for Fe(III)

The paramagnetic nature of the Fe$^{3+}$ is well known to quench the fluorescence from the organic fluorophores and, therefore, the majority of the reported Fe$^{3+}$-selective fluorescent probes show fluorescent turn-off responses. Also, it is challenging to develop fluorescent probes for an iron that showed turn-on and/or ratiometric fluorescent responses. The fluorescent probes with the turn-on response have several analytical advantages like high sensitivity, low background, and their potential applications in live-cell imaging. The literature survey revealed that the rhodamine/fluorescein derivatives are extensively applied for the development of fluorescent turn-on probes for various ionic and neutral analytes because of the reversible fluorescence changes with respect to the structural
changes occurred in the spirocyclic ring [10]. The closed ring spirocyclic form of the rhodamine is colorless and non-fluorescent, while the open-ring spirocyclic form is highly fluorescent and colored. The general mechanism to design rhodamine/fluorescein-based fluorescent turn-on probes for Fe$^{3+}$ is described in Scheme 2. The carboxyl frame of rhodamine is converted into a closed ring form by reacting with small molecules possessing –NH$_2$ group, and then the complexation-induced opening of the spirocyclic ring results in strong fluorescence emission. With this mechanism, the recently developed rhodamine-based Fe$^{3+}$-selective fluorescent probes 1–40 are summarized in Table 1.

Scheme 2. (A) The structure of fluorescein, rhodamine B, and rhodamine 6G; (B) The general schematic representation of the mechanism of complexation-induced opening of the spirocyclic ring to give fluorescent enhancement in rhodamine-based fluorescent turn-on probes.
The general mechanism to design rhodamine/fluorescein-based fluorescent turn-on probes results in strong fluorescence emission. With this mechanism, the recently reacting with small molecules possessing probes.

### Table 1. Fe³⁺-selective rhodamine/fluorescein-based fluorescent turn-on probes.

| Probes | Rh/FL | Rh/FL-Y | Medium | Ex/Em. λ (nm) | LOD | Cells Imaging | Ref. |
|--------|-------|---------|--------|---------------|-----|---------------|------|

The summarized rhodamine-based probes in Table 1 detect Fe\(^{3+}\) either in aqueous or semi-aqueous medium, as well as within live cells by forming complex either in 1:1 or 1:2 ratio followed by the opening of the spirocyclic ring of the probes. The mechanism of sensing for all the probes is similar, as described in Scheme 2. The reversible fluorescent probe 1 forms complex with Fe\(^{3+}\) in 1:1 binding stoichiometry and opens the spirocyclic ring (Scheme 3), which allows to detect Fe\(^{3+}\) down to 0.1 µM [11]. This probe shows stable fluorescence over pH 3.5–8.2. The probe shows promising results to locate the intracellular Fe\(^{3+}\) ions in live SH-SY5Y cells in real-time. Also, the probe has been applied to detect the labile Fe\(^{3+}\) pools in mitochondria and endosomes/lysosomes of SH-SY5Y cells (Figure 1). The probe 2 has been applied to detect Fe\(^{3+}\) down to 50 nM and non-cytotoxic up to 6 µM [12]. Because of its high specificity from amino acids, BSA protein, and human blood serum, the probe 2 is useful in monitoring intracellular Fe\(^{3+}\) ions concentration. The probe 3 with a quinoline moiety bound to rhodamine 6G hydrazide shows good cell permeability and the ability to locate the subcellular distribution of Fe\(^{3+}\) in EJ (lung cancer) cells by fluorescence imaging experiments [13]. The probe 4 detects Fe\(^{3+}\) concentration down to 2.2 µM and is suitable between the pH 6–7.5 [14]. This cell-permeable probe has been applied to image intracellular Fe\(^{3+}\) ions in HeLa cells. The probe 5 shows permeability of the plasma membrane to rhodenal and potential to locate the iron pools in the cells [15]. The probe 6 can detect Fe\(^{3+}\) over wide pH ranges from 5 to 11 with the minimum detection limit estimated down to 3 µM [16]. Probe 6 has been applied for bioimaging experiments in L-929 cells (mouse fibroblast cells) and BHK-21 (hamster kidney fibroblast), revealing good biocompatibility, cell permeability, and minimum toxicity.

![Scheme 3. Proposed binding mode of 1 with Fe\(^{3+}\) and the opening of the spirocyclic ring.](image-url)

The probe 7 selectively forms a complex with Fe\(^{3+}\) in 1:1 stoichiometry and opens the spirocyclic ring to give significant fluorescence turn-on response [17]. Probe 7 can detect Fe\(^{3+}\) down to 0.031 µM, and the in situ generated 7-Fe\(^{3+}\) complex has been applied for the selective sensing of S\(^2-\) anions. The probe 8 is useful in detecting Fe\(^{3+}\) in the biologically relevant pH from 6 to 9 and has shown very low cytotoxicity [18]. A confocal fluorescence imaging study of 8 reveals good cell permeability and the ability to monitor intracellular Fe\(^{3+}\) in live cells. The probes 9 and 10 show similar high selectivity towards Fe\(^{3+}\) with the detection limit down to 66 nM and 44.5 nM, respectively [19]. The probe 11 bearing the di-2-picolylamine as a binding unit shows high selectivity towards Fe\(^{3+}\), eliminates the Cr\(^{3+}\) interference during Fe\(^{3+}\) detection, and the selectivity is maintained over the pH range 6 to 7.5 [20]. The Fe\(^{3+}\)-selective probe 12 shows good linear fluorescence response from 2 µM to 20 µM with the limit of detection (LOD) estimated down to 0.32 µM [21]. The probes 13 and 14 show linearity range from 0.9–20 µM and 5–20 µM with the detection limit down to 0.9 µM and 5 µM, respectively [22]. The probe 15 alone is not-fluorescent above pH = 6, but the selective complexation with Fe\(^{3+}\) opens the spirocyclic ring to give significant turn-on fluorescence at 581 nm [23]. The probe 15 can detect Fe\(^{3+}\) down to 0.396 µM and is applied successfully for detecting Fe\(^{3+}\) in human liver cells (L-02) and rat neuronal (PC12) cells.
The rhodamine-triazine aminopyridine derivative 16 shows the detection limit of 41 nM for Fe3+, and the probe has been applied to monitor Fe3+ ions in real water samples and living HL-7702 cells [24]. The probe 17 is applied for the cascade detection of Fe3+ and the thiols (glutathione, homocysteine, cysteine) in solution and live cells [25]. The reversible fluorescent probe 18 shows turn-on fluorescence response between 10 and 70 µM of Fe3+ with the detection limit of 0.195 ppm [26]. The probe 19 is suitable to detect Fe3+ in the pH range from 4 to 7, with the estimated LOD of 0.26 µM [27]. The fluorescent enantiomer 20 shows a detection limit of 183 nM Fe3+ and detects Fe3+ in living cells with low cytotoxicity [28]. The probe 21 is ideal for detecting Fe3+ in the pH range from 4 to 8, with the LOD of 57 nM [29]. Also, the fluorescence turn-on response from the 21-Fe3+ complex formed in solution is shown to reverse upon addition of Na4P2O7. The benzothiazole-functionalized fluorescein derivative 22 shows nanomolar detection limit (7.4 nM) for Fe3+ with the potential to detect intracellular Fe3+ ions in live Hep G2 cells with low cytotoxicity [30].

The thiophene-modified rhodamine 6G derivative 23 shows selectivity towards Fe3+ and Al3+ with the LOD of 5 and 6 µM [31]. The rhodamine-furan-5-carbaldehyde chemosensor 24 shows high Fe3+ selectivity with the LOD of 17 nM. The probe 24 is safe for biological use and is non-toxic to living cells [32]. The turn-on colorimetric and fluorescent sensor 25 shows the LOD 0.768 µM Fe3+ and bioimage Fe3+ ions in live HeLa cells [33]. The probe 26 detects Fe3+, Al3+, and Cr3+ with the estimated LOD of 0.29, 0.34, and 0.31 µM, respectively [34]. The probe 26 has been applied to mimic the Boolean logic gates with two and four inputs. The probe 26 has been successfully applied to monitor the selective cations and also the native cellular iron pools. The fluorescence of rhodamine-2-thioxoquinazolin-4-one derivative 27 is increased linearly at 555 nm with the addition of Fe3+ from 0 to 75 µM, and the LOD is estimated down to 4.11 µM [35]. The concentration of Fe3+ is determined in various real water samples and is successfully applied to monitor intracellular Fe3+ ion in living cells. The probe 28 is designed
by reaction rhodamine hydrazide with two equivalents of 2-(thiophen-2-yl)acetyl chloride [36]. The turn-on fluorescence from 28 can be applied to detect Fe$^{3+}$ down to 0.13 $\mu$M, and the probe is suitable in the pH range from 4 to 9. The probe 29 shows a good linearity range from 0.8 to 20 $\mu$M with the estimated LOD of 11.6 nM [37]. The probe 30, possessing rhodamine and anthracene, detects Fe$^{3+}$ down to 42 nM and has been applied successfully to monitor Fe$^{3+}$ ions in living cells and zebrafish (Figure 2) [38]. The furfuran-based rhodamine B fluorescent probe 31 can be applied to detect Fe$^{3+}$ down to 0.025 $\mu$M, and the turn-on fluorescence due to the 31-Fe$^{3+}$ complex formation is shown to be reversed upon addition of $\text{B}_4\text{O}_7^{2-}$ [39].

The Fe$^{3+}$-selective fluorescent turn-on probe 32 is suitable in the pH range from 5 to 9 [40]. The probe 32 has been applied to detect basal level Fe$^{3+}$ and the dynamic changes in Fe$^{3+}$ levels in live bovine aortic endothelial cells (BAEC) at a subcellular resolution that reveal two Fe$^{3+}$ pools in endosomes/lysosomes and mitochondria. The probe 33 forms complex with Fe$^{3+}$ in 2:1 binding ratio and shows significant fluorescence enhancement at 588 nm [41]. The probes detect Fe$^{3+}$ better in the basic condition (pH 7 to 10), and the estimated LOD is 92 nM. The probe 34 fluorescence enhances linearly from 1 to 170 $\mu$M of Fe$^{3+}$ with the estimated LOD of 1.2 $\mu$M [42]. The rhodamine-based quinoline conjugated probe 35 shows distinct UV-Vis spectral changes upon addition of Fe$^{3+}$ and Cu$^{2+}$, but the fluorescence is enhanced selectively in the presence of Fe$^{3+}$ [43]. The turn-on fluorescence from 35 allows to detect Fe$^{3+}$ down to 33 nM, and the probe has been applied to detect Fe$^{3+}$ ions in zebrafish embryos. The furan-2-carbonyl chloride modified rhodamine B derivative 36 selectively forms a complex with Fe$^{3+}$ in 1:1 ratio and shows significant fluorescence enhancement at 582 nm that allows to detect Fe$^{3+}$ down to 0.437 $\mu$M [44]. The pyridine-type rhodamine B fluorescent probes 37 and 38 are developed to detect Fe$^{3+}$ down to 0.067 $\mu$M and 0.345 $\mu$M, respectively [45]. Its analytical applicability has been tested by monitoring Fe$^{3+}$ concentrations in various real water samples and live cells. The probe 39, developed by combining rhodamine and piperonaldehyde, shows LOD of 11.8 nM.

**Figure 2.** Fluorescence images of Fe$^{3+}$ in zebrafish using the probe 30 ($\lambda_{ex} = 546$ nm, fluorescent signals were collected at 550–650 nm). (a) Fluorescent image, (b) bright field image, and (c) merged image of zebrafish incubated with the probe 30 (10 nM) for 20 min. (d) Fluorescent image, (e) bright field image, and (f) merged image of probe 30-loaded zebrafish incubated with Fe$^{3+}$ (40 $\mu$M) for 20 min (Reproduced from Ref. [38] with permission from Elsevier).
The fluorescence enhancement occurred due to the inhibition of the PET from cryptand to BODIPY probes (Table 2). Belfield and his co-workers [48] introduced a novel PET-based reversible fluorescence turn-on probe 41 for the selective detection of Fe$^{3+}$. The probe 41 was designed by connecting boron-dipyrrromethene (BODIPY) fluorophore with a 1,10-di-aza-18-crown-6-based cryptand that acts as the analyte binding unit. The weakly fluorescent 41 (PET process is active) showed significant fluorescence enhancement at 512 nm ($\lambda_{\text{exc}} = 480$ nm) upon addition of Fe$^{3+}$ in H$_2$O-CH$_3$CN (9:1 v/v). The fluorescence enhancement occurred due to the inhibition of the PET from cryptand to BODIPY fluorophore upon complexation with Fe$^{3+}$. The probe showed a LOD of 1.3 $\times$ 10$^{-7}$ M and was applied for the detection of intracellular Fe$^{3+}$ ions in living HCT-116 cells. Using the Calix [4] arene framework, the quinoline-appended dipodal fluorescent probe 42 has been developed, and its cations sensing ability has been examined in CH$_3$CN [49]. Upon complexation of Fe$^{3+}$ with 42 in 1:1 binding ratio, significant fluorescence enhancement has been observed at 418 nm ($\lambda_{\text{exc}} = 310$ nm), and the LOD of 0.334 µM Fe$^{3+}$ has been estimated from the fluorescence titration experiment. Further, the 42-Fe$^{3+}$ complex has been applied as an intracellular fluorescent agent in MDA-MB-231 cells.

### Table 2. Physiochemical properties of some iron(III) selective turn-on probes.

| Probes (L) | Medium | Ex. $\lambda$ (nm) | Em. $\lambda$ (nm) | Fe$^{3+}$/L | LOD | Ref. |
|------------|--------|--------------------|--------------------|------------|-----|------|
| 41         | H$_2$O-CH$_3$CN (9:1, v/v) | 480 | 512 | 1:1 | 0.13 µM | [48] |
| 42         | CH$_3$CN | 310 | 418 | 1:1 | 0.334 µM | [49] |
| 43         | Aqueous CH$_3$CN | 314 | 554 | 1:1 | 0.74 nM | [50] |
| 44         | EtOH/0.01 M PBS buffer (v/v, 1:1, pH 7.4) | 465 | 578 | 2:1 | 8 nM | [51] |
| 45         | MeOH-H$_2$O (1:1, v/v), TRIS-HCl buffer (pH = 7.2) | 373 | 396,421,447 | 2:1 | 0.58 µM | [52] |
| 46         | CH$_3$CN.H$_2$O (1:7, v/v) at pH 7 | 376 | 406,429,456 | 2:1 | 0.1 µM | [53] |
| 47         | H$_2$O | 420 | 458 | 1:2 | 1 µM | [54] |
| 48         | CH$_3$CN | 395 | 500 | 1:2 | 0.106 µM | [55] |
| 49         | CH$_3$CN-acetone (v/v = 99:1) | 382 | 501 | 1:1 | 0.35 nM | [56] |
| 50         | CH$_3$CN.H$_2$O (1:7, v/v) | 403 | 524 | - | 0.35 nM | [57] |
| 51         | THF.H$_2$O (6:4, v/v) | 408 | 528 | 1:1 | 0.373 µM | [58] |
| 52         | H$_2$O | 332 | 430 | 1:1 | 0.235 µM | [59] |
| 53         | H$_2$O.EtOH (6:4, v/v) | 397 | 550 | 1:1 | 0.8 ppb | [60] |
| 54         | CH$_3$CN.H$_2$O (1:1, v/v) | 380 | 482 | 1:1 | 0.89 nM | [61] |
| 55         | CH$_3$CN | 380 | 516 | 1:2 | 0.45 µM | [62] |

Nandre et al. [50] developed a novel fluorescent probe 43 based on the benzo-thiazolo-pyrimidine unit for the selective turn-on sensing of Fe$^{3+}$ in aqueous acetonitrile medium. The probe 43 showed a remarkable fluorescence enhancement at 554 nm ($\lambda_{\text{exc}} = 314$ nm) in the presence of Fe$^{3+}$ due to the inhibition of PET. The sensor formed a host-guest complex in 1:1 stoichiometry with the limit of detection down to 0.74 nM. Further, the sensor was successfully utilized for the qualitative and quantitative intracellular detection of Fe$^{3+}$ in live HepG2 cells and HL-7701 cells by a confocal imaging technique (Figure 3). The diketopyrrolopyrrole-based supramolecular fluorescent probe 44 shows selective response in the presence of Fe$^{3+}$ and Au$^{3+}$ [51]. In EtOH/0.01 M PBS buffer (v/v, 1:1, pH 7.4), the weakly emission from 44 shows significant enhancement at 578 nm (465 nm) due to the inhibition of C=N isomerization at the excited state due to the formation of a 44-Fe$^{3+}$ complex in 1:2 ratio. From the fluorescence enhancement, the LOD for Fe$^{3+}$ has been estimated as 8 nM, and the probe is suitable to detect Fe$^{3+}$ over a pH range from 3 to 8. Besides, the probe 44 is cell-permeable and detects the intracellular Fe$^{3+}$ concentration in human lung adenocarcinoma cells (A549).
The novel quinolone-based fluorescent turn-on probe 45 containing anthracene fluorophore shows weak emission at 398, 421, and 447 nm ($\lambda_{\text{exc}} = 373$ nm) in Tris-HCl buffer (20 mM, pH 7.2) containing 50% methanol (v/v) [52]. In the presence of Fe$^{3+}$, the formation of a 45-Fe$^{3+}$ complex in 1:2 ratio inhibits the PET process, causing significant fluorescence enhancement. Probe 45 shows a linear response range from 1 µM to 10 µM with the LOD of 0.58 µM Fe$^{3+}$. Confocal imaging discloses that the probe 45 possesses the ability of cell membrane permeability and also the cytosolic Fe$^{3+}$ imaging ability in SKOV-3 cells. Recently, Kim and his co-workers [53] introduced a simple anthracene-based fluorescent turn-on probe 46 substituted with 9,10-diethanolamine for the detection of Fe$^{3+}$. In CH$_3$CN:H$_2$O (3:7, v/v) at pH 7, the weakly emissive probe showed emissions enhancement at 406, 429, and 456 nm characteristic of the anthracene monomer ($\lambda_{\text{exc}} = 376$ nm). Experimental results revealed that the probe 46 formed a complex with Fe$^{3+}$ in 1:2 binding stoichiometry with the association constant of $9.29 \times 10^6$ M$^{-1}$. The chelation-induced enhanced fluorescence (CHEF) effect along with the inhibition of PET resulted in the fluorescence enhancement. The limit of detection of 46 for Fe$^{3+}$ was estimated down to 0.1 µM, and the probe was applied for the monitoring of Fe$^{3+}$ ions in Candida albicans (C.A., KCTC-11282) cells. Further, the 46-Fe$^{3+}$ complex ensemble was applied for the selective detection of CN$^-$, and also an INHIBIT type logic gate was proposed by taking the two inputs, Fe$^{3+}$ and CN$^-$. 

The novel quinolone-based fluorescent turn-on probe 47 has been developed for the detection of Fe$^{3+}$ and Cr$^{3+}$ [54]. The analytical study of 47 towards Fe$^{3+}$ exhibits a significant fluorescence enhancement at 458 nm ($\lambda_{\text{exc}} = 420$ nm). The formation of a 47-Fe$^{3+}$ complex in 2:1 ratio restricts the rotation of thiophene, resulting in the fluorescence enhancement both in ethanol and aqueous medium. The probe shows LOD of 1 µM for Fe$^{3+}$. The probe has been applied for the biological applications in live HepG2 cells to monitor intracellular Fe$^{3+}$, and also the probe has been applied to detect the autophagosome-lysosome fusion during the autophagy process. The restriction of molecular rotation after forming aggregation also results in significant fluorescent enhancement. The pyrene-based Schiff base 48 solution in CH$_3$CN undergoes nano-aggregation by adding poor solvent water and shows significant emission enhancement at 465 nm due to the aggregation-induced emission enhancement (AIEE) [55]. The cations sensing ability of 48 in CH$_3$CN has been tested by adding different metal ions from their water solution, revealing significant fluorescence enhancement at 500 nm ($\lambda_{\text{exc}} = 395$ nm) in the presence of Fe$^{3+}$, Cr$^{3+}$, and Al$^{3+}$. The fluorescence enhancement in the presence of the selective
trivalent metal ions has occurred due to the formation of pyrene excimer upon complexation between 48 and Fe$^{3+}$/Cr$^{3+}$/Al$^{3+}$ in 2:1 ratio. With 48, the LOD is estimated down to 0.106 µM, 0.111 µM, and 0.117 µM for Fe$^{3+}$, Cr$^{3+}$, and Al$^{3+}$, respectively. Besides, the probe shows the ability to detect the selective metal ions within the live Raw264.7 cells. With the excimer formation mechanism, the pyrene-based fluorescent probe 49 has been developed for the selective detection of Fe$^{3+}$ [56]. In acetonitrile-acetone ($v/v = 99:1$), the probe 49 shows weak emission due to the transfer of the electrons on the nitrogen atom to pyrene (PET active). However, upon complexation with Fe$^{3+}$ in 1:1 binding ratio, the probe shows fluorescence enhancement at 507 nm due to the formation of pyrene excimer ($\lambda_{exc} = 382$ nm). The quantum yield of the probe ($\Phi = 0.001$) is enhanced 41-fold ($\Phi = 0.041$) upon complexation. Besides, the Fe$^{3+}$-directed formation of a pyrene excimer has also been detected in live HeLa cells.

Han et al. [57] introduced a novel naphthalimide-diethylenetriamine-quinoline-based fluorescent turn-on probe 50 for the selective detection of Fe$^{3+}$ that operated with AIEE and PET mechanisms. The weakly emissive 50 at 513 nm ($\lambda_{exc} = 403$ nm) in pure CH$_3$CN showed maximum fluorescence enhancement along with the red-shift from 513 to 524 nm in CH$_3$CN containing 70% water due to the formation of nano-aggregates, and the red-shift is due to the restriction of intramolecular rotation. The
fluorescent organic nanoparticles (FONs) of 50 showed stable fluorescence in the pH interval from 7–14 and also showed selective fluorescence enhancement in the presence of Fe3+. The FONs showed a linear range from 1 nM to 100 mM with the LOD of 0.35 nM Fe3+. It was proposed that the FONs fluorescence was disrupted due to the PET from the diethylenetriamine unit to the electron-deficient naphthalimide group. Upon complexation of 50 with Fe3+ in the FONs, the PET was forbidden, and a dramatic increase in fluorescent intensity was observed. In the cellular medium, the FONs showed low cytotoxicity, and the intracellular Fe3+ ions were detected in HeLa by using a fluorescence microscope (Figure 4).

![Image of HeLa cells after incubation with FONs](Figure 4)

Figure 4. Images of HeLa cells after incubation with FONs (fluorescent organic nanoparticles) 50. (A) Bright-field image of HeLa cells incubated with Fe3+/FONs (10 mM); (B) fluorescence image of (A); (C) the overlay image of (A) and (B); (D) bright-field image of HeLa cells incubated with FONs (10 mM); (E) fluorescence image of (D); (F) the overlay image of (D) and (E). The fluorescence images were acquired with green light excitation (Reproduced from Ref. [57] with permission from The Royal Society of Chemistry).

Dwivedi et al. [58] utilized the naphthalimide as a signaling unit and the suitably connected thiophene and piperazine rings as recognition unit to develop a highly selective fluorescent turn-on probe 51 to detect Fe3+ in solution and live cells. The PET active probe 51 was non-fluorescent in 40% aqueous THF solution, but significant fluorescent was observed at 528 nm (λexc = 408 nm) with the addition of Fe3+. The S atom of thiophene unit and the N atoms of piperazine of 51 formed a complex with Fe3+ in 1:1 ratio, inhibiting the PET and resulting in the fluorescence enhancement. With this probe, the LOD was estimated as 0.373 μM, and the probe was applied over a wide pH range (pH 6 to 14) to detect Fe3+. The probe showed excellent biocompatibility and cell permeability to detect the intracellular Fe3+ ions in live MCF-7 cells. Further, the in-situ generated Fe3+-51 complex was applied for the fluorescent turn-off sensing of AcO−. Applying the PET mechanism, recently, an easy-to-prepare amide-quinoline-based fluorescent probe 52 has been developed for the detection of Fe3+ and Al3+ in aqueous medium [59]. The probe forms complex with Fe3+ and Al3+ in the 1:1 binding ratio that diminishes the electron donation from the isoquinoline nitrogen atom towards the pyridyl ring and
inhibits the PET. The suppression of PET at the excited state results in the significant fluorescence enhancement at 430 nm ($\lambda_{ex} = 332$ nm). The probe shows micromolar LOD of 0.092 and 0.235 $\mu$M for Al$^{3+}$ and Fe$^{3+}$, respectively. Also, the low cytotoxicity of 52 allows monitoring intracellular Fe$^{3+}$ and Al$^{3+}$ ions in live HeLa cells by fluorescence microscopy.

The Schiff-based probe 53 shows fluorescence quenching due to the excited-state intramolecular proton transfer (ESIPT) in H$_2$O:EtOH (6:4, v/v) [60]. With the addition of Fe$^{3+}$, the formation of a 53-Fe$^{3+}$ complex in 1:1 ratio suppresses the ESIPT and results in a significant fluorescent enhancement at 550 nm ($\lambda_{ex} = 397$ nm). The probe shows a wide linear range from 0–200 $\mu$M with the LOD of 0.8 ppb. Finally, the probe has been applied to detect intracellular Fe$^{3+}$ ions in the cancer HeLa cells. Another Schiff base probe 54 has been developed for the selective fluorescent turn-on sensing of Fe$^{3+}$ in CH$_3$CN:H$_2$O (1:1, v/v) [61]. The probe shows two weak emissions at 430 nm and 574 nm ($\lambda_{ex} = 380$ nm). The formation of a 54-Fe$^{3+}$ complex in 1:1 ratio facilitates the charge transfer from the imino group of 54 to Fe$^{3+}$ ion, resulting in an enhanced emission peak centered at 482 nm. The probe can be applied to detect Fe$^{3+}$ down to the nanomolar level (0.89 nM) and is effective at a pH range of 6 to 7. The probe shows good cells permeability, and its ability to detect intracellular Fe$^{3+}$ ions has been tested in live HeLa cells.

Erdemir et al. [62] introduced an anthracene-based fluorescent probe 55 containing benzothiazole group as a binding unit for the fluorescent turn-on sensing of Fe$^{3+}$ and Cr$^{3+}$. In CH$_3$CN, probe 55 shows a weak emission at 428 nm due to the PET process ($\lambda_{ex} = 380$ nm). Addition of Fe$^{3+}$/Cr$^{3+}$ suppresses the PET, and the complexation of the cations with 55 in 1:2 ratio results in the formation of the anthracenyl static excimer that give distinct fluorescence at 576 nm. The fluorescence titration experiments have estimated the LOD for Cr$^{3+}$ and Fe$^{3+}$ as 0.46 and 0.45 $\mu$M, respectively. Finally, the probe has been applied for the fluorescence imaging of living cells and for monitoring Fe$^{3+}$ ions in live PC-3 cells.
3. Ratiometric Fluorescent Probes for Fe(III)

The ratiometric fluorescent probes generally refer to the chemosensors that detect the target analyte from the changes in fluorescence intensity occurring at two emission bands [63]. The ratio of the change in fluorescence intensity of the probe at two different emission peaks is calibrated to monitor the target analyte. Because of the presence of two different emission bands for detection, the ratiometric probes provide several analytical advantages over the probe operated only at a single emission band and also minimize the interferences of the external environments like the concentration of the probe, instrumental parameters, photobleaching, etc. Therefore, great efforts have been given to develop ratiometric fluorescent probes with their potential applications in the field of environmental detection and biological analysis. The well-established mechanisms like fluorescence resonance energy transfer (FRET), through-bond energy transfer (TBET), excimer/exciplex formation, intramolecular charge transfer (ICT), etc. can be adopted for the designing of ratiometric fluorescent probes. Several Fe$^{3+}$-selective ratiometric fluorescent probes have been reported in the last few years (Table 3), which are mainly based on the FRET, TBET, and ICT mechanisms.

Table 3. Physiochemical properties of some iron(III) selective ratiometric fluorescent probes.

| Probes (L) | Medium | Ex.$\lambda$ (nm) | Em.$\lambda$ (nm) | Fe$^{3+}$: L | LOD | Ref. |
|------------|--------|------------------|------------------|-------------|-----|-----|
| 56         | Tris HCl-CH$_3$CN (1:1, v/v, pH 7.4) | 420 | 532, 580 | 1:1 | 50 nM [64] |
| 57         | Tris-HCl-CH$_3$CN (1:1, v/v, pH 7.4) | 400 | 532, 580 | 1:1 | 0.03 µM [65] |
| 58         | EIOH-H$_2$O (2:1, v/v, HEPES buffer, pH 7) | 330 | 455, 585 | 1:1 | 540 nM [66] |
| 59         | Tris-HCl, pH = 7.2 | 400 | 442, 538 | 1:1 | 300 nM [67] |
| 60         | EIOH-H$_2$O (4:1) | 371 | 431, 594 | 1:1 | 6.93 µM [68] |
| 61         | CH$_3$CN-Tris-ну | 380 | 515, 605 | 1:1 | 0.64 µM [69] |
| 62         | EIOH | 420 | 520, 577 | 1:1 | 0.418 µM [70] |
| 63         | CH$_3$OH/H$_2$O (2:3, v/v, pH = 7.2) | 370 | 470, 558 | 1:1 | 53.9 nM [71] |
| 64         | EIOH-H$_2$O (9:1, v/v, Tris-HCl, pH = 7.4) | 450 | 475, 550 | 1:1 | 4.05 µM [72] |
| 65         | CH$_3$OH/H$_2$O (4:6, v/v) | 420 | 535, 585 | 1:1 | 0.105 µM [73] |
| 66         | CH$_3$CN-HEPES buffer (1/4, v/v, pH 7.4) | 365 | 412, 445 | 1:1 | 3.5 µM [74] |
| 67         | CHCl$_3$-MeOH (1:1, v/v) | 300 | 400, 480 | 1:1 | 1.17 µM [75] |
| 68         | DMSC/H$_2$O (1.95, v/v) | 320 | 443, 380 | 1:1 | 2 µM [76] |
| 69         | CH$_3$CN-Tris buffer = 9:1, v/v, pH = 7.4 | 380 | 431, 517 | 1:2 | 4.47 µM [77] |
| 70         | Aqueous CH$_3$CN | 420 | 504, 526 | 1:1 | 10 nM [78] |

The FRET-based probe consists of two fluorophore units separated by a spacer, where the excited state of one fluorophore (donor) transfers its energy to the closely located another fluorophore (acceptor) in a non-radiative manner, and then the energy is released in a radiative manner from the second fluorophore [63]. In designing FRET-based probes, care must be taken that the donor to acceptor distance and orientation is appropriate for energy transfer. Besides, there must be spectral overlap between the fluorescence profile of the donor fluorophore with the UV-Vis absorption spectra of acceptor fluorophore. By utilizing the naphthalimide and rhodamine dyes, the FRET-based fluorescent probe 56 has been designed for the ratiometric detection of Fe$^{3+}$ in aqueous acetonitrile (1:1, v/v, 0.01 M Tris HCl-CH$_3$CN, pH 7.4) medium [64]. In this probe, the triazole appended quinoline-rhodamine conjugate acts as a selective ionophore for Fe$^{3+}$ and FRET energy acceptor, whereas the 8-piperazinonaphthalimide moiety acts as the FRET energy donor. In the presence of Fe$^{3+}$, the emission at 532 nm from the naphthalimide moiety is decreased, and a new emission band appears at 580 nm ($\lambda_{exc} = 420$ nm). The ratiometric response from the probe 56 is due to the complexation-induced opening of the spirocyclic ring of the rhodamine moiety that facilitates the FRET from the naphthalimide donor. The FRET is possible because of the excellent spectral overlap of the naphthalimide emission spectrum with the absorption spectrum of the rhodamine unit of 56. With this probe, the LOD has been estimated down to $5 \times 10^{-8}$ M (-3 ppb) and applied successfully for the monitoring of trace levels of intracellular Fe$^{3+}$ ions in NIH 3T3 cells (Figure 5). Subsequently, the same group uses the naphthalimide-rhodamine combination to develop a FRET-based multi-analytes (Fe$^{3+}$, Al$^{3+}$, and Cr$^{3+}$)-selective fluorescent probe 57 [65]. This probe shows a decrease in the naphthalimide emission at 532 nm and concomitant appearance of a new emission peak at 583 nm upon addition of Fe$^{3+}$, Al$^{3+}$, and Cr$^{3+}$ ions in aqueous acetonitrile (1:1, v/v, 0.01 M Tris HCl-CH$_3$CN, pH 7.4) medium. The formation of the metal complex...
between 57 and the metal ions in 1:1 binding stoichiometry opens the spirocyclic ring of the rhodamine unit, allowing the FRET process to give the ratiometric signal. Also, the probe has been applied to detect the intracellular Fe$^{3+}$ ions in W138 cells.

Figure 5. Bright-field and fluorescence microscopic images of NIH 3T3 cells obtained using a Leica DM IRB microscope equipped with an EBQ-100 UV-lamp. Top row: NIH 3T3 cells incubated with 56 (5 mM) for 30 min and observed under bright-field (a), green channel (b), and red channel (c). Bottom row: NIH 3T3 cells incubated with 56 (5 mM) for 30 min, treated with Fe$^{3+}$ (5 mM) for 15 min, and observed under bright-field (d), green channel (e), and red channel (f) (Reproduced from Ref. [64] with permission from The Royal Society of Chemistry).

Das and his co-workers [66] developed the FRET-based fluorescent probe 58 containing a 2-hydroxynaphthalene unit as a donor and rhodamine B as an acceptor for the selective detection of Cr$^{3+}$ and Fe$^{3+}$ in HEPES buffered (0.1 M) EtOH-H$_2$O (2:1, v/v, pH 7). The fluorescence of 58 at 455 nm ($\lambda_{exc} = 330$ nm, blue fluorescence) from the 2-hydroxynaphthalene moiety is quenched, and a new fluorescence band appears at 585 nm (red fluorescence) in the presence of Fe$^{3+}$ and Cr$^{3+}$. The complexation-induced ring-opening of the spirolactam unit has resulted in energy transfer from the donor to the acceptor unit. With 58, the concentration of Cr$^{3+}$ and Fe$^{3+}$ can be detected down to 10 nM and 0.54 µM, respectively. Further, the probe has been applied for the detection of intracellular Cr$^{3+}$ and Fe$^{3+}$ ions in Bacillus sp. cells and Candida albicans cells by recording the fluorescence images. Applying the FRET mechanism, the rhodamine spirolactam has been connected to the blue fluorescent water-soluble ionic conjugated polymers (CPs) to develop a ratiometric probe for Fe$^{3+}$ [67]. Exciting the probe 59 at 400 nm in a buffer solution (Tris-HCl, pH = 7.2), the fluorescence of CPs at 442 nm is quenched, and a new peak appears at 538 nm in the presence of Fe$^{3+}$ due to the complexation-induced spirocyclic ring-opening of rhodamine 6G. Also, the quenching of CPs emission is due to the possible FRET to the rhodamine 6G unit. Using the ratiometric signal changes (I$_{538}$/I$_{442}$), the detection limit has been estimated as 0.3 µM. The FRET efficiency between CPs and rhodamine 6G is 61.8%, and the distance between the acceptor and donor as 4.06 nm, supporting the efficient FRET between the two fluorophores. Using the probe 59, the confocal fluorescence imaging experiment has been carried to monitor the intracellular Fe$^{3+}$ ions in live HeLa cells.
Chen et al. [68] introduced a new ratiometric fluorescent sensor 60 by suitably combining the naphthalene and rhodamine dyes for the selective detection of mitochondrial Fe\(^{3+}\) in live HeLa cells. The fluorescence of 60 at 431 nm was quenched, and concomitantly a new emission appeared at 594 nm (\(\lambda_{\text{exc}} = 371\)) upon addition of Fe\(^{3+}\) in EtOH-H\(_2\)O (4:1). The ratiometric emission from the probe 60 was observed due to the possible FRET from the conjugated naphthalene donor to the rhodamine acceptor. Without any noticeable interference from other tested metal ions, the concentration of Fe\(^{3+}\) could be detected down to 6.93 \(\mu\)M. Besides, due to the presence of a lipophilic alkyltriphenylphosphonium (alkylTTP) cation that helps in passing directly through the phospholipid bilayers and accumulate selectively within the mitochondria inside cells, the probe 60 showed satisfactory cell permeability and detected the mitochondrial Fe\(^{3+}\) in live HeLa cells (Figure 6).

The FRET-based fluorescent probe 61 containing a dansyl unit as a donor and rhodamine 101 as an acceptor has been developed to detect Fe\(^{3+}\) in CH\(_3\)CN-Tris buffer (9:1, v/v, pH 7.05) [69]. Fe\(^{3+}\)-induced ring-opening of the spirolactam rhodamine moiety results in the formation of fluorescent derivative that can serve as the FRET acceptor (\(\lambda_{\text{exc}} = 380\) nm). Ratiometric sensing of Fe\(^{3+}\) is accomplished by plotting the fluorescence intensity ratio at 605 nm and 515 nm versus Fe\(^{3+}\) ions concentration. The large Stokes shift (225 nm) shown by the probe can eliminate the back-scattering effects of excitation light. The probe displays a linear response to Fe\(^{3+}\) in the range of 5.5–25 \(\mu\)M with a detection limit of 0.64 \(\mu\)M. Combining naphthalimide and rhodamine B by using the ethylenediamine connector, a new Fe\(^{3+}\)-selective FRET-based ratiometric fluorescent probe 62 has been developed [70], where the naphthalimide acts as an energy donor, while the spirocyclic ring-open form of rhodamine as the energy acceptor. Upon complexation with Fe\(^{3+}\), the emission from the naphthalimide unit of the probe 62 at 520 nm is decreased, and a significant enhancement of the characteristic fluorescence of the rhodamine is observed at 577 nm (\(\lambda_{\text{exc}} = 420\) nm) in ethanol solution. The probe shows a linear range for Fe\(^{3+}\) from 0.2 to 1 \(\mu\)M with the LOD of 0.418 \(\mu\)M. Besides, the probe shows the cell permeability to detect the intracellular Fe\(^{3+}\) ions in live EC109 cells in the fluorescence imaging study.

The FRET-based benzothiazole conjugated quinoline derivative appended with rhodamine-6G ratiometric fluorescent probe 63 has been introduced for the detection of Fe\(^{3+}\) [71]. The probe shows a strong emission at 470 (\(\lambda_{\text{exc}} = 370\) nm) from the benzothiazole moiety in CH\(_3\)OH/H\(_2\)O (2/3, v/v, pH = 7.2). The complexation-induced opening of the spirocyclic ring of the rhodamine unit results in FRET from the energy donor (benzothiazole moiety) to the energy acceptor (rhodamine-6G domain). As a result, a new peak appears at 558 nm with the gradual decrease in the intensity at 470 nm. The ratio of the emission intensities at the two wavelengths (I\(_{558}/I_{470}\)) exhibits good linearity with the added concentration of Fe\(^{3+}\) from 0–14 \(\mu\)M with the estimated LOD of 53.9 nM. The FRET-based probe 64 has been designed by suitably connecting the coumarin (energy donor) with the rhodamine moiety (energy
acceptor) [72]. In EtOH-H$_2$O (9:1, v/v, Tris-HCl, pH = 7.4), the receptor shows only the coumarin emission band at 475 nm ($\lambda_{exc}$ = 450 nm), whereas a new emission band appears at 550 nm upon addition of Fe$^{3+}$ due to the complexation-induced opening of the spirocyclic ring of the rhodamine. With this probe, the concentration of Fe$^{3+}$ can be detected down to 4.05 µM.
The FRET-based energy transfer mechanism is most popular for the designing of ratiometric fluorescent probes, and their FRET efficiency is primarily controlled by the spectral overlap between the emission spectrum of the energy donor and the absorption spectrum of the energy acceptor. In contrast to the FRET systems, the through-bond energy transfer (TBET) systems are not limited to such spectral overlap for the energy transfer between two fluorophores. The probes based on TBET mechanisms are well-known to show fast energy transfer rates and large pseudo-Stokes shift. In probe 65, the energy donor (4-morpholine)-1,8-naphthalide moiety is linked to the energy acceptor rhodamine by a rigid and conjugated spacer p-phenylenediamine [73]. This rigid connection efficiently prevents the fluorescence quenching of naphthalimide. In the absence of Fe\(^{3+}\), the excited energy of the naphthalimide donor is not transferred to the closed form of rhodamine acceptor, and the characteristic peak of naphthalimide is observed at 535 nm in CH\(_3\)OH-H\(_2\)O (4:6, v/v). The complexation of 65 with Fe\(^{3+}\) opens the spirocyclic ring of the rhodamine ring, resulting in a significant fluorescence enhancement at 585 nm (\(\lambda_{\text{exc}} = 420\) nm). Simultaneously, the naphthalimide emission at 535 nm quenches due to the TBET. The ratiometric probe 65 shows a linear fluorescence response from 0 to 20 µM with the LOD of 0.105 µM Fe\(^{3+}\). Further, the probe has been applied for ratiometric fluorescence imaging of Fe\(^{3+}\) ions in living EC109 cells (Figure 7).
Chattopadhyay and his co-workers [74] introduced the ratiometric fluorescent probe 66, which undergoes a 1,5-sigmatropic shift in solution to form the benzimidazole derivative with the more chelating environment. The intensity of the weakly fluorescence benzimidazole derivative of 66 at 412 nm ($\lambda_{\text{exc}} = 365 \text{ nm}$) was decreased, and a new fluorescence peak appeared at 445 nm upon addition of Fe$^{3+}$ in CH$_3$CN-HEPES buffer (1/4, v/v, pH 7.4) due to the chelation enhanced fluorescence (CHEF) effect. Similar ratiometric fluorescence changes were also observed in the presence of Fe$^{2+}$. With 66, the ratiometric fluorescence response could be used to detect Fe$^{3+}$ and Fe$^{2+}$ ions down to 3.5 $\mu$M and 2 $\mu$M, respectively. Further, the probe was applied to detect intracellular Fe$^{3+}$ ions in live HeLa cells. Based on the efficient ligand metal charge-transfer effect, the piperazine-based dipodal fluorescent probe 67 appended with 8-hydroxyquinoline has been introduced for the ratiometric detection of Fe$^{3+}$ [75]. In CHCl$_3$-MeOH (1:1, v/v), the probe has shown monomer emission of the quinoline moiety at 400 nm ($\lambda_{\text{exc}} = 300 \text{ nm}$). Upon addition of Fe$^{3+}$, the emission peak at 400 nm is quenched, and a new broad emission appears at 480 nm. This ratiometric fluorescence quenching in the presence of Fe$^{3+}$ is attributed to the strong interaction of Fe$^{3+}$ with the triazolmethyloxyquinoline (as tridentate ligand) motifs of 67. Calibrating the intensity ratio ($I_{480}/I_{400}$) with the change in concentration of Fe$^{3+}$ gives LOD of 1.17 $\mu$M. Receptor 67 is cells permeable and detect intracellular Fe$^{3+}$ ions in live HeLa cells with no cytotoxicity. Sequentially, the 67-Fe$^{3+}$ complex ensemble is applied for the selective detection of fluoride anion.

**Figure 7.** Images of EC109 cells treated with the ratiometric 65: (a) bright-field image of EC109 cell incubated with 65 (5 $\mu$M); (b) fluorescence image from green channel; (c) fluorescence image from red channel; (d) bright-field image of EC109 cell incubated with 65 (5 $\mu$M) for 15 min, and then further incubation with Fe$^{3+}$ (5 $\mu$M) for 15 min at 37 °C; (e) fluorescence image from green channel; (f) fluorescence image from red channel (Reproduced from Ref. [73] with permission from Elsevier).
The dipodal clip-type ratiometric fluorescent probe 68 containing two benzimidazole groups has been applied for the selective detection of Cr$^{3+}$ and Fe$^{3+}$ ions in DMSO/H$_2$O (1:99, v/v) [76]. When excited at 320 nm, the probe 68 fluorescence at 443 nm quenches and simultaneously enhances at 378/380 nm upon addition of Cr$^{3+}$/Fe$^{3+}$. It has been proposed that the blue-shift in the fluorescence of 68 is due to the intramolecular charge transfer (ICT), whereas the enhancement of fluorescence intensity upon Cr$^{3+}$/Fe$^{3+}$ complexation is most likely due to the inhibition of PET processes. With the probe, the minimum detection limit is estimated as 25 µM and 2 µM for Cr$^{3+}$ and Fe$^{3+}$, respectively. Further, the selective UV-Vis spectral changes of 68 in the presence of Fe$^{3+}$ allow discriminating the presence of both Cr$^{3+}$ and Fe$^{3+}$. Using the robust fluorophore 2-pyridylthiazole and ICT mechanism, an easy-to-prepare ratiometric fluorescence probe 69 has been developed for the selective detection of Fe$^{3+}$ [77]. In an aqueous system (CH$_3$CN/Tris buffer = 9:1, v/v, pH = 7.4), the probe emission at 431 nm quenches with the concomitant appearance of a new emission at 517 nm ($\lambda_{exc}$ = 380 nm) in the presence of Fe$^{3+}$. The LOD of this probe is estimated to be 4.47 µM for Fe$^{3+}$. Recently, the easy-to-prepare linear Schiff base receptor 70 has been developed for the ratiometric detection of Fe$^{3+}$ and fluorescence turn-off sensing of Cu$^{2+}$ in aqueous acetonitrile medium [78]. Upon addition of Fe$^{3+}$, receptor 70 induces a selective fluorescence enhancement with a 22 nm red-shift from 504 nm to 526 nm, making it easily distinguishable from the other tested metal ions. The fluorescence enhancement is observed presumably due to deprotonation of the phenolic-OH protons on coordination with Fe$^{3+}$, inhibiting the –C=N isomerization and/or the ESIPT process in the excited state. Also, the red-shift indicates that the possible ICT occurs in 70 on interaction with Fe$^{3+}$. In contrast, the fluorescence of 70 quenches upon addition of Cu$^{2+}$. The quenching by Cu$^{2+}$ is most likely due to an energy transfer process occurring between 70 and paramagnetic Cu$^{2+}$. From the emission titrations, the LOD for the sensing of Fe$^{3+}$ and Cu$^{2+}$ ions are estimated to be 10 nM and 15 nM, respectively. Besides, the organic nanoparticles (ONPs) of the probe 70 has been developed and applied for the detection of Fe$^{3+}$ and Cu$^{2+}$ in different drug supplements available in the market. Also, the probe fluorescence response has been applied to mimic the IMP (IMPLICATION) type logic gate with the two-inputs as Fe$^{3+}$ and Cu$^{2+}$.

4. Fluorescent Chemodosimeters for Fe(III)

The design of Fe$^{3+}$-selective fluorescent turn-on probes with high selectivity and sensitivity can be achieved by chemodosimeter approach, where the Fe$^{3+}$ ions mediate the breaking of some important bonds in the probe, leading to the irreversible transduction of a detectable fluorescent signal [79]. Recently, a few one-time use fluorescent chemodosimeters are reported for the detection of Fe$^{3+}$ (Table 4) and are also applied successfully to detect the intracellular Fe$^{3+}$ ions in live cells by bioimaging.

Table 4. Physiochemical properties of some iron(III) selective reaction-based fluorescent probes.

| Probes (L) | Medium                                      | Ex. λ (nm) | Em. λ (nm) | LOD     | Ref.  |
|-----------|---------------------------------------------|------------|------------|---------|-------|
| 71        | HEPES aqueous buffer (pH 7, 40 mM)          | 585        | 615        |         | [80]  |
| 72        | Potassium phosphate buffer/acetone (1:4, v/v, pH = 7) | 360        | 522        | 0.12 µM | [81]  |
| 73        | Aqueous DMSO                                | 325        | 441        | 4.3 µM  | [82]  |
| 74        | DMSO/H$_2$O (v/v = 70:30)                   | 396        | 440        | 1.37 µM | [83]  |
| 75        | DMSO/H$_2$O (v/v = 9/1, HEPES buffer, pH = 7.4) | 390        | 440        | 75.7 nM | [84]  |
| 76        | MeOH/H$_2$O (9/1, v/v)                      | 388        | 430        | 0.118 µM | [85]  |
| 77        | THF-H$_2$O (8:2)                            | 330        | 430        | 0.38 nM | [86]  |

Chen et al. [80] introduced a novel chemodosimeter-based fluorescent probe 71, consisted of a BODIPY dye, as a signal transducer that is suitably linked to a hydroxylamine unit (Figure 8). Above pH = 5.8, the electron-donating ability from the hydroxylamine to the fluorophore unit quenched the fluorescence at 615 nm ($\lambda_{exc} = 585$ nm) due to the PET. In HEPES aqueous buffer (pH 7, 40 mM), the addition of Fe$^{3+}$ selectively oxidized the hydroxylamine that inhibited the PET process, and a significant fluorescence enhancement was observed (from $\Phi = 0.01$ to $\Phi = 0.35$). The probe 71 showed a good linear dependence of fluorescence intensity on Fe$^{3+}$ concentration (0–50 µM) and applied successfully for the monitoring of Fe$^{3+}$ concentration in live MCF-7 cells by using the confocal fluorescence microscope (Figure 8).

Subsequently, considering the ability of Fe$^{3+}$ to mediate the deprotection of acetal reaction, the ratiometric fluorescent probe 72 has been designed for the highly selective detection of Fe$^{3+}$ in 20 mM potassium phosphate buffer/acetone (pH 7, 1:4 (v/v)) at room temperature [81]. The acetal group of 72 is deprotected into aldehyde by Fe$^{3+}$, increasing the $\pi$-electrons conjugation, and, therefore, the effective ICT from the phenanthroline unit to the aldehyde results in the red-shift in the emission band from 390 nm to 522 nm ($\lambda_{exc} = 360$ nm). The fluorescence titration of 72 with Fe$^{3+}$ shows satisfactory linearity in the range of 0–30 µM between the emission ratio ($I_{522}/I_{390}$) and the concentration of Fe$^{3+}$. With 72, the concentration of Fe$^{3+}$ can be detected down to 0.12 µM. Further, the probe has been successfully applied for imaging Fe$^{3+}$ in living pancreatic cancer cells (Figure 9).
specific for the detection of Fe3+, and the concentration of Fe3+ could be monitored by using both back-formation of 2,5-dimethoxybenzaldehyde and 1-aminopyrene. The probe has been successfully applied for imaging Fe3+ in living pancreatic cancer cells (Figure 9).

[81] with permission from Elsevier).
Sahoo and his co-workers [82] introduced an easy-to-prepare chemodosimeter-type optical chemosensor 73 for the selective detection of Fe$^{3+}$ by condensing 1-aminopyrene with pyridoxal. Probe 73 showed weak emission at 441 nm ($\lambda_{\text{exc}} = 325$ nm) due to the PET process occurring from the pyridoxal imine to the pyrene fluorophore. Addition of Fe$^{3+}$ hydrolyzed the imine linkage of 73, leading to the back-formation of 1-aminopyrene and pyridoxal, resulting in a significant fluorescence enhancement at 441 nm in the aqueous DMSO medium. The probe 73 showed good linearity from 0 M to $6.98 \times 10^{-5}$ M with the limit of detection down to 4.3 $\mu$M for Fe$^{3+}$. The probe 73 was highly specific for the detection of Fe$^{3+}$, and the concentration of Fe$^{3+}$ could be monitored by using both spectrophotometer and smartphone. Besides, the probe 73 could be applied to monitor Fe$^{3+}$ within the live HeLa cells. With a similar approach, three more Fe$^{3+}$-selective fluorescent probes 74-76 have been reported [83–85]. The probe 74 shows significant fluorescence enhancement at 440 nm ($\lambda_{\text{exc}} = 396$ nm) selectively in the presence of Fe$^{3+}$ in DMSO/H$_2$O (v/v = 70:30) due to the Fe$^{3+}$-mediated hydrolytic cleavage of the imine linkage [83]. Using 74, the concentration of Fe$^{3+}$ can be detected down to 1.37 $\mu$M and successfully applied to detect intracellular Fe$^{3+}$ ions in live RAW264.7 cells by fluorescence microscopy. The same group reports the Fe$^{3+}$-selective chemodosimeter 75, showing selective fluorescence enhancement at 440 nm ($\lambda_{\text{exc}} = 390$ nm) in DMSO/H$_2$O (v/v = 9/1), buffered with HEPES, pH = 7.4) [84]. The probe 75 shows nanomolar detection limit of 75.7 nM for Fe$^{3+}$. The probe 75 shows good cell-membrane permeability, and also the Fe$^{3+}$-directed hydrolysis of imine linkage is shown to be detected in live HeLa cells by fluorescence microscopy. Recently [85], the probe 76 is introduced for the selective detection of Fe$^{3+}$ in MeOH/H$_2$O (9/1, v/v). The weakly emissive probe 76 shows gradual fluorescence enhancement at 430 nm upon successive incremental addition of Fe$^{3+}$ due to the back-formation of 2,5-dimethoxybenzaldehyde and 1-aminopyrene. The probe 76 shows the LOD of 0.118 $\mu$M without any interference from other tested metal ions. Similar to the other chemodosimeters, probe 76 has been successfully applied to detect intracellular Fe$^{3+}$ ions in live RAW264.7 cells by fluorescence microscopy. Adopting the hydrolytic cleavage of imine linkage, the multi-analytes selective chemodosimeter 77 has been developed for the detection of trivalent metal ions (Fe$^{3+}$, Cr$^{3+}$, and Al$^{3+}$) in THF-H$_2$O (8:2) medium [86]. The strong Lewis acidity of trivalent cations (Fe$^{3+}$/Al$^{3+}$/Cr$^{3+}$) selectively breaks the imine linkage, resulting in significant fluorescence enhancement at 430 nm ($\lambda_{\text{exc}} = 330$ nm). With the probe, the concentration of selective cations Fe$^{3+}$, Al$^{3+}$, and Cr$^{3+}$ can be detected down to 0.38 nM, 0.38 nM, and 0.36 nM, respectively. Further, the probe has been applied to image the native cellular iron pools in Candida albicans cells.
5. Conclusions

Because of the quenching effect of Fe^{3+}, the designing of fluorescent turn-on and ratiometric probes are very challenging, and, therefore, we observed during the literature search that the majority of the reported fluorescent probes for Fe^{3+} are based on fluorescence quenching process. However, by applying the sensing mechanisms like the complexation-induced opening of the spirocyclic ring, PET, FRET, TBET, AIEE, excimer formation, etc., several Fe^{3+}-selective fluorescent turn-on and ratiometric probes have been reported after 2012. This critical review presents a total of 77 Fe^{3+}-selective fluorescent turn-on and ratiometric probes that can monitor Fe^{3+} ions, both in solution as well as within live cells. The analytical parameters like selectivity, specificity, and sensitivity of the summarized probes are suitable for their potential applications in monitoring Fe^{3+} ions concentration in various real environmental and biological samples. We believe the advantages of fluorescent probes like low-cost and simplicity would encourage the real applications of the probes summarized in this review. However, despite several analytical advantages, further research is required to develop probes that function in a pure aqueous medium because the use of organic solvents can limit their use in biological samples. Therefore, there is a wide-open scope for further research to develop novel Fe^{3+}-selective fluorescent probes with potential analytical applications.
