Accurate massively parallel sequencing (MPS) of genetic variants is key to many areas of science and medicine, such as cataloging population genetic variation and diagnosing genetic diseases. Certain genomic positions can be prone to higher rates of systematic sequencing and alignment bias that limit accuracy, resulting in false positive variant calls. Current standard practices to differentiate between loci that can and cannot be sequenced with high confidence utilize consensus between different sequencing methods as a proxy for sequencing confidence. These practices have significant limitations, and alternative methods are required to overcome them. We have developed a novel statistical method based on summarizing sequenced reads from whole-genome clinical samples and cataloging them in “Incremental Databases” that maintain individual confidentiality. Allele statistics were cataloged for each genomic position that consistently showed systematic biases with the corresponding MPS sequencing pipeline. We found systematic biases present at ∼1%–3% of the human autosomal genome across five patient cohorts. We identified which genomic regions were more or less prone to systematic biases, including large homopolymer flanks (odds ratio = 23.29–33.69) and the NIST high confidence genomic regions (odds ratio = 0.154–0.191). We confirmed our predictions on a gold-standard reference genome and showed that these systematic biases can lead to suspect variant calls within clinical panels. Our results recommend increased caution to address systematic biases in whole-genome sequencing and alignment. This study provides the implementation of a simple statistical approach to enhance quality control of clinically sequenced samples by flagging variants at suspect loci for further analysis or exclusion.

[Supplemental material is available for this article.]
sequencing. Another drawback is that clinically collected samples can vary in quality, and contamination may introduce variants with low allelic fractions not seen in reference genomes. Furthermore, the number of reference genomes used may be quite small, so sample-specific structural variants, which are not representative of the diversity of clinically sequenced genomes, can cause genomic regions to be missing from the ‘high confidence’ list despite having accurate sequencing for most samples.

Other top-down approaches of evaluating thresholds for allelic fraction or read quality may differ depending on the variant calling pipelines used (Sandmann et al. 2017). Benchmarking these different approaches on cohorts of genomes may be insightful for research but impractical for clinical applications, and it risks leaking sensitive genetic information. Furthermore, standard quality control measures for variant calling can often be overly simplistic, such as fixed read depth thresholds for calling variants across the genome, which are not tailored to wide regional differences in systematic biases. A reliance on high read depth for accurate variant calling increases the costs of sequencing studies, which are forced to compromise between the number of genomes sequenced and the depth of coverage achieved (The 1000 Genomes Project Consortium 2010).

A ‘bottom-up’ approach to learning about sequencing error looks at different cohorts of clinically sequenced genomes independently and does not rely on consensus between multiple sequencing technologies. This study aims to address the limitations affecting other quality control methods described above, by developing a ‘bottom-up’ method to evaluate position-dependent systematic bias in detected allele fractions across whole genomes. We also seek to quantify its utility using results from its application to five small whole genome sequencing (WGS) noncancer cohorts, to detect how common these systematic biases are and the extent to which they affect different genomic regions and to gauge whether the systematic bias predictions from our method are supported by gold-standard reference data.

Results

Biased variant allelic fractions occur across the genome and are persistent across individuals

Five separate ethnically mixed patient cohorts in the USA and UK (Table 1) were previously sequenced under confidential conditions using distinct WGS pipelines prior to this study by Personalis, Inc. and the 100,000 Genomes Project. Incremental Databases (IncDBs) were generated using these data, containing between-patient standard deviation of allelic fractions for each autosomal genomic locus and also the corresponding aggregate allelic fraction values (Fig. 1), without maintaining any sample-specific information. This ensured that individuals remained anonymous during the quality control process of examining reads using an IncDB. An aggregate allelic fraction was defined as the mean of all of the allelic fractions across the patient cohort for that specific allele at a specific single-nucleotide genomic position. All patients were noncancer patients, and in addition, patients in data sets 2–5 all had neurological disorders. The main differences between data sets were the use of the reference genome GRCh37 for alignment in data sets 1 and 2, while GRCh38 was used for data sets 3–5, and the use of BWA-MEM (Li 2013) for alignment in data set 1, while the Isaac-aligner (Raczy et al. 2013) was used in data sets 2–5. Since clinical sequencing facilities will continually upgrade their sequencing pipelines with new versions of algorithms and genome builds as time goes on, we wanted to make comparisons between different sequencing protocols in different cohorts of patients. In order to verify our findings, we also sequenced two additional cohorts (data sets 4 and 5) using exactly the same protocol as data set 3.

The observed relationship between standard deviation and the aggregate allelic fraction at each genomic locus was
Genomic loci prone to systematic sequencing bias

Enrichment of suspect loci within specific genomic regions

Unique suspect loci were found to be present across the entire sequenced autosomal genome and only absent in unsequenced sections, although their prevalence varied across sequenced regions both locally and showing larger trends across chromosomes (Fig. 3). We examined the distribution of unique suspect loci across different regions of the genome (Fig. 4) and recorded the regional enrichment of unique suspect loci (Supplemental Table S1) using odds ratios (ORs). All odds ratios calculated were highly statistically significant due to the very large number of genomic positions sampled, even when the odds ratios were close to 1. The 95% confidence interval lower and upper bounds were both equal to the reported odds ratios to three significant figures in all cases. The highest/least significant P-value recorded was for the enrichment of suspect loci in the intellectual disability gene panel in data set 2 (OR = 1.01, \( P = 8.69 \times 10^{-45}\)). All other P-values ranged from \(10^{-322}\) to \(10^{-79}\). The 100 base-pair flanks of large (≥20 bp) homopolymers were the most heavily enriched for suspect loci by a large amount (OR = 23.29, 33.69, 30.37 for data sets 1, 2, 3). Small (<20 bp) homopolymers’ 100 base-pair flanks (OR = 12.40, 5.99, 7.36), GC-rich regions (OR = 8.19, 6.47, 7.99), and Alu repeats (OR = 5.70, 6.74, 6.21) were also strongly enriched for suspect loci. Large homopolymers (OR = 1.93, 2.92, 1.84) and the RepeatMasker regions (OR = 1.85, 2.96, 2.18) were mildly enriched for suspect loci in data sets 1–3. Small homopolymers, on the other hand, were depleted or unenriched (OR = 0.525, 1.03, 0.519), and the NIST GIAB high-confidence region was strongly depleted (OR = 0.191, 0.154, 0.172) for suspect loci. The NonUnique100 region showed much greater enrichment of suspect loci in data sets 2 (OR = 3.26) and 3 (OR = 2.17), than in data set 1 (OR = 1.30), and segmental duplications also displayed this (OR = 1.17, 2.15, 1.74).

Systematic biases confirmed in the gold-standard reference sample

Our analysis on aggregate allele fraction statistics found the presence of suspect loci in all cohorts. In order to confirm that these loci occur independently from the samples examined, specific suspect loci were examined in the reference sample NA12878 cell line, which was sequenced and had variants called by Personalis, Inc. using the same pipeline as data set 1 for comparison but which was not part of any of the data sets used to generate the IncDBs. We divided the SNVs called using this pipeline into groups based on whether they were annotated as suspect or non-suspect, whether they occurred in the NIST GIAB benchmark genome, and whether the data sets were used to generate the IncDBs.
regions, and whether they matched the v3.3.2 NIST GIAB benchmark variants at those positions.

Suspect SNVs, which accounted for ∼5% of all SNV calls, mostly reported low allele fractions (0.300 median compared to 0.579 in nonsuspect SNVs) in the read pileup of NA12878, with the exception of suspect SNVs within the benchmark region that matched the benchmark variants. These were the least common type of suspect SNV and most closely resembled the allelic fraction distribution of nonsuspect SNVs (1358 SNVs) (Fig. 5A), suggesting that suspect loci that matched the benchmark variants were likely to be false positives. Suspect SNVs within the benchmark regions usually did not match the benchmark variants within those high-confidence regions (1839 SNVs) (Fig. 5B). Most suspect SNVs occurred outside of the benchmark regions (23,802 SNVs) (Fig. 5C).

In contrast, most called SNVs in NA12878 were nonsuspect, were within the GIAB high-confidence benchmark region, and matched the GIAB benchmark variants for those positions (263,288 SNVs) (Fig. 5D). These conformed to the expected distribution of allele fractions for heterozygous or homozygous SNVs, with peaks around 50% and 100%. Nonsuspect SNVs that were inside the high-confidence benchmark region but which did not match the benchmark variants were the least common and only showed a peak around 100%, with no peak observed for heterozygous variants and low levels of SNVs at all allelic fractions, suggesting that these were sequenced the worst of the nonsuspect loci (665 SNVs) (Fig. 5E). Nonsuspect SNVs outside of the benchmark regions were also numerous and had a similar pattern to nonsuspect SNVs which matched benchmark variants, although the peaks were broader (43,169 SNVs) (Fig. 5F), suggesting that the allelic fractions recorded for these were slightly less accurate.

Suspect loci called as SNVs occurred across all types of genomic regions, including clinically important positions (Fig. 5G). Altogether, this suggests that the systematic biases at suspect loci can contribute to false positive variant calls in clinically important regions, even within the NIST GIAB high-confidence regions. However, suspect SNVs that match the v3.3.2 NIST GIAB benchmark variants should be treated with caution, since their allelic fraction distributions suggest that these may indeed be true variants, so the NIST GIAB benchmark variants are a necessary and complementary resource to combine with IncDB-based methods for annotating systematic errors accurately.

Discussion

The main aim of this study has been to develop and evaluate a novel statistical method to identify positions of the genome that are prone to systematic bias in genomic sequencing and alignment, using anonymized summary patient data. We developed an approach to quality control sequenced reads in the autosomal genome by cataloging genomic positions that persistently present a low-fraction alternate allele across patients rather than reflecting true biological variation, which we have labeled as ‘suspect loci.’ We have explored the extent to which these systematic biases occur across varied genomic regions, including regions known to be difficult to sequence, higher confidence regions, and clinical panels. We have also confirmed the existence of these systematic biases in an independent gold-standard reference genome and the utility of our approach.

For the purposes of this paper, we have defined systematic biases as locus-specific errors in the accurate quantification of an allelic fraction that affect all samples sequenced with the same pipeline to a similar extent. Within this definition, our method should successfully identify almost all single-nucleotide allelic fraction biases >1.5%, but it does not have the sensitivity to detect smaller biases at the confidence level chosen (Supplemental Fig. S2). For example, using a confidence interval of 99.9% and a sample size of 150 (reflecting the parameters used to classify suspect loci for data set 1), ∼9.6% of sites with a 1% systematic error rate were classified as suspect loci, while ∼99.2%/99.8%/100%/100% of sites with a 2%/3%/4%/5% systematic error rate were classified as suspect loci, respectively, when we simulated sites with these systematic error rates, representing a very high resolution. We have not tested this method for identifying systematic biases in
Genomic loci prone to systematic sequencing bias

The detection of indels or structural variants, but, with modifications, a similar approach could in theory be used to identify those types of systematic error. We carried out Monte Carlo simulations to check if this method could be used to identify CNVs, but found that CNVs were not annotated by this method below a population frequency of 10% and could only be detected if intervening SNP alleles had unbalanced aggregate allelic fractions >10%. We expect that CNVs that fulfill these criteria are exceedingly rare, so this is unlikely to cause much of the systematic bias this method identifies. Our method cannot be used for identifying types of systematic bias that are not locus-specific, such as general biases in the detection of certain alleles (e.g., GC bias) (Chen et al. 2013), biases that systematically affect the ends of genomic reads being sequenced (Ma et al. 2019), or other context-specific biases that do not occur in a systematic or locus-specific manner. For example, we would not expect to identify mosaicism unless this was systematic, with a high proportion of individuals having the same alternative genotypes at the same genomic coordinates in the same fraction of cells in their tissue. To evaluate whether age-related mosaicism could have been present in our results, we compared the numbers of suspect loci (54.6 million) and suspect SNVs (43,832) in data set 5, which used a more elderly cohort of patients, with data set 3 (63.2 million suspect loci and 46,287 suspect SNVs) and data set 4 (90.3 million suspect loci and 59,634 suspect SNVs), which both used the same sequencing pipeline. We did not observe an increase in suspect loci in the gene TP53, which is thought to be correlated with this (Yizhak et al. 2019), or in general across the genome (Supplemental Fig. S3), so we could not find evidence for mosaicism affecting suspect locus annotation. The main aim of our approach is not to identify a specific cause of systematic bias but rather to act as a quality control method, to catalog where these systematic biases occur so that they can be filtered out of scientific and clinical results where they may lead to inaccurate conclusions. As a result, our study does not seek to identify why the systematic biases we have identified occur, even if some of our results suggest possible causes that could be followed up by future studies.

To investigate the extent to which differences in mutations between large patient cohorts affected the annotation of suspect loci when technical procedures were held constant, we compared the overlap between suspect loci for data sets 3–5, for which all patients were sequenced using the same protocol and pipeline. These three data sets showed considerable overlap of suspect loci overlap (mean overlap = 65.7%) and suspect SNV overlap (mean overlap = 71.9%) in the intersection of all three data sets, although there were some differences likely due to private mutations (Supplemental Fig. S3). Compared with the overlap between data sets 1 and 2, for which separate technical procedures were used (mean overlap = 34.8% for suspect loci, 66.4% for suspect SNVs), the overlap was ~30% greater for suspect loci but only ~5% greater for suspect SNVs, suggesting that differences in the technical procedures used played a large role in suspect locus annotation in general, but genetic differences between cohorts were particularly important when identifying systematic biases that could affect variant calls. We would therefore recommend users increase the size of IncDBs they generate as much as is reasonably possible, to maximize the numbers of systematic biases they can detect by this method, at least until overlap between separate IncDBs approaches a maximum percentage.

For loci unaffected by systematic bias, the standard deviation and aggregate allelic fraction stored in the IncDB were expected to relate to each other in accordance with Hardy-Weinberg equilibrium. However, ~1%–3% of autosomal loci had a significantly lower standard deviation than predicted by Hardy-Weinberg equilibrium (P = 0.0005), suggesting the presence of systematic bias across numerous genomic loci. At these loci, most individuals appear to present a low-fraction allele. Persistent low-fraction alleles would be inconsistent with our understanding of human genetics and are presumably a technological artifact: a bias or systematic error in the sequencing technology itself or perhaps in the read mapping. The impact of these suspect loci is magnified in the context of studies looking at large numbers of genomic positions, since a small percentage of this would still correspond to a high number of genomic positions affected by systematic bias. It is therefore clear that these systematic biases are of concern and deserve

---

**Figure 4.** Enrichment of unique suspect loci in different types of genomic regions. All odds ratios shown are statistically significant and equivalent to the 95% upper and lower confidence intervals to three significant figures. (A) Log2 scale bar plot showing the odds ratios for regional enrichment of unique suspect loci across all autosomal chromosomes from three different data sets. All odds ratios were calculated and shown to be significant using Fisher’s exact test. Regions were compared to “All sequenced regions” (odds ratio of 1). (B) Bar plot showing the number of unique suspect loci per kb across all autosomal chromosomes from three different data sets. Although clinical and high-confidence regions had a lower rate of suspect loci per kb, over the entire genome they still contained a large number of suspect loci overall in high-confidence regions (24.1/45.1/34.6 million in data sets 1, 2, and 3) and clinical regions (2.55/4.64/3.55 million in data sets 1, 2, and 3 within the intellectual disability panel alone).
variants (<10 supporting reads) were excluded from this analysis. In the IncDBs used to identify them. NA12878 cell line are indicated (A = green, C = blue, G = brown, T = red). Suspect SNVs and their respective read proportions in the Chromosome 1 that were called as variants separately in NA12878. NA12878 was sequenced with Integrative Genomics Viewer (Robinson et al. 2017), highlighting suspect loci from data set 1 in 2019). Reads are shown in gray with colored bands where nonreference allelic reads were observed further attention. Previous studies examining systematic sequencing bias have primarily focused on biases in total coverage across loci and have not examined position-dependent systematic biases in the allelic fraction (Cheung et al. 2011; Ross et al. 2013); therefore, no previous estimates for the prevalence of systematic sequencing bias in allelic fractions were available to compare with our estimate of ~1%–3% of all autosomal loci in the human genome. Our estimate indicated a very large number of genomic sites affected by systematic bias, potentially more than might be expected. Therefore, we analyzed what proportion of these would be filtered out by applying a strongly conservative confidence threshold (99.999%) in addition to the default threshold used in this study (99.9%) to data sets 1–3 and compared how this affected suspect locus numbers, allelic fractions, and overlap between data sets 1 and 2. This filtered out a very high proportion (99.98%/91.06%/92.68% in data sets 1, 2, and 3, respectively) of the suspect loci that had allelic fractions <0.03, since it was rare for loci exhibiting very small systematic biases to have a standard deviation lower than the 99.999% confidence threshold (Supplemental Fig. S4) compared to the 99.9% confidence threshold (Supplemental Fig. S5). In contrast, a much lower proportion (25.95%/17.74%/23.40% in data sets 1, 2, and 3, respectively) of the suspect loci with larger systematic biases (allelic fractions >0.03) were filtered out at the 99.999% confidence threshold. Since it is the larger systematic biases that are most likely to affect variant calling, this shows that the method is robust for identifying most important systematic biases, even at a strongly conservative confidence level. The percentage overlap of suspect loci between data sets 1 and 2 decreases slightly when a more conservative threshold (99.999% confidence interval) is used for defining suspect loci (from 47.9%/21.7% to 41.1%/16.1% of data sets 1 and 2, respectively) (Supplemental Fig. SS).

Suspect loci were widespread across all sequenced chromosomal segments, but there was variability between different types of genomic region. Despite this, there was little or no depletion of suspect loci in some regions expected to have more accurate sequencing, such as exons and the clinical gene panels, suggesting that greater caution in these areas is justified when calling variants. The NIST high-confidence regions displayed the greatest depletion of suspect loci as expected and had the lowest proportion of suspect loci per kb, while homopolymer flanks displayed the greatest enrichment of suspect loci. The correlation between chromosomal suspect locus density and the proportions of chromosomes within large homopolymer flanks was high (Spearman’s rho = 0.955, 0.861, 0.820, F = 5.11 × 10−12, 2.76 × 10−7, 3.07 × 10−6 for data sets 1, 2, and 3, respectively), accounting for the majority of the variability in the proportion of suspect loci in autosomal chromosomes (Supplemental Fig. S6). The flanks of large homopolymers are particularly prone to errors in alignment compared to other types of sequencing error, especially for Illumina sequencing (Laehnemann et al. 2016) as was done here, suggesting that the misalignment of reads could be a source of systematic biases. One hundred base pairs was chosen as the flank length because it is of the same order of size as the read lengths used for the illumina sequencing and we would not expect anything outside of 100 bp from a homopolymer to be covered by sequencing reads, so the 100-bp length is the theoretical maximum length at which we might expect effects to occur. Homopolymers cannot affect the sequencing beyond one read length from their edge. In practice, most suspect locus enrichment occurred within the 3-bp flanking regions however, with enrichment odds ratios greatly increasing when the flank size was reduced to 3 bp in both large homopolymers (from 23.3/33.7/30.4 in data sets 1, 2, and 3, respectively, in 100-bp flanks, to 171.3/97.6/3-bp flanks) and small homopolymers (from 12.4/6.0/7.4 in 100-bp flanks in data sets 1, 2, and 3, respectively, to 30.9/12.2/13.3 in 3-bp flanks).
In addition, we found differences in regional systematic biases between data sets. For example, the NonUnique100 region showed much greater enrichment of suspect loci in data sets 2 (OR = 3.26) and 3 (OR = 2.17) than in data set 1 (OR = 1.30). This region is defined as containing all sequenced positions where a single 100-nt read cannot map uniquely, so we would expect a large proportion of systematic biases here to mainly correspond to alignment errors rather than sequencing chemistry. The higher enrichment of suspect loci in NonUnique100 in data sets 2 and 3 could therefore indicate that the different aligners used (Isaac aligner [Raczy et al. 2013] for data sets 2 and 3 rather than BWA-MEM [Li 2013] for data set 1) could be the main explanation for the different levels of systematic bias found between the data sets in this region. The Isaac aligner is known to be a faster aligner than BWA-MEM, but previous validation attempts found that it was slightly worse than BWA-MEM in terms of accuracy, especially outside of NA12878 (Mainzer et al. 2015). The increased frequency of systematic biases we detected with the Isaac aligner in data sets 2 and 3 seems to indicate that BWA-MEM is still superior in terms of accuracy, at least compared with the versions of the Isaac aligner used (SAAC00776.15.01.27 and iSAAC-03.16.02.19, respectively).

We also found great variability in the distribution of suspect loci within individual genes tested (Supplemental Data S1, S2). For example, within the clinical gene panels, there were very low proportions of suspect loci (0% out of 2021 total loci in LIPT2 in data set 2) to very high proportions of suspect loci (36.6% out of 3759 total loci in NPRPL2 in data set 2), suggesting that some genes might be particularly prone to systematic sequencing biases. This is likely because the genes intersect with the problematic regions we examined in different ways. Both of these genes are associated with genetic epilepsy syndromes, but LIPT2 is not affected by systematic sequencing biases at all, while these heavily affect with genetic epilepsy syndromes, but we examined in different ways. Both of these genes are associated might be particularly prone to systematic sequencing biases. This 3759 total loci in data set 2) to very high proportions of suspect loci (36.6% out of when assessing pathogenic variants in those genes (Table 2). This demonstrated that low-quality reads were more frequent among suspect loci to a large degree, suggesting that improving sequencing and alignment quality could help with decreasing these systematic biases. However, there was still significant overlap between read quality at suspect and nonsuspect loci. Finally, we analyzed whether read depth could be used to quality-control for suspect loci (Supplemental Fig. S9). Kolmogorov-Smirnov tests confirmed that there was a different distribution of read depths between the sets of genomic positions with and without suspect loci (D = 0.4289, 0.2885, 0.3079 and P < 10^-15 for data sets 1, 2, and 3, respectively), but there was not a clear correlation between read depth and likelihood of a position having suspect loci. While the lower quartile and median values for read depth were slightly lower for unique suspect loci, for data sets 2 and 3 the upper quartiles were significantly higher at unique suspect loci. We could only

conclude that there was a greater breadth of read depth in positions annotated as unique suspect loci than other positions. A possible explanation for our results could be that most unique suspect loci have slightly lower read depths than nonsuspect loci, but some unique suspect loci have extremely high read depth, perhaps as a result of systematic alignment errors attributing reads from multiple locations in the genome to the same genomic position at these suspect loci. Our analyses therefore suggest that the existing read depth thresholds and quality control procedures commonly used in sequencing would not be sufficient to filter out the systematic biases, and the reported variants in large population studies such as gnomAD may need to be reassessed.

We have demonstrated the utility of IncDBs to assess the quality of clinical whole genomes of five independent cohorts sequenced by commercial and public healthcare organizations while maintaining patient anonymity. In addition to showing the utility of this approach on whole-genome Illumina sequencing, IncDBs could be applied to data from different types of sequencing platforms in the future, including specific targeted, exome-sequencing, and long-read technologies such as Pacific Biosciences (PacBio) and Oxford Nanopore. Our agile approach for detecting suspect loci could be deployed in various settings where the raw data for individual genomes cannot be accessed—for instance, when patient confidentiality must be maintained. Under those conditions, being able to identify systematic biases would enable improvements to variant calling and has the potential to reduce errors in clinical genomic testing.

**Methods**

**Data sources**

**Data set 1 (Personalis, Inc.)**

WGS data were obtained by Personalis, Inc. using Illumina HiSeq and the standard library prep and sequencing protocol. Paired-end reads of 100-bp length were mapped with BWA-MEM (Li 2013) to align reads against the GRCh37 reference human genome (Table 1). The mean depth of coverage across patients was 45x. There were 150 noncancer individuals in the cohort, including triplets (infant and two parents) recruited from hospitals in the USA and a mix of ethnicities, but specific age or ethnic data were not available.

**Data set 2 (100,000 Genomes Project)**

Blood samples were taken from 215 distinct patients of mixed ethnicities with noncancer neurological diseases in each cohort, recruited from hospitals in the UK. The libraries were prepared using Illumina TrueSeq DNA PCR-Free Library Prep for the majority of the samples. For a small proportion of samples, when the concentration was <20 ng/µl at Illumina, the Nano DNA library prep method was used. All main program samples were sequenced using 150-bp length paired-end sequencing on HiSeq X, and the mean depth of coverage across patients was 30x. WGS data were obtained by Genomics England’s 100,000 Genomes Project, using Illumina HiSeq sequencing and mapped with the Illumina Isaac-aligner (version SAAC00776.15.01.27) (Raczy et al. 2013) to align reads against the GRCh37 reference human genome. All variants were called using Isaac Variant Caller (Starling, v2.1.4.2) (Raczy et al. 2013) and annotated using Ensembl database (v72) (Cunningham et al. 2019). The median age of patients was 13 yr (Supplemental Fig. S10).

**Data sets 3, 4, and 5 (100,000 Genomes Project)**

No patients were in multiple data sets. Blood samples were collected and library-prepped in the same way as data set 2. WGS data were obtained by Genomics England’s 100,000 Genomes Project, using Illumina HiSeq sequencing and mapped with the Illumina Isaac-aligner (SAAC-03.16.02.19) to align reads against the GRCh38 reference human genome. The reads were aligned by Illumina with the Illumina Isaac-aligner (v03.15.09.04) and variants called by Isaac Variant Caller (Starling, v2.3.13) (Raczy et al. 2013) with annotation by Ensembl (v81) (Cunningham et al. 2019). Data sets 3, 4, and 5 all used 215 distinct patient samples from the noncancer neurological diseases cohort, but the patients in data sets 3 and 4 were randomly sampled, so these data sets can be treated as technical replicates. For data set 5, we used data from the same cohort but selected all of the oldest patients available since the patients in data sets 3 and 4 were generally very young. The age distributions of patients in cohorts 2–5 are illustrated in Supplemental Figure S10 and had median ages of 13, 16, 13, and 64 yr, respectively. The numbers of patients across different ethnic categories in data sets 2–5 were recorded in Supplemental Table S2.

**Incremental Database Generation**

The read depth values for each allele (A, C, G, T) at every autosomal genomic locus were calculated from aligned BAMs and divided by the total read depth at the corresponding loci to get the allelic coverage fraction, $x_p$, for each allele at each locus in each patient. Individual IncDBs were created for each data set from the aggregate allelic fraction and standard deviation values for each allele at each locus across the entire cohort, which were calculated from $x_p$ as described below:

$$\text{Aggregate allelic fraction} = \frac{1}{N} \sum_{p=1}^{N} x_p,$$  \hspace{1cm} (1)

$$\text{Standard deviation} = \sqrt{\frac{1}{N} \sum_{p=1}^{N} (x_p - \bar{x})^2} = \sqrt{\frac{1}{N} \sum_{p=1}^{N} x_p^2 - \left(\frac{1}{N} \sum_{p=1}^{N} x_p\right)^2}.$$

(2)

$N$ is the number of patients, $p$ is the patient identifier, $x_p$ is the allelic coverage fraction for a specific allele in patient $p$, and $\bar{x}$ is the mean of all of the allelic coverage fractions for that same allele across all patients (aggregate allelic fraction).

Notice that to compute the aggregate allelic fraction, we do not store each individual’s $x_p$ values but the sum of $x_p$ across all individuals. Similarly, we can compute the standard deviation across individuals by storing the sum of $x_p$, as well as the sum of $x_p^2$. This approach not only removes all individual-specific genomic information but also allows the IncDB to grow indefinitely, as more samples are sequenced and analyzed: They can simply contribute to the running sums of $x_p$ and $x_p^2$. Also, note that the sums in the equations above do not take up more size on the disk as the number of samples increases, so the overall IncDB file size does not increase as new samples are added.

**Identifying loci affected by systematic bias (suspect loci)**

For each locus in all autosomal chromosomes, the standard deviation and aggregate allelic fraction values were taken from the IncDB and plotted against each other in a density plot using MATLAB 9.6, R2019a (www.mathworks.com/downloads). The main bown-shaped feature of this plot (Fig. 2A–C) was the expected result of
Mendelian alleles in the human population, present at a variety of population frequencies, while observed loci with standard deviations below the 99.9% expected confidence interval for a given nucleotide were defined as suspect loci for that allele. Autosomal positions that displayed at least one suspect allele at that position were termed unique suspect loci. The total count of unique suspect loci was therefore lower than the total count of allele-specific suspect loci, since some positions had multiple suspect alleles.

The 99.9% confidence interval was estimated using Monte Carlo sampling as detailed in the pseudocode below. Monte Carlo sampling used three nested loops which respectively simulated the standard deviation at a single genomic locus between \( n \) individual patient allelic fractions (loop 3), \( 1000 \) times to calculate the upper and lower 99.9% confidence intervals (loop 2), for each aggregate allelic fraction from 0 to 1 in intervals of 0.01 (loop 1). The standard deviation values were recorded and used to classify suspect loci as visually illustrated (Fig. 2A–C); \( n = 150 \) for data set 1, and \( n = 215 \) for data sets 2/3. The model assumed an error rate of 0.01, corresponding to an approximation of the error rate of Illumina WGS (Wall et al. 2014). Approximately 90% of genomic reads in data set 1 had a quality score of 20 or above, corresponding to this error rate (Supplemental Fig. S8). Decreasing the assumed error rate increases the numbers of sites with very low systematic allelic biases that get annotated as suspect loci by increasing the standard deviation threshold for classification as suspect (Supplemental Fig. S11). The distribution of the suspect locus allelic fractions at an assumed error rate of 0 of 0.01, is illustrated in Supplemental Figure S12, for comparison with the allelic fractions at an assumed error rate of 0.01 (Supplemental Fig. S2).

Monte Carlo simulation of standard deviation (pseudocode)

1. For each representing a simulated single autosomal genomic position with that aggregate allelic fraction across all patients do {
   2. repeat 1000 times {
      3. repeat for \( n \) simulated patients {
         Randomly generate diploid genotype for each simulated patient using the binomial distribution (assuming two alleles) at the given AAF value;
         Assuming a sequencing error rate of 0.01, randomly draw \( c \) reads from the binomial distribution to simulate observed major/minor allelic reads for the simulated diploid genotype;
         Divide by total read depth, \( c \), to get the individual allelic fractions for each patient;
      }
      Calculate the standard deviations between the individual allelic fractions for all \( n \) patients at the simulated genomic position;
   }
   Maximum and minimum values of 1000 repetitions mark upper and lower 99.9% confidence intervals for standard deviation at given AAF;
}

Analysis of regional enrichment of unique suspect loci

Histograms of suspect locus density across Chromosome 1 were plotted in MATLAB alongside chromosome ideograms taken from the UCSC Genome Browser (Kent et al. 2002) (GRCh37, http://hgdownload.cse.ucsc.edu/goldenpath/hg19/database/cytoBandIdeo.txt.gz; and GRCh38, http://hgdownload.cse.ucsc.edu/goldenpath/hg38/database/cytoBandIdeo.txt.gz) in order to show suspect locus density in comparison with chromosomal banding patterns.

BED files for 18 different types of genomic region were analyzed to check enrichment of unique suspect loci using a Fisher’s exact test to calculate the exact significance values. Full contingency tables for all regions in data sets 1–3 (autosomal chromosomes only) are available in Additional Table S1 to show how these were calculated.

The regions tested were the NIST GIAB high-confidence regions, \( Alu \) repeats, GCg70 (>70% GC content) regions, NonUnique100 regions (defined as all regions where a single 100-bp read could not map uniquely), segmental duplications, small/large homopolymers, flanking regions of small/large homopolymers, the RepeatMasker region, introns, exons, genes, intergenic regions, ClinVar short variants, and three neurological clinical panels (see next section for full list and details of BED files used).

“All sequenced regions” referred to all genomic loci where the number of aligned reads was greater than zero. There were no suspect loci outside of this region by definition, so the odds ratio was 1 by default.

Genomic region BED file sources

NIST GIAB high-confidence region (Xiao et al. 2014; Zook et al. 2014, 2019)—a selection of genomic loci covering the majority of the human genome that are considered to have high-confidence calls (ftp://ftp-trace.ncbi.nlm.nih.gov/giab/ftp/release/NA12878_HG001/latest/GRCh37HG001_GRCh37_GIAB_highconf_CG-III_FB-IIIGATKHC-Ion-10X-SOLID_CHROM1-X_v.3.3.2_highconf_nosomaticdel.bed).

NonUnique100—all regions where a single 100-bp read cannot map uniquely (so all stretches on the reference that are 100 bp or longer that are repeated on the GRCh37 reference).

Segmental duplication—long DNA sequences (>10 kb) that are found in multiple locations across the human genome as a result of duplications.

GCg70, small/large homopolymers and their 100-bp flanking regions were all calculated as described below, and BED files (available at https://doi.org/10.15131/shef.data.9927053) were generated in-house rather than downloaded from another source.

GCg70 (GC content >70%)—regions with >70% GC content. Loci were annotated as within this region if the surrounding 100 bp around each locus had >70% GC content.

Small/large homopolymer—region of DNA containing a single nucleotide (9–19 bp for small homopolymers, >20 bp for large homopolymers).

Small/large homopolymer flanks—100-bp flanks surrounding the small/large homopolymer regions, respectively.

RepeatMasker region—a BED file containing a variety of different types of repeats (Smit et al. 2013–2015). The open-3-2-7 version of RepeatMasker was downloaded from the UCSC Table Browser (https://genome.ucsc.edu/cgi-bin/hgTables) (Karolchik et al. 2004).

\( Alu \) repeats (Hasler and Strub 2007)—the most common type of transposable element in the human genome, of which there are over one million copies. The BED file was composed of all RepeatMasker Regions downloaded from the UCSC Table Browser (https://genome.ucsc.edu/cgi-bin/hgTables) that were annotated as \( Alu \) repeats in the repName column.

BED files were also downloaded for generic regions, intergenic regions, exonic regions, intronic regions (March 22, 2019), and ClinVar short variants (June 12, 2019), acquired from the UCSC Table Browser (https://genome.ucsc.edu/cgi-bin/hgTables).

Clinical panel BED files were also downloaded for the three most reviewed neurological clinical panels on PanelApp (Martin et al. 2019) (for intellectual disability [October 19, 2018], genetic...
epilepsy syndromes [February 7, 2019], and hereditary spastic paraplegia [February 7, 2019], respectively; https://panelapp.genomicsengland.co.uk/panels/).

Calculating allelic fractions at suspect loci in NA12878
An indexed BAM file for NA12878 Chromosome 1, sequenced using the same pipeline used in data set 1, was provided by Personalis, Inc. We used the Integrative Genomics Viewer (IGV) (Robinson et al. 2017) to examine NA12878’s read pileup at data set 1 suspect locus positions at which Chromosome 1 SNVs had previously been called, to confirm that NA12878 exhibited low-fraction alleles at these positions. NA12878 was not part of any cohorts used to build the IncDBs in this study. Chromosome 1 SNVs in NA12878 were extracted from a VCF file corresponding to the sequencing pipeline used for data set 1, which was also provided by Personalis, Inc. SNVs were classified as suspect if they corresponded to the same alleles at the same positions as suspect loci calculated for data set 1. The allelic fractions for these variants were calculated from the NA12878 BAM file using SAMtools v1.9 (http://www.htslib.org/download/) mpileup (Li et al. 2009; Li 2011). Variants with fewer than 10 supporting reads were deemed to have insufficient coverage and were not included.

Analyzing the proportion of gnomAD SNVs that are suspect
A list of all gnomAD variants (Karczewski et al. 2019), along with their allelic fraction and annotation as PASS-flagged or not, was obtained from a TSV file (available at https://doi.org/10.15131/shef.data.9927062). This was filtered to only include autosomal SNVs. These were classified as suspect and nonsuspect SNVs as above. Variants in gnomAD were annotated as PASS variants if they were marked this way in gnomAD v2.1 (https://macarthurlab.org/2018/10/17/gnomad-v2-1/).

Comparing sequencing quality between suspect and nonsuspect loci
The coverage of different allelic reads across all loci/nucleotide combinations on Chromosome 1 was available for data set 1 (Cov), along with the corresponding coverage of allelic reads filtered to only include reads with sequencing and mapping quality scores greater than 20 (Cov20). The filtered coverage values of allelic reads (Cov20) were divided by the corresponding unfiltered coverage values (Cov) to get the proportion of allelic reads with sequencing and mapping quality scores both greater than 20 at each locus/nucleotide combination. The cumulative distributions of these values were calculated separately for locus/nucleotide combinations that were annotated as suspect loci or nonsuspect loci.

Using suspect loci to check the quality of your own sequenced samples
To address the limitations of existing quality control procedures used in WGS and variant calling pipelines discussed in this study, we have created resources for researchers and clinicians to carry out quality control of suspect variants occurring at positions that show a consistent systematic allelic bias (see “Data access”). We have provided BED files containing all of the suspect loci that we have identified in all five data sets used for every allele, along with their corresponding aggregate allelic fractions, standard deviation between individuals’ allelic fractions, and allelic fractions corresponding to z values of −2, −1, +1, and +2. We suggest that researchers and clinicians using sequencing pipelines that are similar to any of the three pipelines used in this study identify the corresponding BED files and check the allelic fractions of any variants that they have previously called that are present in these BED files. If the allelic fraction of a called variant is not significantly greater than would be obtained by systematic bias alone, i.e., if it is lower than the suspect allelic fraction at a z value of +1 for a milder filter or +2 for a stricter filter, then we would advise annotating or even removing that called variant. Researchers can also design custom filters based on their own preference if they wish to use different z value thresholds or other combinations of information. Researchers who are using Illumina WGS pipelines that have less in common with the pipelines shown here may also use a more conservative BED file of suspect loci to filter their data, containing only suspect loci found in both data sets 1 and 2, which is also included in the data set.

The suspect loci BED files provided by this study were only generated for specific WGS pipelines using Illumina HiSeq, and it is unlikely that these results could be used reliably for quality control of sequencing and alignment pipelines that are not similar to these. We would therefore recommend that researchers who have access to sequence data from a large cohort of patients should develop their own IncDB and calculate suspect loci for their sequencing pipelines based on that. The drawback of this, as opposed to using the suspect loci BED files above, is that this is computationally demanding and requires that researchers have access to large sequence data sets for their pipeline.

Data access
Links to the sources of all nonconfidential data used in this article are referenced in the text at first mention and also below. We do not provide public links to download the raw sequence data we used in this study to generate the IncDBs for individual genome sequences since these are confidential. Data set 1 individuals were sequenced for commercial purposes. While raw sequence reads are no longer accessible for data set 1, we provide summary statistics from the BAM files stored in the Incremental Database (link below). In order to protect participants in data sets 2 and 3, the 100,000 Genomes Project data can only be accessed through a secure research environment. To access the data for research, you must be a member of the Genomics England Clinical Interpretation Partnership (GeCIP), the research community set up to analyze the Project data. You can apply to join the GeCIP (https://www.genomicsengland.co.uk/join-a-gecip-domain/). To be eligible for data access, you must have your affiliation verified at an institution that has signed the GeCIP Participation Agreement and have your application to join a valid GeCIP domain accepted by the domain lead or a member of the GeCIP team. The Incremental Database containing the variant summary statistics at all loci for each data set is available for download at https://doi.org/10.15131/shef.data.9995945, and the gnomAD TSV file generated in this study is available for download at https://doi.org/10.15131/shef.data.9927062. The code used to generate and analyze the IncDBs used in this study is publicly available at GitHub (https://github.com/tmfreeman400/IncDB_code) and as Supplemental Code.
