Nontrapping arrest of Langmuir wave damping near the threshold amplitude

A. V. Ivanov and Iver H. Cairns
School of Physics, The University of Sydney, NSW 2006, Sydney, Australia

Evolution of a Langmuir wave is studied numerically for finite amplitudes slightly above the threshold which separates damping from nondamping cases. Arrest of linear damping is found to be a second-order effect due to ballistic evolution of perturbations, resonant power transfer between field and particles, and organization of phase space into a positive slope for the average distribution function $f_{av}$ around the resonant wave phase speed $v_0$. Near the threshold trapping in the wave potential does not arrest damping or saturate the subsequent growth phase.

Plasma theory has usually been pursued independently of the theory of critical phenomena. Recently, however, it has been revealed that evolution of a monochromatic electrostatic Langmuir wave of finite amplitude in a Maxwellian plasma is a threshold phenomenon. Specifically, after a short initial period of approximately linear damping according to Landau’s classic theory, a wave with initial amplitude $A_0$ greater than a threshold $A_0^*$ stops decreasing and starts to grow approximately exponentially before undergoing irregular oscillations in amplitude (Fig. 1). Both the amplitudes and times at which the wave first ceases to damp and grow (labelled “arrest” and “saturation”) are power-law functions of the difference $(A_0 - A_0^*)$ (right axis, black dash-dotted line). Diamonds mark the “arrest” time $t_{\text{min}}$ and “saturation” time $t_{\text{sat}}$. The absolute Landau damping rate $\omega_L$ is often suggested as a nonlinear mechanism to stop the initial exponential damping phase and to saturate the wave’s growth. Trapping and its associated Bernstein-Greene-Kruskal (BGK) modes also imply a certain shape of the DF plus trapped and untrapped orbits in velocity phase space. However, it is controversial whether trapping is relevant to the damping threshold. For instance, one analysis assumes ergodicity of trapped particles in a single-wave potential and predicts the threshold initial electric field amplitude $E_0$ through the critical ratio $q_c = |\gamma_L|/\omega_L$ $\approx$ 0.06 of the absolute Landau damping rate $|\gamma_L|$ to the trapping frequency $\omega_{tr} = (kE_0/e/m_e)^{1/2}$. In contrast full Vlasov-Poisson (V-P) simulations for a Maxwellian plasma yield $q_c \approx 0.85$ from the asymptotic evolution and $q_c \approx 1.0$ from the initial evolution, with constants of proportionality slightly different from unity for other thermal plasmas.

Other conflicting evidence exists on the role of trapping. Consider the critical exponents $\tau_{\text{min}}$, $\beta_{\text{min}}$, $\tau_{\text{sat}}$ and $\beta_{\text{sat}}$ for the power-law functions of $(A_0 - A_0^*)$ obeyed by the critical potential is often suggested as a nonlinear mechanism to stop the initial exponential damping phase and to saturate the wave’s growth. Trapping and its associated Bernstein-Greene-Kruskal (BGK) modes also imply a certain shape of the DF plus trapped and untrapped orbits in velocity phase space. However, it is controversial whether trapping is relevant to the damping threshold. For instance, one analysis assumes ergodicity of trapped particles in a single-wave potential and predicts the threshold initial electric field amplitude $E_0$ through the critical ratio $q_c = |\gamma_L|/\omega_L$ $\approx$ 0.06 of the absolute Landau damping rate $|\gamma_L|$ to the trapping frequency $\omega_{tr} = (kE_0/e/m_e)^{1/2}$. In contrast full Vlasov-Poisson (V-P) simulations for a Maxwellian plasma yield $q_c \approx 0.85$ from the asymptotic evolution and $q_c \approx 1.0$ from the initial evolution, with constants of proportionality slightly different from unity for other thermal plasmas.

Other conflicting evidence exists on the role of trapping. Consider the critical exponents $\tau_{\text{min}}$, $\beta_{\text{min}}$, $\tau_{\text{sat}}$ and $\beta_{\text{sat}}$ for the power-law functions of $(A_0 - A_0^*)$ obeyed by,
respectively, the time \( t_{\min} \) and amplitude \( A_{\min} \) at which the initial damping phase finishes, as well as the time \( t_{\text{sat}} \) and amplitude \( A_{\text{sat}} \) at which the first exponential growth phase saturates. \( \text{E.g., } t_{\min} \propto (A_0 - A_0^*)^{-\tau_{\min}} \) and \( A_{\min} \propto (A_0 - A_0^*)^{\beta_{\min}} \). First, the temporal exponents \( \tau_{\min} = 0.901 \pm 0.008 \) and \( \tau_{\text{sat}} = 1.039 \pm 0.011 \) are measurably different from each other and the value 0.5 expected from the definition of \( \omega_{tr} \). Second, the field exponents \( \beta_{\text{sat}} = 1.88 \pm 0.07 \) and \( \beta_{\min} = 2.72 \pm 0.09 \) are remarkably different from each other and the value \( \beta_{tr} = 1 \) expected for trapping \( \text{[11]}. \) These points argue against trapping causing either of the arrest and saturation phenomena. Third, calculations with \( A_0 > A_0^* \) lead to \( \tau \) and \( \beta \) exponents closer to 0.6 and 1.3, respectively, and the oscillation spectrum has clear peaks near \( \omega_{tr} \), suggesting that trapping plays a role well above \( t \).

In this Letter we first simulate one-dimensional (1-D) V-P two-component plasma with initially Maxwellian distributions for electrons and ions and demonstrate that ion mobility does not affect the threshold phenomenon for Langmuir wave damped seen in V-P simulations without ions. Then, using one-component electron V-P simulations, we demonstrate that the DF phase portrait when the wave first ceases to damp is much simpler than a BGK equilibrium \( \text{[12]} \) and shows no evidence for trapping. Instead, we demonstrate that the initial DF resonantly evolves a positive slope in velocity space that stops the initial Landau damping and supports the subsequent exponential growth. We also demonstrate that the DFs are different at the arrest and saturation times and are not consistent with trapping.

To clarify the importance of ion mobility we employ first the two-component 1-D V-P model, normalizing to electron quantities:

\[
\frac{\partial f_a}{\partial t} + v \frac{\partial f_a}{\partial x} - \mu_a E \frac{\partial f_a}{\partial v} = 0 \tag{1}
\]

\[
E(x,v) = \int_{-\infty}^{\infty} (f_p - f_e) \, dv \tag{2}
\]

Here \( a = e, p \), \( \mu_a \) is the particle mass, \( f_a \) the component’s DF, \( \mu = 1, \mu_p = -m_e/m_p \), and \( E(x,t) \) is the electric field. The boundary conditions are assumed to be periodic. The initial electron distribution is

\[
f_e(x,v,0) = \frac{1}{\sqrt{2\pi} \nu_{\text{the}}} \exp\left(-v^2/2\nu_{\text{the}}^2\right) \left[1+A_0 \cos(k_m x)\right],
\]

where \( \nu_{\text{the}} \) is the Maxwellian thermal speed for electrons, \( A_0 \) the initial electric amplitude, \( k_m = 2\pi m/L \) is the wave number of the mode \( m \) and \( L \) is the length of the system. The ions are initially uniform and Maxwellian-distributed in velocity space with \( T_p = T_e \).

The simulations use \( m = 1, \nu_{\text{the}} = 0.4 \), Debye length \( \lambda_{pe} \approx 0.31 \), and \( L = 2\pi \approx 20.18 \lambda_{pe} \). They have \( N_x = 256 \) cells in the \( x \) direction both for electrons and ions, and \( N_{ce} = 20000 \) and \( N_{ci} = 2000 \) cells in speed for electrons and ions, respectively, within the domains \([-10 \nu_{\text{the}}, 10 \nu_{\text{the}}]\]. The Cheng-Knorr method \( \text{[15]} \) was used to solve Eqs (1) and (2) with double precision. System invariants \( I_{ea} = \int f_e^2 \, dx \, dv \) are conserved better than \( \Delta I_{e}\text{sat}(0) < 10^{-6} \) for electrons, and \( \Delta I_{p}\text{sat}(0) < 10^{-9} \) for ions.

Fig. 1 shows the evolution of the mode \( m = 1 \) for initial amplitude \( A_0 = 0.012, A_0^* = (8.51 \pm 0.06) \times 10^{-3} \), and \( m_p/m_e = 1836 \). This type of evolution is observed experimentally \( \text{[16]} \). The existence of significant ion motion in Fig. 1(a) seems, at first glance, to suggest that the evolution is seriously affected by ion mobility. However, the envelope field amplitude of the electron oscillations in Fig. 1(a) is almost identical to that for immobile ions \( \text{[Fig. 1(b)]}. \) Quantitatively, the initial damping phase in Fig. 1 stops at time \( t_{\text{min}} \approx 441 \omega_{pe}^{-1} \) and amplitude \( A_{\min} \approx 1.64 \times 10^{-5} \), and is then followed by almost exponential growth which saturates at \( t_{\text{sat}} \approx 1365 \omega_{pe}^{-1} \) and \( A_{\text{sat}} \approx 2.42 \times 10^{-4} \). These quantities are identical to those calculated in the electron V-P simulations of Ref. \( \text{[2]}, \) where \( m = 4 \) was assumed for the perturbation and \( \nu_{th} = 0.1 \) for the electron thermal speed. This is expected because \( k\lambda_{De} \), the wave frequency \( \omega \), and \( \gamma_L \) are the same for the two simulations.

Analytic theory predicts that \( \omega \approx 1.2851 \omega_{pe} \), but the simulated value \( \omega^* = 1.2705 \pm 9 \times 10^{-4} \) is slightly shifted from \( \omega \) due to the large value of \( A_0 \) and varies slightly with time \( \text{[Fig. 1(b)]}. \) Linear damping rate is \( \gamma_L \approx -0.0661 \omega_{pe} \). For smaller \( A_0 = 10^{-5} \) both \( \omega^* \) and \( \gamma_L \) match the standard Landau theory \( \text{[1]} \) very well (not shown), with \( ||(\omega^* - \omega)/\omega|, |(\gamma_L^* - \gamma_L)/\gamma_L|| < 2 \times 10^{-4} \).

These two-component V-P results demonstrate that the threshold phenomenon for Langmuir wave damping is robust against ion effects. Accordingly one-component simulations, with ions acting as a neutralizing background, are used below.

The DF near the phase velocity \( v_{ph} = \omega^*/k_1 \approx 1.271 \) at these moments is shown in Fig. 2 and reveals drastic discrepancies between the evolution which ends with arrest of damping at \( t = t_{\text{min}} \) and the subsequent evolution until the growth saturates at \( t = t_{\text{sat}} \). At the moment \( t = t_{\text{min}} \) the phase space portrait reveals no signs of particle trapping – only filamentation due to phase mixing \( \text{[Fig. 2 the upper view]} \). Moreover, instead of a stationary state this distribution supports approximately linear (meaning exponential) growth on the interval \( t_{\text{min}} < t < t_{\text{sat}} \), as Fig. 1(b) shows. Crucially, the DF at \( t_{\text{sat}} \) does not consist of the closed orbits (or whorls in velocity-position space) expected for trapping. Instead, the orbits are still open, although they clearly indicate progress towards trapping. Trapping is therefore responsible for neither the arrest of damping nor the saturation of the growth phase.

In the linear theory developed by Landau \( \text{[1]} \) growth is due to a positive slope in the DF at the phase velocity of the wave, \( |v| = v_{ph} \). Fig. 3 shows the DF averaged on \( x \) coordinate, \( f_0(v,t) = (1/L) \int_0^L f(x,v,t) \, dx \) at \( t = \)
$t_{\text{min}}$. Instead of the flattening of $f_0$ near the resonant velocities $v = \pm v_\phi$ predicted by quasilinear theory \[1\], $f_0(v, t_{\text{min}})$ acquires a positive slope in a small vicinity of $v_\phi$, and therefore can support (approximately) linear growth after the moment $t = t_{\text{min}}$ as Fig. 2(b) shows.

Contrary to the situation near $t = t_{\text{min}}$ when damping ceases and the physics looks quite smooth and regular, $f_0$ becomes quite irregular near the time $t = t_{\text{sat}}$ when growth saturates (Figs. 2 and 4). In particular, the lower panel of Fig. 2 is strongly reminiscent of trapping, although strictly closed trajectories do not appear for this $A_0$. Also, while on average the slope of $f_0(v, t_{\text{sat}})$ at $v = \pm v_\phi$ seems to have decreased compared with time $t = t_{\text{min}}$ [Fig. 4(a)], it varies irregularly in the neighborhood of $\pm v_\phi$ and therefore may support excitation of oscillations with a wide range of phase speeds.

Fig. 5 shows the evolution of, and power transfers between, the average DF $f_0(v, t)$ and the DF components $f_1(v, t)$ and $f_2(v, t)$ at $k_1$ and $k_2$, respectively, with $|f_m(v, t)| = \{\text{Re}^2[f_m(v, t)] + \text{Im}^2[f_m(v, t)]\}^{1/2}$. It shows that the dynamical picture can be divided into regions...
with distinct characteristics that identify the processes causing the evolution. Fig. 5 shows that the turbulent processes responsible for the (relative) flattening of \( f_0 \) in the resonant area near \( v_\phi \) start only after \( t_{\text{sat}} \), when spatial Fourier components \( E_m \) other than \( m = 1 \) become comparable to \( E_1 \) (not shown here).

The ripples of \( f_0 \), \( |f_1| \), and \( |f_2| \) in time and velocity appear to be “fingerprints” of ballistic change of initial perturbation and power transfer between the field and particles. The latter claim is justified by Fig. 6 which illustrates the power transfer rate for a wave growing/damping linearly by resonant wave-particle interactions given by Eq. (15) in Ref. [17]. Together with Fig. 7 which shows the evolution of \( \delta f_0(v, t) = [f_0(v, t) - f_0(v, 0)]/f_0(v, 0) \) on the interval \( 0 \leq t \leq t_{\text{min}} \), Figs 5 and Fig. 6 clearly demonstrate that the physical process responsible for arrest of linear damping is the resonant power transfer between the wave and the \( m = 0 \) and higher order components of the DF.

An insight into the striking difference between the critical exponents \( \beta_{\text{min}} \) and \( \beta_{\text{sat}} \) comes from critical phenomena theory: critical exponents depend on the properties of correlations for a specific system (e.g., on its dimensionality) and/or a universality class (e.g., Ising, percolation, surface growth etc.) [7]. The DFs in full phase space (position and velocity) are different at times \( t_{\text{min}} \) and \( t_{\text{sat}} \) (see Figs 2–5 and Fig. 7), so the critical exponents might be different. This difference is contrary to the idea that trapping explains both the arrest and saturation phases, which should result in the same exponents. Some plausibility for velocity-space structures having this effect follows from 1-D V-P self-gravitating calculations: varying the resolution in \( v \) seriously affected estimates of the “trapping scaling” exponent \( \beta = 2 \) [5].

In summary, we studied the V-P model for initial Langmuir wave amplitudes slightly above the threshold that separates damping and non-damping evolution. Electron-ion simulations show that ion mobility does not modify the threshold found for Langmuir damping in electron-only simulations. Phase space diagnostis show no signs of trapping or the DF flattening near \( t = t_{\text{min}} \) – instead the combined effects of ballistic evolution of perturbations and resonant power transfer at \( |v| \approx v_\phi \) are responsible for arrest of the linear (Landau) damping then. Since the spatially-averaged DF is not flat at \( t_{\text{min}} \) but instead has a positive slope near the resonant velocity \( v_\phi \), this state is not stationary but instead leads to (linear) growth which is saturated at \( t = t_{\text{sat}} \). The saturation time \( t_{\text{sat}} \) marks the boundary between the regular and stochastic evolution of the wave electric field, again with no evidence for trapping saturating the growth phase.
