ABSTRACT

Introduction: Though relevance and importance of emotional intelligence have been documented in various fields, yet, the emotional intelligence dimension of health care professionals has not been given adequate attention and very little empirical research has examined the role of EI on occupational stress.

Objective: To systematically explore and describe the relationship between EI and the dimensions of occupational stress.

Methods: To this aim, a sample of 257 nurses and 131 doctors working in hospitals, PHC’s, CHC’s, & sub-centres were selected from all the hospitals, CHC’s, and PHC’s. The study included 4 questionnaires: Emotional Quotient Test, Occupational Stress Index (OSI), Oldenburg Burnout Inventory (OLBI), and Perceived stress scale (PSS). Data obtained were analyzed using ANOVA, Pearson correlation, and multiple regression.

Results: The results highlighted an inverse significant relationship between the dimensions of occupational stress and emotional intelligence. Additionally, a positive relationship was also found between age, working experience, and stress, with younger healthcare professionals and those with a shorter length of service experiencing more stress. However, EI and health are not related to age or length of service.

Conclusion: The study concluded that emotional intelligence can help in reducing occupational stress among health care not only by decreasing or controlling the stressors present in the workplace but also by increasing the potential of employees to effectively deal with those stressors.

Key Words: Emotional Intelligence, Occupational Stress, Burnout, Perceived Stress, Healthcare, Doctors, Nurses

INTRODUCTION

For long the emotional component of human service, though crucial, but has been ignored. Within the many contexts in the present complex healthcare system, numerous experiences and expressions of emotions occur, ranging from providers disclosing bad news to patients to offering emotional support to hospitalized or institutionalized patients. Emotions are fundamental to health care and crucial to providing empathetic and patient-focused care.¹ The present healthcare system is experiencing a change with pressures to make the health care system more efficient, the attendant being more focused towards rationalization, managed care, and curtailment of care and services¹ apart from these work overload, time tables, interpersonal conflicts, shift work, dealing with deaths and seriously ill patients and lack of mental support. Stress occurs in response to a lack of ability to cope up with the stressor present in the work-setting² resulting in making mistakes with negative outcomes such as depression,³ decreased professional satisfaction,⁴ disrupted personal relationships,⁵ psychological distress⁶, and even suicide.⁷,⁸ One of the ways to deal with occupational stress is through the management of emotions, which is now being considered by intellectuals more than ever. Studies in psychology have also highlighted that success at work-life does not depend on IQ and it determines only 20% of a person’s success, but rather it depends on a person’s emotional intelligence which determines 80% of success.⁹ Emotional intelligence assumes that emotions are the essence of life and different persons differ in their ability in perceiving understanding, and managing emotions in themselves and others; which in turn af-
flect their adaptableness to different environmental contexts, including the workplace. In the Western countries, there is a greater awareness and sensitivity to the problems that are faced by healthcare professionals and several studies have focused on the importance of emotional intelligence training in the health care profession as a means for preventing stress and burnout, and for improving communication skills and performance.11-14

The healthcare system in Meghalaya is strangled due to the serious shortage of specialized medical and para-medical staff, infrastructure facilities, drugs, etc. Apart from these the hilly topography and poor road infrastructure are making the health sector scenario even worst making their life stressful. Under the circumstances, health care professionals need to learn how to cope and control strong emotions so that they can provide better services. However, researchers dealing with health care sectors have ignored the occupational stress and emotional intelligence dimension of health care professionals.12 The present study intends to fill this gap by exploring the emotional intelligence dimension of health care professionals in dealing with stressful situations. The present study proposes to measure the extent of occupational stress and level of emotional intelligence of health care professionals and study the relationship between emotional intelligence and occupational stress of health care professionals.

MATERIALS AND METHODS

(a) Instruments and Measures

The present research uses a conceptual model to study the relationship between emotional intelligence and occupational stress and burnout. This model was made by the represented test of the Emotional Quotient Test, Occupational Stress Index, Oldenburg Burnout Inventory (OLBI), and Perceived Stress Scale (PSS) (Figure 1). In this study, emotional intelligence is considered as an independent variable, and variables occupational stress and burnout are considered as the dependant variable.

Sample and Data Collection

To examine the relationships between Emotional intelligence, occupational stress, and burnout, 131 doctors and 257 nurses working in all the hospitals as well as PHC’s, CHC’s, and sub-centres were selected. All the four tests were administered on two groups of healthcare professionals, that is, Doctors and Nursing Staff in selected hospitals/CHC/PHC/ UHC. Throughout the testing, the doctors and nurses were informed that their responses are anonymous and confidential, and the collected data will not be used for any professionals or healthcare evaluation. The tests were administered in the following sequence to all the respondents: Emotional Intelligence15, Occupational Stress Index16, Perceived Stress Scale17, and Oldenburg Burnout Inventory.18

Statistical Analyses

The obtained data were subjected to several statistical analyses pertinent to the research objectives of the study. To test the significance of mean difference across different professional groups and gender, ANOVA was applied. The correlations among variables were obtained by applying Pearson’s Product Moment method. Regressions of Burnout on Occupational Stress and Emotional Intelligence were computed by employing standard multiple regression analyses.

RESULTS AND DISCUSSION

Occupational Stress & Emotional Intelligence of Health Care Professionals

Table 1 describes the mean, S.D, and the relation between occupational stress and emotional intelligence related to demographic variables for the sample under investigation. The results showed a high level of occupational stress among doctors and nurses and doctors and nurses differ significantly on occupational stress and the mean OSI score for nurses was high as compared to doctors. Concerning gender, the results indicated that females experienced more stress as compared to male healthcare professionals with a mean of [76.00 (S.D=9.51)] for males and [79.83 (S.D=8.65)] (p-value 0.002) (Table 1). The results also highlighted a difference in mean scores of respondents based on the age group they belong to. It is found that respondent with the younger age group that is 20-30 years experience high stress followed by the age group 30-40 years. It was also found that there exists a difference based on the marital status of the respondents, number of dependents, working experience, and income. However, the living arrangement of the respondents shows a non-significant difference. Results confirmed that socio-demographic variables of healthcare professionals significantly influenced occupational stress. The results are comparable to some earlier studies.19-21

Figure 1: Research Framework of the Study.
As indicated in table 1 emotional intelligence vary according to the age of the respondents (p < .001) and the age group of 50-60 years has scored highest (342.2) on emotional intelligence. This implies that age has a significant role to play in the healthcare professional’s emotional intelligence. This indicates the development of EQ with age. The variation in scores, i.e., the standard deviation is also found to be higher in the older group. This shows that the older age group among health care professionals is higher on EQ than the younger age group. In other words, it appears that EQ is dependent on age. Similar results have been found in another study\(^2\) where it was found that EQ is dependent on age. When EQ was compared based on the marital status of the healthcare professionals it was found that emotional intelligence varies according to the marital status of the healthcare professionals and healthcare professionals who are either not married or single have the lowest EQ. In the case of living arrangement, it was found that there is no significant difference between the mean value of EI (p-value =0.17). For the number of dependent significant difference was found in the emotional intelligence score of the healthcare professionals (p-value = .009) with healthcare professionals with more dependent scoring lowest in EQ. In tune with working experience, a significant difference was found between the healthcare professionals (p < .001), and healthcare professionals with working experience of 15-20 years have reported the highest EQ. With regards to income, a significant difference was found in the emotional intelligence score of the health-
care professionals (p < .001) with health care professionals in the income group of 4-6 lakh and 6-8 lakh have reported scoring highest on EQ (Table 1).

**Perceived Stress and Burnout of Health Care Professionals**

Inspection of Table 2 indicates that significant differences have been observed among the two groups in the means scores of perceived stress, burnout, and its two dimensions of emotional exhaustion and depersonalization. The mean perceived stress score for doctors (13.95) and nurses (15.60) indicates a significant difference (p < .001). Results also indicate that there exist a significant difference in the mean score of Emotional Exhaustion [doctors (18.31), nurses (20.21) (p < .001)] and depersonalization [doctors (17.11), nurses (18.52) (p < .001)] (Table 2) dimensions of burnout. This depicts that doctors and nurses differ in these two dimensions of burnout. For perceived stress, burnout, and its two dimensions, the mean score of nurses is higher than doctors. This shows that perceived stress and burnout is experienced more by nurses than doctors.

**Table 2: Mean Perceived Stress and Burnout**

| Variables                  | Category | Mean ± SD | p   |
|----------------------------|----------|-----------|-----|
| Perceived Stress           | Doctor   | 13.95 ± 4.53 | 0.001 |
|                            | Nurse    | 15.60 ± 3.76 |       |
| Burnout                    | Doctor   | 35.37 ± 8.45 | 0.001 |
|                            | Nurse    | 38.73 ± 7.02 |       |
| Emotional Exhaustion       | Doctor   | 18.31 ± 4.38 | 0.001 |
|                            | Nurse    | 20.21 ± 3.74 |       |
| Depersonalization          | Doctor   | 17.11 ± 4.30 | 0.001 |
|                            | Nurse    | 18.52 ± 3.48 |       |

**Correlation between Emotional Intelligence, Occupational Stress, Perceived Stress and Burnout of Health Care Professionals**

To investigate the relationship between different variables Pearson’s correlations were computed for the two occupational groups of healthcare professionals- Doctors and nurses (Table 3). The inter-correlations among the dimensions of emotional intelligence, occupational stress, burnout, and perceived stress are presented under separate headings. To have a convenient comparison, all three groups were taken at the same time.

Results of the correlation analysis for doctors and nurses reveal that emotional intelligence and its three dimensions emotional sensitivity, emotional maturity, and emotional competency had a significant negative correlation with the dimensions of occupational stress, perceived stress, and burnout, which indicates that where respondents report a lower level of emotional intelligence it is more likely that they will report higher levels of occupational stress and vice versa. These suggest that an increase in the level of emotional intelligence could have a negative impact on the level of reported stress and burnout.

Further, the result of correlations also indicates a significant positive correlation between the dimensions of occupational stress, perceived stress, and burnout for doctors and nurses. This means that high perceived stress is related to high occupational stress and burnout in healthcare.

**Correlation between Emotional Intelligence, Occupational Stress, Perceived Stress and Burnout of Health Care Professionals**

To investigate the relationship between different variables Pearson’s correlations were computed for the two occupational groups of healthcare professionals- Doctors and nurses (Table 3). The inter-correlations among the dimensions of emotional intelligence, occupational stress, burnout, and perceived stress are presented under separate headings. To have a convenient comparison, all three groups were taken at the same time.

Results of the correlation analysis for doctors and nurses reveal that emotional intelligence and its three dimensions emotional sensitivity, emotional maturity, and emotional competency had a significant negative correlation with the dimensions of occupational stress, perceived stress, and burnout, which indicates that where respondents report a lower level of emotional intelligence it is more likely that they will report higher levels of occupational stress and vice versa. These suggest that an increase in the level of emotional intelligence could have a negative impact on the level of reported stress and burnout.

Further, the result of correlations also indicates a significant positive correlation between the dimensions of occupational stress, perceived stress, and burnout for doctors and nurses. This means that high perceived stress is related to high occupational stress and burnout in healthcare.

**Correlation between Emotional Intelligence, Occupational Stress, Perceived Stress and Burnout of Health Care Professionals**

To investigate the relationship between different variables Pearson’s correlations were computed for the two occupational groups of healthcare professionals- Doctors and nurses (Table 3). The inter-correlations among the dimensions of emotional intelligence, occupational stress, burnout, and perceived stress are presented under separate headings. To have a convenient comparison, all three groups were taken at the same time.

Results of the correlation analysis for doctors and nurses reveal that emotional intelligence and its three dimensions emotional sensitivity, emotional maturity, and emotional competency had a significant negative correlation with the dimensions of occupational stress, perceived stress, and burnout, which indicates that where respondents report a lower level of emotional intelligence it is more likely that they will report higher levels of occupational stress and vice versa. These suggest that an increase in the level of emotional intelligence could have a negative impact on the level of reported stress and burnout.

Further, the result of correlations also indicates a significant positive correlation between the dimensions of occupational stress, perceived stress, and burnout for doctors and nurses. This means that high perceived stress is related to high occupational stress and burnout in healthcare.
Relationship between Emotional Intelligence, Occupational Stress, Perceived Stress and Burnout

To determine which dimensions of emotional intelligence predicts the greatest variance in the dimensions of occupational stress burnout and perceived stress, a series of standard multiple regressions were performed between the dimensions of occupational stress (under load, high demand, strictness, extrinsic time pressure, noxious exposures, threat avoidance, conflict/uncertainty), burnout (emotional exhaustion and depersonalization) and perceived stress respectively as a dependent variable and various dimensions of Emotional Intelligence (Emotional Sensitivity, Emotional Maturity, and Emotional Competency) as independent variables. The results are presented in Tables 4 to 13.

Table 4 presents the results of the standard regression for the dependent variable under load, as a dimension of occupational stress among doctors and nurses. Results for doctors indicated that none of the predicting variables has been found contributing significantly towards predicting under load. The results from the sample of nurses indicated that the model was significant (p < 0.001) and that it explained 49% variance in under load. All the three predictor variables entered into the regression model made a unique contribution in explaining the variance in under load and with one unit change in the predictors. Emotional sensitivity, emotional maturity, and emotional competency record a corresponding change of 0.002, 0.001, 0.001 respectively (Table 4).

| Model | R    | R Square | Adjusted R Square | Std. Error of the Estimate | F- Statistics |
|-------|------|----------|-------------------|---------------------------|---------------|
| Doctors | 0.300* | 0.090 | 0.068 | 0.65374 | 4.172602 | 0.007 |
| Nurses | 0.706* | 0.498 | 0.492 | 0.35225 | 84.071 | 0.001 |

| Predictor Variables | Doctors | Nurses |
|---------------------|---------|--------|
| B                   | t       | Sig.   | β      | Std. Error | t     | Sig.   |
| Emotional Sensitivity | -0.102  | 3.492  | 0.001 | -0.106     | 0.013 | -8.015 | 0.001 |
| Emotional Maturity  | -0.091  | 4.539  | 0.001 | -0.092     | 0.008 | -10.893 | 0.001 |
| Emotional Competency | -0.066  | 3.640  | 0.001 | -0.086     | 0.007 | -12.310 | 0.001 |

The results presented in Table 12, indicated that the three predictor variables Emotional Sensitivity, Emotional Maturity, and Emotional Competency contributed 74% (doctors) and 89% (nurses) of variance in Emotional Exhaustion. The contributions made by all the three dimensions of Emotional intelligence on with Emotional Exhaustion were significant.

Table 12: Relationship of Emotional Intelligence with Emotional Exhaustion

| Model | R     | R Square | Adjusted R Square | Std. Error of the Estimate | F-Statistics F | Sig |
|-------|-------|----------|-------------------|---------------------------|----------------|-----|
| Doctors | 0.891a | 0.794    | 0.789             | 1.97802                  | 162.690        | 0.001 |
| Nurses  | 0.947a | 0.896    | 0.895             | 1.21265                  | 731.660        | 0.001 |

Regression Coefficients

| Predictor Variables | Doctors | Nurses |
|---------------------|---------|--------|
| B                   | t       | Sig.   | β      | Std. Error | t     | Sig.   |
| Emotional Sensitivity | -0.063  | 2.698  | 0.008 | -0.066     | 0.011 | -5.820 | 0.001 |
| Emotional Maturity  | -0.101  | 6.286  | 0.001 | -0.090     | 0.007 | -12.444 | 0.001 |
| Emotional Competency | -0.082  | 5.661  | 0.001 | -0.109     | 0.006 | -18.244 | 0.001 |

The results presented in Table 13, indicated that the three predictor variables emotional sensitivity, emotional maturity, and emotional competency contributed 83% (doctors) and 86% (nurses) of variance in depersonalization. The contributions made by all the three dimensions of emotional intelligence on with depersonalization were significant.

Table 13: Relationship of Emotional Intelligence with Depersonalization

| Model | R     | R Square | Adjusted R Square | Std. Error of the Estimate | F-Statistics F | Sig |
|-------|-------|----------|-------------------|---------------------------|----------------|-----|
| Doctors | 0.911 | 0.831    | 0.827             | 1.82210                  | 207.681        | 0.001 |
| Nurses  | 0.930 | 0.864    | 0.863             | 1.29115                  | 538.869        | 0.001 |

Regression Coefficients

| Predictor Variables | Doctors | Nurses |
|---------------------|---------|--------|

The study justifies the main assumption of the research that high emotional intelligence leads to lower occupational stress among healthcare professionals. This study also indicated that occupational stress among health care professionals can be reduced by not only by decreasing or controlling the stressors present in the workplace but also by increasing the potential of employees to effectively deal with those stressors. Increasing the emotional sensitivity, competency and maturity can help the healthcare professionals deal more effectively with the stress present in the workplace which indirectly leads to better work performance.

CONCLUSIONS

Winding up, the results of various regression analyses suggested that in general, the dimensions of emotional intelligence, emotional sensitivity, emotional maturity, and emotional competency have been reported to significantly predict the all the seven dimensions of occupational stress and the dimensions of burnout and the order and strength of the predictors differ across the two groups of healthcare professionals.

IMPLICATIONS

The findings of the study emphasize the use of emotional intelligence for assessments and academic results as a prerequisite to entering the profession. The incorporation of an emotional intelligence test in recruitment and selection procedures seems to improve the projecting validity of the selection method. The study also suggests emotional intelligence as a tool for reducing the stress related to health care professionals. Apart from all these the study also highlights the need to develop intervention programs specifically aimed at increasing the EI level and reducing occupational stress.

FUTURE RESEARCH

The study can be considered as a basis for research focusing on cognitive ergonomics dimensions of occupational stress rather than sociological theory which was ignored by earlier studies in the field of emotional intelligence. A similar study can be undertaken with a larger sample comparing different types of healthcare setting like CHC’s, PHC’s and district hospitals separately as different types of healthcare setting has different work environment and constrains and stressors which result in different stress levels among healthcare professionals employed in the different healthcare setting.

ACKNOWLEDGEMENT

Authors acknowledge the immense help received from the scholars whose articles are cited and included in references to this manuscript. The authors are also grateful to authors/editors/publishers of all those articles, journals and books from where the literature for this article has been reviewed and discussed.
