I. INTRODUCTION

Since the discovery of high-temperature superconductivity in copper-based transition-metal oxides, a tremendous effort has been devoted to establish a convincing theory that covers the general aspects of their unusual and fascinating physics. The attempts are complicated by the fact that strong electron correlations play a key role in the physics of the cuprates. A central question in this context concerns the emergence of small energy scales, much smaller than the bare (Coulomb) interactions between the electrons, which govern the existence and the competition of different phases at low temperatures. This can be studied by considering prototypical lattice models of strongly correlated electrons. Some agreement has been achieved that the relevant physics of the cuprate superconductors is covered by the two-dimensional one-band Hubbard model\(^1\),

\[
H = \sum_{i,j,\sigma} t_{ij} c_{i\sigma}^\dagger c_{j\sigma} + U \sum_i n_{i\uparrow} n_{i\downarrow} - \mu \sum_i n_i. \tag{1}
\]

Here \(t_{ij}\) denote the hopping matrix elements, \(n_{i\sigma}\) is the density at site \(i\) with spin \(\sigma\), \(n_i = n_{i\uparrow} + n_{i\downarrow}\), \(\mu\) the chemical potential, and \(U\) the local Coulomb repulsion.

In recent years there has been substantial progress in the understanding of the ground-state properties of the Hubbard model due to the development of quantum-cluster theories\(^2\) such as cluster extensions of the dynamical mean-field theory (DMFT), i.e. the dynamical cluster approximation\(^3\) and the cellular DMFT\(^4,5\), or the variational cluster approach (VCA)\(^6,7\). These cluster calculations confirm the fact that the ground state away from half-filling has a non-vanishing superconducting order parameter\(^8,9,11,12,13\), with a pairing interaction of predominantly \(d\)-wave character\(^12\). Recent VCA calculations\(^8,9,12\) suggest that at low electron and hole doping the two-dimensional Hubbard model is in a symmetry-broken mixed AF+SC state where both the antiferromagnetic (AF) and the superconducting (SC) order parameters are finite. This is consistent with recent cellular DMFT calculations\(^13\). When going to higher dopings, the system displays a tendency to phase separate into an AF+SC phase at lower doping and a pure SC phase at higher doping.

The VCA accesses the physics of a lattice model in the thermodynamic limit by optimizing trial self-energies generated by a reference system. The above-mentioned VCA calculations are based on a reference system consisting of small (\(2 \times 2\)) isolated clusters tiling the infinite lattice. This generates trial self-energies which are very short ranged spatially. Hence, there is the obvious question for the robustness of the results as a function of the size of the individual clusters. Up to now, it was not possible to consider larger cluster sizes and, at the same time, reach a sufficient accuracy to resolve the tiny energy scale driving phase separation, especially in the electron-doped case. The reason is that an accurate evaluation of the VCA grand potential has required a full diagonalization of the cluster Hamiltonian (see Ref.\(^3\) for details) which has severely restricted the available cluster sizes.

The purpose of this paper is to present a new method for the evaluation of the VCA grand potential based on the Lanczos method which leads to sufficiently accurate results even for larger clusters where full diagonalization...
is no longer possible. Using this method we investigate the competing phases in the two-dimensional Hubbard model at zero temperature for clusters up to 10 sites. This implies a substantial qualitative step forward as short-range correlations between different Cooper pairs can be included – opposed to calculations based on 2 × 2 clusters.

II. VARIATIONAL CLUSTER APPROACH

The variational cluster approach is one of the possible approximation schemes that can be constructed within the self-energy-functional theory (SFT). The SFT provides a variational scheme to use dynamical information from an exactly solvable “reference system” (for example an isolated cluster) to approximate the physics of a system in the thermodynamic limit. For a system with Hamiltonian \( H = H_0(t) + H_1(U) \) and one-particle and interaction parameters \( t \) and \( U \), the grand potential is written as a functional of the self-energy \( \Sigma \) as

\[
\Omega[\Sigma] = F[\Sigma] + \text{Tr} \ln (G_0^{-1} - \Sigma)^{-1},
\]

with the stationary property \( \delta \Omega[\Sigma_{\text{phys}}] = 0 \) for the physical self-energy. Here, \( G_0 = (\omega + \mu - t)^{-1} \) is the free Green’s function of the original model in the thermodynamic limit at frequency \( \omega \), and \( F[\Sigma] \) is the Legendre transform of the universal Luttinger-Ward functional. Due to its universality it is the same as the functional for a “simpler” problem with the same interaction but a modified one-particle part \( t' \). The stationary solutions are obtained within the subspace of self-energies \( \Sigma = \Sigma(t') \) of the simpler problem that is spanned by varying \( t' \). This restriction constitutes the approximation. Details of the approach are described in Refs. 13, 16.

The VCA is generated within the SFT by choosing as a reference system a set of isolated clusters which tile up the original infinite lattice. By construction, the VCA correctly incorporates correlation effects in the electron self-energy up to the length scale given by the cluster size. Beyond this scale it acts like a mean-field approximation. One of the main advantages of the VCA as compared to the simpler cluster perturbation theory consists in its ability to describe (normal and off-diagonal) long-range order by including suitably chosen fictitious symmetry-breaking Weiss fields in the set of variational parameters. Microscopically coexisting phases can be obtained using several Weiss fields. The method links in a consistent way the static thermodynamics with the frequency-dependent one-particle excitation spectra (photoemission). Details of the approach have been described elsewhere. 2, 8, 12

The VCA grand potential to be calculated in practice reads

\[
\Omega = \Omega' + \text{Tr} \ln (G_0^{-1} - \Sigma)^{-1} - \text{Tr} \ln (G') .
\]

Here, \( G_0 \) is the free Green’s function of the model given by Eq. 4, \( \Omega' \), \( \Sigma \), and \( G' \) are the grand potential, the self-energy and the Green’s function of the cluster reference system which depend on the one-particle parameters \( t' \). In the present study we consider clusters with \( L_c = 4, 8 \), and 10 sites to search for the stationary solution characterized by the condition \( \partial \Omega/\partial t' = 0 \). This stationary point provides a good approximation to the exact solution for the system in the thermodynamical limit if the self-energy is sufficiently “short ranged”, i.e. sufficiently localized within the cluster.

As discussed in Refs. 8, 9, it is important to evaluate \( \Omega \) with high accuracy in order to resolve the relevant energy scales of the competing phases, especially in the electron-doped case. Here, we present a method in which this evaluation can be done without a numerical integration over frequencies (note that frequency integration is implicit in the Tr ln ⋯ terms in Eq. 3). We start from the expression derived in Ref. 13 which expresses the Tr ln ⋯ terms as a sum over the single-particle excitation energies:

\[
\text{Tr} \ln (G_0^{-1} - \Sigma)^{-1} = - \sum_m T \ln (1 + e^{-\beta \omega_m}) - R
\]

\[
\text{Tr} \ln (G') = - \sum_m T \ln (1 + e^{-\beta \omega_m'}) - R
\]

and

\[
\text{Tr} \ln (G_0^{-1} - \Sigma)^{-1} = - \sum_m T \ln (1 + e^{-\beta \omega_m}) - R
\]

\[
\text{Tr} \ln (G') = - \sum_m T \ln (1 + e^{-\beta \omega_m'}) - R
\]

Here \( \Theta(\omega) \) is the Heaviside step function, \( \beta = 1/T \) the inverse temperature. \( \omega_m \) are the one-particle excitation energies of the reference system, i.e. the poles of \( G' \), and \( \omega_m' \) are the poles of the VCA Green’s function \( (G_0^{-1} - \Sigma)^{-1} \). \( R \) represents a contribution due to the poles of the self-energy (see Ref. 15) which cancels out in Eq. 3 and can

FIG. 1: The SFT grand potential \( \Omega \) of the half-filled \( n = 1 \) Hubbard model with nearest-neighbor hopping \( t = -1 \) and \( U = 8t \) as a function of the variational parameter \( h_{AF} \) (staggered magnetic Weiss field). Reference system (inset): \( L_c = 10 \) clusters. We compare results obtained by integration over real frequencies with Lorentzian broadenings \( \eta = 0.1 \) (dotted lines) and \( \eta = 0.05 \) (dashed lines), as well as for the “Q-matrix” evaluation (see text, solid lines). \( S_L = 100 \) Lanczos iteration steps have been performed.
thus be ignored. The excitation energies \( \omega'_m = E_r - E_s \) of the reference system (i.e. of the cluster) can be readily obtained with the help of the Lanczos algorithm from the eigenenergies \( E_r \) of the reference system. Here, we introduce the notation \( m = (r, s) \), to indicate an excitation between two states \( s \) and \( r \). The major difficulty consists in finding the poles \( \omega_m \) of the VCA Green’s function. This can be done in the following way: Consider the Lehmann representation of \( G' \) which can be cast into the form\(^{13}\)

\[
G'_{\alpha\beta}(\omega) = \sum_m Q_{\alpha m} \frac{1}{\omega - \omega'_m} Q^\dagger_{m\beta},
\]

where \( \alpha \) refers to the one-particle orbitals of the cluster (typically \( \alpha = (\text{site } i, \text{ spin } \sigma) \) but it can also include an orbital index). The “\( Q \)-matrix” is defined as:

\[
Q_{\alpha m} = \langle r | c_\alpha | s \rangle \sqrt{\exp(-\beta E_r) + \exp(-\beta E_s)} \mathcal{Z}' \]

\[
T = 0 \equiv \delta_{r,0} (0 | c_\alpha | s) + \delta_{s,0} (r | c_\alpha | 0). \tag{7}
\]

The spectral weight (residue) of \( G'_\alpha(\omega) \) at a pole \( \omega = \omega'_m \) is given by \( Q_{\alpha m} Q^\dagger_{m\beta} \mathcal{Z}' = \sum_\sigma e^{-\beta E_\sigma} \) is the grand-canonical partition function at finite temperature, and \( |0\rangle \) denotes the (grand-canonical) ground state of the reference system. Introducing the diagonal matrix \( g_{mn}(\omega) = \delta_{mn}/(\omega - \omega'_m) \), we have:

\[
G'(\omega) = Q g(\omega) Q^\dagger. \tag{8}
\]

Defining \( V = t - t' \), which in case of the VCA typically includes the inter-cluster hopping terms, the “subtraction” of the fictitious Weiss fields, as well as shifts of the one-particle energies (see below)\(^8\) the VCA expression for the lattice Green’s function can be written as:

\[
G = -1 \left( G_0^{-1} - \Sigma \right) = \frac{1}{(G')^{-1} - V}. \tag{9}
\]

This expression can be transformed with the help of the \( Q \)-matrix Eq. (7) and Eq. (5):

\[
G = \frac{1}{(Q g Q)^{-1} - V} = Q g Q^\dagger + Q g Q^\dagger \cdot V \cdot Q g Q^\dagger + \cdots = Q \left( g + g \cdot Q^\dagger V Q \cdot g + \cdots \right) Q^\dagger = Q \frac{1}{g^{-1} - Q^\dagger V Q} Q^\dagger. \tag{10}
\]

Note that \( Q \) is not a square matrix and that \( QQ^\dagger \neq 1 \). Since \( g^{-1} = \omega - \Lambda \) with \( \Lambda_{mn} = \delta_{mn} \omega'_m \), the poles of \( G \) are now simply given by the eigenvalues of the (frequency-independent) matrix \( M = \Lambda + Q^\dagger V Q \) and can be easily found by diagonalization. The dimension of \( M \) is given by the number of poles of \( G' \) with non-vanishing spectral weight\(^9\). Hence, the above scheme requires the knowledge of all excited states of the reference system.

In Refs.\(^8\), these states have been obtained by a full diagonalization of a rather small \((2 \times 2)\) cluster.

For larger clusters, where a full diagonalization is not possible, the Lanczos algorithm should, in principle, provide precisely the required poles and matrix elements Eq. (7). In practice, however, there are some difficulties, as we discuss below. Within the Lanczos method the matrix elements \( G_{\alpha\beta}(\omega) = \langle c_\alpha \mid c_\beta \rangle_\omega \) of a cluster Green’s function at \( T = 0 \) are determined in \( 2L_c \) separate Lanczos procedures. In each procedure, one takes as a Lanczos initial vector one element of the sets \( \{ c_{1,\sigma} | 0 \}, \{ c_{1,\sigma} | 0 \}, \{ c_{L,\sigma} | 0 \}, \{ c_{L,\sigma} | 0 \} \) where \( |0\rangle \) is the cluster ground state. In principle the poles should be the same for all matrix elements of the Green’s function. In practice, however, the poles obtained by the \( 2L_c \) runs are slightly different from each other due to the limited numerical accuracy of the Lanczos method. Therefore, this kind of Lanczos algorithm is not suited for the “\( Q \)-matrix” evaluation of the grand potential described above, since merging all matrix elements of \( G' \) into the compact form Eq. (3) would result in a too large matrix \( M \) that cannot be diagonalized.

Fortunately, the problem can be overcome by means of the so-called \textit{band Lanczos} method.\(^{22}\) The difference with respect to the standard algorithm is that the sets of initial vectors given above are used \textit{simultaneously} within one single Lanczos run. This yields the same set of poles for all index pairs \((\alpha, \beta)\) as well as the corresponding weights. The dimension of the matrix \( M \) is given by the number of iteration steps \( 2S_L \) in the Lanczos procedure. In this case, one only needs two Lanczos procedures instead of \( 2L_c \). Using this method, one introduces an error due to the limited set \((2S_L)\) of the excited states in the reference system that are kept in the Lanczos calculation. Generally, however, this error is extremely small since excitations with large weight result from states which converge very fast with increasing \( S_L \). These excitations with large weight, on the other hand, are just those which are dominant in Eq. (4) compared to excitations with small weight\(^{23}\).

We have checked the accuracy of our method by considering the symmetry-broken antiferromagnetic phase of the Hubbard model at half-filling (Fig. 1). One can clearly see that the \( Q \)-matrix evaluation perfectly gives the extrapolation of results obtained by numerical frequency integration with finite but small Lorentzian broadenings \( \eta \). We also verified that the results converge very fast with \( S_L \), i.e., typically \( S_L \approx 100 \) is fully sufficient. Last but not least, this improved method substantially reduces the computational time. For example, a factor of approximately 15 is gained for the \( L_c = 10 \) cluster.

### III. RESULTS FOR COMPETING PHASES

On the basis of this improved evaluation, we investigate the finite-size behavior of the phase-separation ten-
FIG. 2: (Color online) Chemical potential $\mu$ as function of hole doping $x$. Results for $L_c = 4$ (top), $L_c = 8$ (middle), and $L_c = 10$ clusters. The horizontal dashed lines mark the critical $\mu_c$, and the vertical dotted lines mark the boundaries $x_1$ and $x_2$ of the phase separation region in between.

As a matter of fact, the exact function $\mu(x)$ changes sign and $\mu_c$ the chemical potential at the transition point. However, this fact does not necessarily imply the absence of macroscopic phase separation in the exact ground state of the model under study. As a matter of fact, the exact function $\mu(x)$ must have a non-positive slope. Therefore, in the phase-separated case $\mu(x)$ becomes a straight line between the two boundaries of the phase-separation region $x_1$ and $x_2$. Whether the exact ground state supports phase separation can be derived from the finite-size scaling of the doping discontinuity $\Delta x \equiv x_2 - x_1$, see Tab. I. Unfortunately, no regular finite-size behavior can be inferred from Fig. 2 and Tab. I for hole doping, probably due to the fact that the clusters are still too small. Opposed to the clear trend visible for the electron-doped case (see Tab. I), there is a much weaker $L_c$ dependence of the discontinuities $\Delta x$, $\Delta M$, and $\Delta D$, which we rather interpret as being irregular. However, our results do not exclude microscopic phase separation to persist for $L_c \to \infty$. The inclusion of long-range Coulomb interaction would then be necessary in order to “frustrate” the phase separation occurring in the plain Hubbard model and produce microscopic inhomogeneous phases, such as stripes. We stress that at this point only qualitative estimates for $L_c \to \infty$ rather than a convincing finite-size scaling are possible. For a discussion on these issues see, e.g., Refs. 24,25,26.

We consider the case of hole-doping first. One can immediately see that the phase-separation tendency, found for the $L_c = 4$ cluster, weakens progressively when increasing the cluster size. In particular, the corresponding “energy scale” $\Delta \mu = \mu^* - \mu_c$ diminishes very rapidly with increasing $L_c$ ($\Delta \mu = 0.050$ for $L_c = 4$, $\Delta \mu = 0.027$ for $L_c = 8$, and $\Delta \mu = 0.003$ for $L_c = 10$), and appears to vanish in the $L_c \to \infty$ limit. Here, $\mu^*$ is the point where the slope of $\mu(x)$ changes sign and $\mu_c$ the chemical potential at the transition point.

FIG. 3: (Color online) Same as Fig. 2 but for electron doping. Note that there is no phase separation for $L_c = 10$; the dotted line marks the quantum critical point.

The horizontal dashed lines mark the critical $\mu_c$, and the vertical dotted lines mark the boundaries $x_1$ and $x_2$ of the phase separation region in between.

As variational parameters we use the Weiss fields $h_{AF}$ and $h_{SC}$ to allow for antiferromagnetic (AF) and d-wave superconducting (SC) orders, respectively, as well as an overall shift $\varepsilon$ of the one-particle energies in the cluster to ensure a consistent treatment of the particle density. Fig. 2 shows our results for the two-dimensional Hubbard model with $U = 8t$ and next-nearest-neighbor hopping $t' = -0.3t$ for the case of hole doping. The calculations have been performed for $L_c = 4$ (top), $L_c = 8$ (middle), and $L_c = 10$ clusters (bottom).

We consider the case of hole-doping first. One can immediately see that the phase-separation tendency, found for the $L_c = 4$ cluster, weakens progressively when increasing the cluster size. In particular, the corresponding “energy scale” $\Delta \mu = \mu^* - \mu_c$ diminishes very rapidly with increasing $L_c$ ($\Delta \mu = 0.050$ for $L_c = 4$, $\Delta \mu = 0.027$ for $L_c = 8$, and $\Delta \mu = 0.003$ for $L_c = 10$), and appears to vanish in the $L_c \to \infty$ limit. Here, $\mu^*$ is the point where the slope of $\mu(x)$ changes sign and $\mu_c$ the chemical potential at the transition point. However, this fact does not necessarily imply the absence of macroscopic phase separation in the exact ground state of the model under study.

As a matter of fact, the exact function $\mu(x)$ must have a non-positive slope. Therefore, in the phase-separated case $\mu(x)$ becomes a straight line between the two boundaries of the phase-separation region $x_1$ and $x_2$. Whether the exact ground state supports phase separation can be derived from the finite-size scaling of the doping discontinuity $\Delta x \equiv x_2 - x_1$, see Tab. I. Unfortunately, no regular finite-size behavior can be inferred from Fig. 2 and Tab. I for hole doping, probably due to the fact that the clusters are still too small. Opposed to the clear trend visible for the electron-doped case (see Tab. I), there is a much weaker $L_c$ dependence of the discontinuities $\Delta x$, $\Delta M$, and $\Delta D$, which we rather interpret as being irregular. However, our results do not exclude microscopic phase separation to persist for $L_c \to \infty$. The inclusion of long-range Coulomb interaction would then be necessary in order to “frustrate” the phase separation occurring in the plain Hubbard model and produce microscopic inhomogeneous phases, such as stripes. We stress that at this point only qualitative estimates for $L_c \to \infty$ rather than a convincing finite-size scaling are possible. For a discussion on these issues see, e.g., Refs. 24,25,26.

| $h$-dop. | $\Delta x$ & $\Delta M$ & $\Delta D$ | $e$-dop. | $\Delta x$ & $\Delta M$ & $\Delta D$
|----------|----------|----------|----------|----------|----------|----------|
| $L_c = 4$ & 0.115 & 0.717 & 0.055 & $L_c = 4$ & 0.079 & 0.476 & 0.016
| $L_c = 8$ & 0.094 & 0.699 & 0.043 & $L_c = 8$ & 0.020 & 0.316 & 0.004
| $L_c = 10$ & 0.056 & 0.568 & 0.032 & $L_c = 10$ & 0.000 & 0.000 & 0.000

FIG. 4: (Color online) Magnetization $M$ and d-wave order parameter $D$ as functions of hole and electron doping for $L_c = 4, 8,$ and 10.
The situation is quite different in the electron-doped case. Here, not only the phase-separation energy $\Delta \mu$, but also the doping discontinuity $\Delta x$ appears to vanish for $L_c \to \infty$. In fact, $\Delta \mu$ is already an order of magnitude smaller than for hole doping in the $L_c = 4$ cluster. In addition, already for $L_c = 10$ the transition from the AF+SC to the pure SC phase has become continuous at least within numerical accuracy. In this case, the weak phase separation observed at the mean-field level for small clusters was simply a signal of a tendency of the system to produce microscopically inhomogeneous phases (such as stripes), as conjectured in Ref. [8]. The fact that the corresponding energy scale is already very small for a small cluster could explain why there is no clear sign of stripes in electron-doped materials and could possibly be related to the much smaller pseudogap energy scale, as discussed in Ref. [8].

Contrary to the phase-separation energy, the AF and SC order parameters $M$ and $D$ plotted in Fig. 4 only display a rather weak cluster-size dependence. This shows that already a small $2 \times 2$ cluster describes the static ground-state quantities with a rather good accuracy, except for cases close to a phase transition. Finite-size effects are more pronounced for $D$ because the SC order parameter is a non-local quantity which converges slower with increasing cluster size as compared to $M$. Nevertheless, from our results we can argue that for both, hole and electron doping, at least substantial SC fluctuations remain in the thermodynamic limit even in the AF phase. A more precise finite-size scaling to identify as to whether one really has long-range SC order is not possible since that would involve larger constant cluster shapes ($2 \times 2$, $4 \times 4$,...) which are not accessible by the present VCA.

The comparison of Fig. 4 with previous calculations[12] shows that the inclusion of the energy shift $\varepsilon$ as a variational parameter provides results which depend only weakly on the cluster size $L_c$. For example, we find a mixed AF+SC phase for small doping for all cluster sizes considered. This can be understood by the fact that the inclusion of additional variational parameters “optimize” the ground state of the reference system towards the exact solution of the infinite lattice.

Fig. 5 shows the evolution of the single-particle spectral function upon hole doping calculated with the $L_c = 8$ reference system. In the upper plot for doping $x = 0.025$, the system is still in the mixed AF+SC phase. This is the reason for the “back-turning” of the quasi-particle-like band around $(\pi/2, \pi/2)$ although the chemical potential already “touches” the band at this wavevector. For higher doping (middle and lower panel), we clearly see a transition to a dispersion crossing the chemical potential in the nodal direction, in agreement with angle-resolved photoemission experiments. The low-energy coherent quasi-particle band with a width of the order of a few times $J$ has been replaced by a band of width of a few times $t$. The qualitative trend is well known from QMC calculations[30]. This represents a clear improvement as compared to our previous results for $L_c = 4$ clusters, where the dispersion in the nodal direction showed “back-turning” signals also for higher dopings.

In spite of the improvement for the nodal direction, the d-wave SC gap appears to be too large for the slightly overdoped case $x = 0.25$. Furthermore, for higher dopings one expects a decrease of the weight of the upper Hubbard band which is much stronger than visible in the $x = 0.25$ spectrum. The reason for these shortcomings is probably a too strong admixture of the half-filled cluster ground state: In the absence of superconductivity and for not too high doping, the particle density of the reference system (the isolated cluster) is $n' = 1$. In our case, deviations from cluster half-filling are introduced due to
a non-vanishing SC Weiss field only. For \( L_c = 8 \) we find \( n' = 0.92 \) at \( x = 0.25 \) which is still close to half-filling.

A physically better description of the spectral density at higher dopings can only be achieved when (in the absence of superconductivity) starting from a cluster ground state with \( n' < 1 \). This yields a corresponding SFT grand potential which has to be compared with the SFT grand potential for the \( n' = 1 \) stationary point. Note that for a vanishing SC Weiss field, the VCA cannot give a grand potential that is continuous in the entire doping range. This is an artifact of the VCA which levels off and eventually becomes irrelevant in the large-cluster limit.

In fact, there is a second stationary point for \( x = 0.250 \) with a particle density in the cluster \( n' = 0.755 \). Due to the non-vanishing SC Weiss field, this is close but not equal to the commensurate cluster filling \( n' = 0.75 \). This stationary point, however, exhibits an SFT grand potential which is higher as compared to that of the \( n' = 0.92 \) solution and, consequently, should be disregarded. It is nevertheless interesting to discuss the spectral density of this (metastable) state which is shown in Fig. 13. As could have been expected, the SC gap is much smaller (and actually not visible on the scale of the figure) and, as compared to the corresponding spectrum in Fig. 5, the weight of the upper Hubbard band is clearly reduced. Moreover, signatures of magnetic order are no longer visible in this spectrum.

### IV. CONCLUSIONS

We have developed a new method to evaluate the VCA grand potential which avoids numerical integrations over real or Matsubara frequencies, even for large clusters, for which a complete diagonalization is not feasible. This provides a sufficient accuracy to study the cluster-size dependence of the phase-separation tendency obtained in previous works. The results of the present paper suggest that in the hole-doped case phase separation observed for small clusters persists for \( L_c \rightarrow \infty \), i.e. in the exact ground state, while it eventually disappears in case of electron doping. This would explain why there is no clear sign of stripes in electron-doped materials, and could possibly be related to the much smaller (or even absent) pseudogap energy scale with respect to hole-doped materials.

Occasionally, one of the poles of $M$ may have a vanishing residue in Eq. (10). In this case, one can show that $G'$ has a corresponding pole at the same frequency with a vanishing residue so that the contribution to Eq. (3) from this pole cancels out exactly.

The factor 2 comes from the separate calculation of the photoemission and inverse photoemission part.
