(August 12, 1999)

We show that optimal universal quantum cloning can be realized via stimulated emission. Universality of the cloning procedure is achieved by choosing systems that have appropriate symmetries. We first discuss a scheme based on stimulated emission in certain three-level systems, e.g. atoms in a cavity. Then we present a way of realizing optimal universal cloning based on stimulated parametric down-conversion. This scheme also implements the optimal universal NOT operation.

It is not possible to construct a device that produces an exact copy of an arbitrary quantum system [1]. This impossibility has deep roots. It can be seen as a consequence of the linearity of quantum mechanics. It also prevents the use of EPR correlations for superluminal signaling [2]. Non-perfect copying, or cloning, though, is possible. Since the seminal paper of Bužek and Hillery [3], quantum cloning has been extensively studied theoretically. Upper bounds for the possible fidelity of quantum cloners have been derived [4], and optimal universal quantum cloning transformations have been discovered [5].

All devices proposed so far consist of several quantum gates. This means that it will probably take some time until their practical realization. On the other hand, cloning was originally discussed in the context of stimulated emission [6]. It was realized that perfect copying is prevented by the unavoidable presence of spontaneous emission [7]. The question arises whether optimal cloning (for which the fidelity of the clones saturates the above-mentioned bounds) can be realized with stimulated emission. In this letter, suggesting realistic scenarios, we show that the answer is yes.

The cloning procedure will clearly be universal, i.e. equally good for all possible input states, if the cloning system is symmetric under general unitary transformations of the system that is to be cloned. To be more specific, consider cloning of a general qubit represented by the polarization state of a photon. This requires a population inverted medium whose initial state and whose interaction Hamiltonian with the electromagnetic field are both invariant under general polarization transformations so that it can emit photons of any polarization with the same probability. If a photon enters such a medium, it stimulates the emission of photons of the same polarization in the final state. Starting from one qubit, an optimal universal symmetrical cloner [8] produces $M$ identical clones with a fidelity $F_{\text{opt}}(M) = \frac{\sqrt{M}}{M + 1}$. Note that $M = 2$ which gives $F_{\text{opt}} = 5/6$ means that there is just one additional qubit besides the original.

The first possible practical realization of quantum cloning we discuss is based on stimulated emission in an ensemble of three-level systems. These systems have a ground level $g$ and two degenerate upper levels $e_1$ and $e_2$, connected by two orthogonal modes of the electromagnetic field, $a_1$ and $a_2$ (see fig.1). The field modes define the Hilbert space of our qubits, i.e. we want to clone general superposition states $(\alpha a_1^\dagger + \beta a_2^\dagger)|0\rangle$. Note that we are talking about photons and polarization in order to be specific, but one is free to think of other systems and other degrees of freedom, as long as they are described by the same formalism. In the interaction picture, the Hamiltonian has the following form:

$$H_{\text{int}} = \sum_{i} \sum_{n} |n\rangle \langle n| a_i^\dagger a_i + \alpha |n\rangle \langle n| a_i^\dagger a_i + \beta |n\rangle \langle n| a_i^\dagger a_i$$
We have performed numerical computations for systems of a few (up to $N = 6$) atoms. From (1), the time development operator $U = e^{-iHt}$ for the whole atoms-photon-system was calculated. Use was made of the fact that $N_1$ and $N_2$, which denote the sum of the number of photons plus the number of excited atoms for mode 1 and 2 respectively, are independently conserved quantities. Therefore the whole Hilbert space is decomposable into invariant subspaces, i.e. $H$ and $U$ are block-diagonal.

The final state of the procedure has components with various numbers of photons, where the maximum total number is $N + 1$ (if all atoms have emitted their photons). The probability to find $k$ “right” and $l$ “wrong” photons in the final state, denoted by $p(k, l)$, was calculated for all possible values of $k$ and $l$ and for different values of $\gamma t$, and from it the overall average “fidelity”

$$f_{\text{clones}} = \sum_{k+l=2}^N p'(k, l) \left( \frac{k}{k+l} \right)$$

was determined. This is the average of the relative frequency of photons with the correct polarization in the final state. The average is performed only over those cases where there are at least two photons in the final state, i.e. where at least one clone has been produced. $p'(k, l) = p(k, l)/(1 - p(1, 0) - p(0, 1))$ is used in order to have proper normalization. Note that $p(0, 0)$ is always zero.

That average fidelity for our cloning procedure was compared to the average fidelity that would be achieved by an ensemble of optimal cloners producing the same distribution of numbers of photons, i.e. to

$$f_{\text{opt}} = \sum_{n=2}^{N+1} p'(n) \left( \frac{2n+1}{3n} \right),$$

where $p'(n) = \sum_{k+l=n} p'(k, l)$. We also made a comparison to the case, where, in addition to the incoming photon, photons are just created randomly, i.e. to the fidelity

$$f_{\text{rand}} = \sum_{n=2}^{N+1} p'(n) \left( \frac{n+1}{2n} \right).$$

Figure 2 shows that the fidelity of our cloning procedure approaches the optimum fidelity for early times. For short times the probability for every individual atom to have already emitted its photon is low. The time behaviour of the mean number of photons and also of the mean number of photons of the correct polarization produced is shown in fig. 2(b). Therefore, in order to produce a reasonable average number of clones in this regime, a large number of atoms is necessary.

The practical realization of this scheme probably requires a cavity in order to achieve the interaction of a single spatial mode of the radiation field with several (or
FIG. 3. Setup for optimal cloning by parametric down-conversion [11–13]. The pump-pulse is split at the beam splitter BS. One part of the pump pulse hits the first crystal C1, where photon pairs are created with a certain rate. One photon from each pair can be used as a trigger. The other crystal C2 towards the second crystal C2, where it stimulates emission of photons of the same polarization along the same direction. The path lengths have to be adjusted in such a way that the DC-photon wave packets. There is a trade-off between filtering and crystal length, i.e. one can choose narrower filters in order to be able to use a longer crystal (which leads to longer interaction times).

If the above-mentioned conditions are fulfilled, then a single spatial mode (i.e. one mode for the signal and one for the idler photons) approximation can be used. The PDC process can then be described in the limit of a large classical pump pulse, in the interaction picture, by the Hamiltonian

\[ H = \gamma (a_{V1}^\dagger a_{H2}^\dagger - a_{H1}^\dagger a_{V2}^\dagger) + h.c. \]  

where \( a_{V1}^\dagger \) is the creation operator for a photon with polarization V propagating along direction 1 etc. The coupling constant and the intensity of the classical pump pulse are contained in \( \gamma \).

The Hamiltonian \( H \) is invariant under general common \( SU(2) \) transformations of the polarization vectors \((a_{V1}^\dagger, a_{H1}^\dagger)\) for modes 1 and 2, while a phase transformation will only change the phase of \( \gamma \). This makes our cloner universal, i.e. its performance is polarization independent. Therefore it is sufficient to analyze the “cloning” process in one basis.

The time development operator \( e^{-iHt} \) clearly factorizes into a \( V1 \rightarrow H2 \) and an \( H1 \rightarrow V2 \) part. Consider cloning starting from \( N \) identical photons in the initial state \( |\psi_i\rangle = \frac{(a_{V1}^\dagger)^N}{\sqrt{N!}}|0\rangle \). Making use of the disentangling theorem [15] one finds that (cf. [2])

\[ |\psi_f\rangle = e^{-iHt}|\psi_i\rangle = K \sum_{k=0}^{\infty} \sum_{l=0}^{\infty} (-1)^l \Gamma^k \left( \frac{M - l}{N} \right) |k + l\rangle_{V1} |k\rangle_{H2} \]

where \( \Gamma = \tanh \gamma t \) and \( K \) is a normalizing factor.

The component of this state which has a fixed number \( M \) of photons in mode 1, is proportional to

\[ \sum_{l=0}^{M-N} (-1)^l \sqrt{\left( \frac{M - l}{N} \right)} |M - l\rangle_{V1} |l\rangle_{H1} |l\rangle_{V2} |M - N - l\rangle_{H2}. \]  

This is identical to the state produced by the unitary transformation written down in [3] which can be seen as a special version of the Gisin-Massar cloners [6] that implements optimal universal cloning and the optimal universal NOT-gate at the same time. The \( M \) photons could be possible. The atoms could also fly through the cavity [4].

The second scheme for quantum cloning that we want to present is based on stimulated parametric down-conversion (PDC). We will show that optimal cloning can be realized. In PDC a strong light beam is sent through a crystal. There is a certain (very low) probability for a photon from the beam to decay into two photons such that energy and crystal momentum are conserved. In type-II PDC the two photons that are created have different polarization. They are denoted as signal and idler.

Figure 3 shows the setup that we have in mind. We consider pulsed type-II frequency-degenerate PDC. It is possible to choose two conjugate directions for the signal and idler beams such that photon pairs that are created along these two directions are entangled in polarization. This source of polarization-entanglement [1] has been used in many experiments [14]. We consider the quasi-collinear case (i.e. the two directions almost coincide), so that the transverse motion of the photons in the crystal is not important.

For stimulated emission to work optimally, there has to be maximum overlap of the amplitudes of the incoming photon and of all the photons that are produced in the second crystal. This can be achieved by using a pulsed scheme together with filtering of the photons before detection [3]. The pump pulse can be seen as an active volume that moves through the crystal. If the photons are filtered so much that the smallest possible size of the wavepackets detected is substantially bigger than the pump pulse, then there is maximum overlap between different pairs created in the same pulse. Of course, filtering limits the achievable count rates. Moreover the group velocities of pump pulse, signal (\( V \)) and idler (\( H \)) photons are not all identical. This leads to separations (of the order of a few hundred fs per millimeter in BBO), which have to be kept small compared to the size of the DC-photon wave packets. There is a trade-off between filtering and crystal length, i.e. one can choose narrower filters in order to be able to use a longer crystal (which leads to longer interaction times).

If the above-mentioned conditions are fulfilled, then a single spatial mode (i.e. one mode for the signal and one for the idler photons) approximation can be used. The PDC process can then be described in the limit of a large classical pump pulse, in the interaction picture, by the Hamiltonian

\[ H = \gamma (a_{V1}^\dagger a_{H2}^\dagger - a_{H1}^\dagger a_{V2}^\dagger) + h.c., \]  

where \( a_{V1}^\dagger \) is the creation operator for a photon with polarization V propagating along direction 1 etc. The coupling constant and the intensity of the classical pump pulse are contained in \( \gamma \).

The Hamiltonian \( H \) is invariant under general common \( SU(2) \) transformations of the polarization vectors \((a_{V1}^\dagger, a_{H1}^\dagger)\) for modes 1 and 2, while a phase transformation will only change the phase of \( \gamma \). This makes our cloner universal, i.e. its performance is polarization independent. Therefore it is sufficient to analyze the “cloning” process in one basis.

The time development operator \( e^{-iHt} \) clearly factorizes into a \( V1 \rightarrow H2 \) and an \( H1 \rightarrow V2 \) part. Consider cloning starting from \( N \) identical photons in the initial state \( |\psi_i\rangle = \frac{(a_{V1}^\dagger)^N}{\sqrt{N!}}|0\rangle \). Making use of the disentangling theorem [15] one finds that (cf. [2])

\[ |\psi_f\rangle = e^{-iHt}|\psi_i\rangle = K \sum_{k=0}^{\infty} \sum_{l=0}^{\infty} (-1)^l \Gamma^k \left( \frac{M - l}{N} \right) |k + l\rangle_{V1} |k\rangle_{H2} \]

where \( \Gamma = \tanh \gamma t \) and \( K \) is a normalizing factor.

The component of this state which has a fixed number \( M \) of photons in mode 1, is proportional to

\[ \sum_{l=0}^{M-N} (-1)^l \sqrt{\left( \frac{M - l}{N} \right)} |M - l\rangle_{V1} |l\rangle_{H1} |l\rangle_{V2} |M - N - l\rangle_{H2}. \]  

This is identical to the state produced by the unitary transformation written down in [3] which can be seen as a special version of the Gisin-Massar cloners [6] that implements optimal universal cloning and the optimal universal NOT-gate at the same time. The \( M \) photons...
in mode 1 are the clones, while the $M - N$ photons in mode 2 are the output of the universal NOT-gate, the “anti-clones”.

In order to see that state $\text{6}$ is indeed the output of an optimal cloner, let us calculate the relative frequency of photons of the “right” polarization in mode 1. It is given by

$$f_{\text{clones}}^N(M) = \frac{M-N}{M} \sum_{l=0}^{M-N} \binom{M}{l} \frac{1}{N}.$$  \hfill (9)

Using $\sum_{k=N}^{M} \binom{k}{N} = \binom{M+1}{N+1}$ it follows that

$$f_{\text{clones}}^N(M) = \frac{NM + N + M}{M(N+2)},$$  \hfill (10)

which is exactly the optimum fidelity for an $N$ to $M$ quantum cloner $\text{6}$. A similar calculation demonstrates that the universal NOT is realized in mode 2.

This means that the setup of fig. $\text{6}$ works as an ensemble of optimal universal cloning (and universal NOT) machines, producing different numbers of clones and anti-clones with certain probabilities. Note that each of the modes can be used as a trigger for the other one and therefore cloning or anti-cloning with a fixed number of output-systems can be realized by post-selection.

We have shown a method of realizing optimal quantum cloning machines. We emphasize that this scheme should be experimentally feasible with current technology. In our group, pair production probabilities of the order of $4 \cdot 10^{-3}$ have been achieved with a 76 MHz pulsed laser system (UV-power about 0.3 W) and a 1 mm BBO crystal, for 5 nm filter bandwidth. Past experiments show that good overlap of photons originating from different pairs is achieved under these conditions. With detection efficiencies around 10 percent, this leads to a rate of two-pair detections of the order of one per a few seconds.

A new 300 kHz laser system is currently being set up in our lab. An improvement of the order of 26 in the average rate of pairs per pulse is to be expected, for identical pump power. This will also make several-pair events far more likely. This means that production of a few clones with a reasonable rate should be possible.

Here we have presented possible ways of realizing quantum cloning via stimulated emission. We have first discussed a procedure based on three-level systems that could allow the production of large numbers of clones, and could be easier to realize than comparable schemes using quantum gates. Then we have shown a scheme for realizing optimal universal cloning based on parametric down-conversion. This scheme should be realizable with current technology.

We would like to thank S. Stenholm for a provocative question that triggered or re-animated our interest in the relationship between quantum cloning and simulated emission, and V. Bužek for helpful comments, in particular for bringing the connection between cloning and the universal NOT to our attention. We also thank Č. Brukner, J.I. Cirac, T. Jennewein, J.W. Pan, and H. Weinfurter for helpful comments. This work has been supported by the Austrian Science Foundation (FWF, Projects No. S6502 and F1506).
