Introduction

According to modern epidemiological studies, seborrheic dermatitis is a fairly common chronic dermatosis. Moreover, in the world population, regardless of ethnic, climatic, geographical, socio-economic, sexual factors, there is not only an increase in the incidence of seborrheic dermatitis, but also an increase in the severity of severe, resistant to treatment [3]. Seborrheic dermatitis rarely leads to disability or death of the patient, but significantly impairs the quality of life of the patient, his social and occupational adaptation. Significant financial
costs for therapy are due to long-term current and preventive treatment [11].

The basis of clinical manifestations of seborrheic dermatitis is hyperkeratosis, necrosis of keratinocytes of varying severity. Superficial hyperemia of arterial vessels, insignificant perivascular infiltrate consisting of plasma cells and neutrophils, with the phenomena of leukocytoclasia are observed in the dermis. Increased reproduction of epidermal cells with a violation of the process of differentiation leads to the formation of a defective stratum corneum on the background of inflammatory phenomena in the dermis [12].

Despite the fact that the etiopathogenesis of seborrheic dermatitis is comprehensively and intensively studied, the mechanisms of development of this dermatosis remain much unclear. Numerous publications consider seborrheic dermatitis as a multifactorial disease with polygenic predisposition to the hereditary component of the predisposition. Under the multifactorial development of this dermatosis is the implementation of a genetic program under the influence of numerous exogenous and endogenous causes [1, 13].

There are a number of neurogenic, psychological, hormonal, immune, infectious, metabolic, genetic factors that contribute to the manifestation of this dermatosis, which cause excessive production and quality change of sebum caused by functional activity of sebaceous glands and increased number and activation of fungi of the genus Malassezia. Psychogenic factors act as a link in the chain of successive immunological processes, which explains the occurrence or exacerbation of dermatosis only in close connection with the main factors of pathogenesis [7, 15, 20]. The adult form of seborrheic dermatitis is often associated with neurological diseases, in addition, the tendency to recur may be a skin marker of acquired immunodeficiency syndrome. Seasonal fluctuations in temperature and humidity affect the course of the disease, so that in the cold season, exacerbations of seborrheic dermatitis are more common [2].

The study of the relationship between the constitutional features of man and the course of disease today is an important stage in the development of modern medicine. The type of physique is genetically determined and is a constant objective characteristic of a person during ontogenesis. Age-related changes, diseases, excessive or insufficient physical activity change the contours and size of the body, but not the somatotype [17]. To date, significant clinical and theoretical material has been accumulated, which substantiates the significant role of somatotype in the occurrence and development of dermatoses in humans [6, 8, 9, 10]. At the same time, when analyzing the literature, we did not find any work devoted to the study of the influence of body type on the course of seborrheic dermatitis. The aim of the study was to establish and analyze the features of the width of the distal epiphyses of the long tubular bones of the extremities and the transverse diameters of the body in men and women with seborrheic dermatitis of varying severity.

Materials and methods

On the basis of the Department of Dermatology and Venereal Diseases with a postgraduate course in National Pirogov Memorial Medical University, Vinnytsia and the Military Medical Clinical Center of the Central Region conducted a survey of 40 men and 40 young women (25-44 years according to WHO age period, 2015) patients with generalized fatty seborrheic dermatitis (mild and severe course).

The Bioethics Committee of the National Pirogov Memorial Medical University, Vinnytsya (Minutes № 10 of 26.11.2020) found that the studies did not contradict the basic bioethical standards of the Helsinki Declaration, the Council of Europe Convention on Human Rights and Biomedicine (1977), WHO regulations and Ukrainian law. The diagnosis of seborrheic dermatitis was established on the basis of the subject's complaints, life history and illness, examination of the face, scalp, torso and extremities with assessment of subjective and objective signs of the disease.

Anthropometric survey was conducted in accordance with the scheme of Bunak V. V. [4]. Measurement of the width of the distal epiphyses of the long tubular bones of the extremities (cm) was performed with a caliper, the accuracy of which was up to 0.01 cm Measured: distal shoulder epiphysis (EPPL), distal forearm epiphysis (EPPR), distal femoral epiphysis (EPB) and the width of the distal epiphysis of the shoulder shins (EPG). Measurements of transverse body diameters (cm) and pelvic dimensions (cm) were performed using a large thickness compass. Measured: transverse middle-thoracic diameter (PSG), transverse lower-thoracic diameter (PNG), anterior-posterior middle-sternal diameter (SGK), shoulder width (ACR), intercristol distance (CRIS), interspinous distance (SPIN), intetrochanteric distance (TROCH) and only in women surface conjugate (CONJ).

The control group consisted of distal epiphyseal widths of long tubular limb bones and transverse body diameters of practically healthy men (n=82) and women (n=154) of the same age group, selected from the National Pirogov Memorial Medical University database, Vinnytsya.

Statistical processing of the results was performed in the license package “Statistica 6.0” using non-parametric evaluation methods. The reliability of the difference between the values between the independent quantitative values was determined using the U-Mann-Whitney test.

Results

Table 1 presents the results of comparing the width of the distal epiphyses of the long tubular bones of the extremities and the transverse diameters of the body between healthy and patients with mild and severe seborrheic dermatitis men and/or women.
Discussion

It is suggested that one of the main factors in the development of seborrheic dermatitis is a hereditary predisposition. This is characterized by the so-called "seborrheic constitution", which reflects a high genetic predisposition to the development of this disease. Usually such patients have a family history [2, 3].

Polesko I. V. make [14] analysis of class I HLA antigens and specificity of DRB1, DQA1, DQB1 class II in patients with this skin disease substantiated the existence of genetic determinism of this disease and included among the probable markers class I antigens A10 and A23. This changes the microbiota of the skin and reduces its bactericidal properties, creating a favorable environment for pathogenic flora that provokes inflammation [18].

Clinically significant differences in skin between ethnic groups have been reported, especially not only skin color (more often people with white skin are prone to the disease), but the processes of formation and secretion of sebum [19, 21]. The genetic nature of the disease is justified by the possibility of irregular dominance of seborrheic dermatitis and the most common manifestation in patients with III (B) blood group [16].

Notes: MC - mild course; SC - severe course; P_{h-mc} - the significance of the difference between the values of indicators between healthy and patients with mild seborrheic dermatitis; P_{h-sc} - the significance of the difference between the values of indicators between healthy and patients with severe seborrheic dermatitis; P_{mc-sc} - the significance of the difference between the values of indicators between patients with seborrheic dermatitis of mild and severe severity; * - the reliability of the difference in the values of the relevant indicators between men and women at the level p<0.05; ** - the reliability of the difference in the values of the relevant indicators between men and women at the level p<0.01; *** - the reliability of the difference in the values of the relevant indicators between men and women at the level p<0.001; t - trends in the difference between the values of the respective indicators between men and women.
establishment of the basic patterns of group and intergroup variability of seborrheic dermatitis at the phenotypic level when comparing them with genetic variability was carried out with blood groups or other serological traits. However, in this regard, the constitutional approach is still a little-studied area. The main task of modern integrative anthropology has long been the search for the notorious "mechanisms of inheritance of body type", although such appeals continue to be heard. One of the most promising areas of its development is the establishment of intersystemic patterns of morphological variability of man in line with the establishment of constitutional markers of certain diseases. The search for quantitative morphological regularities and their distribution according to individual dimensional (quantitative) regularities is, first of all, the search for regularities of phenotypic manifestation of cluster genes, which can provide no less new information than direct isolation of genes and study of molecular mechanisms of their expression [5].

When analyzing the width of the distal epiphyses of the long tubular bones of the extremities and the transverse diameters of the body between healthy and patients with seborrheic dermatitis of varying severity in Ukrainian men or women found the following significant or trends of differences (Table 2, see Table 1):

- **between healthy and sick men** - in practically healthy men lower values of transverse middle-thoracic (6.1 % and 6.7 %, respectively), anterior-posterior middle-thoracic (11.8 % and 22.3 %, respectively) diameters and intertrochanteric distance (2.6 % and 3.5 % respectively), as well as higher values of shoulder width (by 13.6 % and 15.0 %, respectively) and width of the distal epiphysis of the shoulder (only compared to mild severity by 2.7 %);

- **between healthy and sick women** - in practically healthy women lower values of width of the distal epiphyses of the forearms (only compared to severe by 2.1 %), thighs (by 5.9 % and 7.3 %, respectively) and shins (only compared to severe by 4.0 %), transverse middle-thoracic (5.1 % and 9.3 % respectively) and lower-thoracic (4.3 % and 9.5 % respectively) diameters, anterior-posterior middle-thoracic diameter (11.2 % and 14.1 % respectively), interspinous (only compared with severe by 5.5 %), intercristal (4.4 % and 6.4 %, respectively), intertrochanteric distances (only 4.8 % compared with severe) and surface conjugates (11.1 % and 12.4 %, respectively), and also higher values of shoulder width (by 12.9 % and 10.6 %, respectively).

When comparing the width of the distal epiphyses of the long tubular bones of the extremities and the transverse diameters of the body between patients with seborrheic dermatitis of varying severity Ukrainian men or women, we found only tendencies to higher values in patients with severe women transverse lower-thoracic diameter by 5.4 % intertrochanteric distance by 4.0 % compared with women with mild disease course, and the tendency to higher values in patients with severe male severity of the width of the distal epiphysis of the forearm by 2.7 % compared with men with mild disease course (see Table 1, 2).

In the analysis of sexual differences in the width of the distal epiphyses of the long tubular bones of the limbs and transverse diameters of the body between patients with seborrheic dermatitis of varying severity in Ukrainian men found significantly greater or greater tendency to greater width of the distal epiphyses (by 10.7 % and 10.9 %, respectively), forearms (respectively by 11.9 % and 13.1 %), thighs (only compared to mild severity by 3.8 %) and shins (by 11.6 % and 8.0 % respectively), transverse middle-thoracic (by 12.4 % and 9.0 % respectively) and lower-thoracic (12.4 % and 8.3 %, respectively) diameters, anterior-posterior middle-thoracic diameter (14.4 % and 22.0 %, respectively), shoulder width (11.7 % and 7.8 %, respectively), and intertrochanteric distance (only compared to mild 3.7 %) (see Tables 1, 2). In contrast to practically healthy men and women, no significant or tendency differences between interspinous and intercristal distance were found between patients (see Tables 1, 2).

Transverse dimensions of the body as morphogenetic markers within the constitutional integrity of the organism involve the identification of their connection with the adaptive abilities of man and they are studied in the process of ontogenesis under the influence of the environment. Establishing the patterns of manifestation of intersystem connections will further develop a system of criteria for

### Table 2. Differences in transverse body sizes between healthy and patients with seborrheic dermatitis of varying severity in men and/or women.

| Indicators | Men | Women |
|------------|-----|-------|
|            | H   | MC    | SC    | H   | MC    | SC    |
| EPPL       |     |       |       |     |       |       |
| EPPR       |     |       |       |     |       |       |
| EPB        |     |       |       |     |       |       |
| EPG        |     |       |       |     |       |       |
| PSG        |     |       |       |     |       |       |
| PNG        |     |       |       |     |       |       |
| SGK        |     |       |       |     |       |       |
| ACR        |     |       |       |     |       |       |
| SPIN       |     |       |       |     |       |       |
| CRIS       |     |       |       |     |       |       |
| TROCH      |     |       |       |     |       |       |

**Notes:** H - healthy; MC - seborrheic dermatitis of mild course; SC - seborrheic dermatitis of severe course; for significant differences between healthy and sick men; for tendencies in differences between healthy and sick men; significant higher indicators are highlighted in green when comparing the respective groups between men and women; tendencies to higher values of indicators when comparing the respective groups between men and women are highlighted in yellow.
Transverse body sizes in men and women with seborrheic dermatitis of varying severity

prognostic assessment of the risk of seborrheic dermatitis based on the phenotypology of body parameters.

Conclusion

1. In patients of varying severity women (more severe course) compared with practically healthy women, in almost all cases (except for the width of the distal epiphysis of the shoulder) found significant or trends in differences in the width of the distal epiphyses of long tubular limbs and transverse body diameters (larger values except for shoulder width). Patients with seborrheic dermatitis of varying severity men, compared with practically healthy men, found fewer differences in the width of the distal epiphyses of the long tubular bones of the extremities and transverse diameters of the body (only greater values of transverse middle-thoracic diameter, anterior-posterior middle-sternal diameter distance, as well as smaller values of shoulder width and width of the distal epiphysis of the shoulder).

2. There are only tendencies to higher values in patient’s female with severe severity in transverse lower-thoracic diameter and intertrochanteric distance, as well as in patient’s male with severe severity in the width of the distal epiphysis of the forearm than in women or men with mild disease course.

3. Among patients with seborrheic dermatitis of varying severity found pronounced manifestations of sexual dimorphism of the width of the distal epiphyses of the long tubular bones of the limbs and transverse diameters of the body (except for pelvis sizes), namely - higher values of these indicators in men.
