(Dated: May 2, 2016)

The normal state of strongly coupled superconductors is characterized by the presence of “preformed” Cooper pairs well above the superconducting critical temperature. In this regime, the electrons are paired, but they lack the phase coherence necessary for superconductivity. The existence of preformed pairs implies the existence of a characteristic energy scale associated to a pseudogap. Preformed pairs are often invoked to interpret systems where some signatures of pairing are present without actual superconductivity, but an unambiguous theoretical characterization of a preformed-pair system is still lacking. To fill this gap, we consider the response to an external pairing field of an attractive Hubbard model, which hosts one of the cleanest realizations of a preformed pair phase, and a repulsive model where s-wave superconductivity can not be realized. Using dynamical mean-field theory to study this response, we identify the characteristic features which distinguish the reaction of a preformed pair state from a normal metal without any precursor of pairing. The theoretical detection of preformed pairs is associated with the behavior of the second derivative of the order parameter with respect to the external field, as confirmed by analytic calculations in limiting cases. Our findings provide a solid testbed for the interpretation of state-of-the-art calculations for the normal state of the doped Hubbard model in terms of d-wave preformed pairs and, in perspective, of non-equilibrium experiments in high-temperature superconductors.

I. INTRODUCTION

In many complex materials and quantum systems we witness the formation of fingerprints of superconductivity well above the critical temperature and clearly distinct from fluctuation phenomena. This often leads to a possible interpretation in terms of electron pairs which are formed at very large temperature but they can condense only at a much lower critical temperature due to the phase fluctuations of their wavefunction. Yet, the unambiguous detection of preformed pairs is elusive, as it does not correspond to an actual phase transition and it can not be unambiguously associated with a direct observable quantity.

The prototypical realization of this physics takes place in model systems with strong pairing interaction, which drives the formation of tightly bound pairs with a reduced phase coherence. In this regime, superconductivity occurs as a Bose-Einstein condensation (BEC) of composite bosons formed by the bound pairs of fermions. When the pairing strength is tuned from weak to strong coupling one observes a continuous crossover from the familiar BCS pairing to this regime.

This BCS-BEC crossover has been intensively studied, both in the context of cold atoms trapped in optical lattices and in high temperature superconductivity, where a preformed pair regime has been invoked for the pseudogap state of underdoped cuprates.

In this work we use the attractive Hubbard model as a theoretical device to set a practical protocol to confirm or disprove the existence of preformed pairs in a specific system under analysis. Comparing regimes where s-wave preformed pairs are certainly present or certainly absent, we identify which properties of the system are so sensitive to their presence to be exploited for their detection. Such an identification will also be applicable to interpret existing analyses of the pseudogap-phase in the cuprates.

We have structured our paper as follows: In Sec. II, we briefly discuss the modellingization of the problem, in terms of the single band (attractive) Hubbard Hamiltonian, and briefly review some of the previous DMFT studies in absence of an external field. In Sec. III, we report our DMFT results in presence of a forcing field at different temperatures and interactions, comparing explicitly the attractive and repulsive models. The physical interpretation of our numerical results in terms of the underlying ground state properties is given in Sec. IV. In Sec. V we discuss the implication of this criterion in a broader context, while the final Sec. VI presents our conclusions.

II. MODELIZATION OF THE PROBLEM

Throughout this paper we will consider a simple Hubbard model in presence of an external field driving an s-wave superconducting order parameter

\[ H = -t \sum_{<ij,\sigma>} c_{i\sigma}^\dagger c_{j\sigma} + U \sum_i n_{i\uparrow} n_{i\downarrow} - \mu \sum_{i\sigma} n_{i\sigma} - \eta \sum_i (c_{i\uparrow}^\dagger c_{i\downarrow}^\dagger + h.c.), \]  

Here, \( t \) represents the nearest-neighbor amplitude, \( \mu \) is the chemical potential, and the effective interaction \( U \) is negative for the attractive and positive for the repulsive Hubbard model. The last contribution in Eq. \( \text{[1]} \) represents the coupling of the system to a forcing, time-independent pairing field \( \eta \), which is assumed to be positive and isotropic (s-wave).

In more than two dimensions the attractive Hubbard model displays a low-temperature \( s \)-wave superconductivity, smoothly evolving from a weak-coupling (BCS) regime to a strong-coupling BEC regime with increasing
In the latter regime, pairs are formed at a very high temperature of order $U$, while they can only condense at a much lower temperature $T = T_c \propto \frac{1}{D}$ because of the large phase fluctuations which contrast the formation of a coherent condensate.[23] In the BCS regime, superconductivity is stabilized by a potential energy gain, while the superconductor has a (slightly) higher kinetic energy than the normal state. In the BEC regime the energetic balance is the opposite: The superconductor is stabilized by a kinetic energy gain with a slight potential energy loss w.r.t. the normal state.[23]

Given the $s$-wave nature of the pairs and the local nature of the interactions, much of the physics for $d > 2$ can be well captured by dynamical mean field theory (DMFT)[23], an approach where spatial fluctuations are frozen, but the local dynamics is included non-perturbatively at every value of the interaction strength. DMFT becomes formally exact in the limit of infinite coordination[23] of the lattice but it can be used as an approximation in finite dimensions, where it provides a fully non-perturbative description. This represents a major advantage to analyze weak and strong coupling regimes on equal footing. Previous DMFT studies[23,26–28] have focused on spectral, thermodynamic properties, and even to some non-equilibrium properties[29]. Here we consider a different aspect, namely the response to an external stimulus which drives a superconducting $s$-wave pairing, also beyond the linear-response regime.

For the sake of definiteness we consider a semicircular density of states $N(\epsilon) = \frac{2}{\pi D^2} \sqrt{D^2 - \epsilon^2}$ ($D$ being its half-bandwidth) which is suitable to represent a finite-bandwidth system in DMFT. To solve the auxiliary impurity problem of DMFT we adopted an exact diagonalization (ED) solver with $n_s = 5$ sites (one impurity and $n_b = 4$ bath electronic sites), and tested the stability of the results by increasing the number of sites in the most relevant intermediate coupling/low-temperature regime. Obviously, due to the external pairing field in Eq. (1), the DMFT treatment has to be extended to the broken-symmetry phase, by recasting DMFT in Nambu formalism (see, e.g.,[27]).

In this section we set up the stage by presenting refined results for the unperturbed attractive Hubbard model. In this way we identify concretely weak-, intermediate- and strong-coupling regions whose definition will be helpful to guide the discussion of the following sections.

Fig. 1 shows the energy difference between the superconducting and the normal state $\Delta E_{\text{tot}} = E_S - E_N$ (resolved in its kinetic and potential energy components) in different interaction regimes for two significant choices of the electron density: $n = 1$ (half-filling) and $n = 0.5$ (quarter-filling). We consider a low value of the temperature $\beta = 50D^{-1}$ which is significantly below $T_c$ for the broad range of $|U|$ used in the figure. Moreover, we verified that discretization effects associated with a finite bath size of the ED solver are negligible.

Our findings are summarized by the different colors in the diagrams, which mark the different regimes (BCS: blue; intermediate: violet; BEC: red). Fig. 1 shows that a qualitative change of the energetic balance w.r.t. BCS only takes place when $U \approx 2D$, where a narrow intermediate region, in which the superconductor gains both potential and kinetic energy starts. At $U \approx 2.5D$ a BEC regime establishes. This evolution of the energetic balance tracks the progressive formation of preformed pairs in the normal state.

These results provide a more accurate determination of the boundaries found in Ref. [23]. We also notice that the results for $n = 1$, and $n = 0.5$ are remarkably similar. This observation shows how weakly the physics of the attractive Hubbard model depends on doping. Half-filling, thus, does not represent a special point for the superconducting solution, despite of its peculiar degeneracy with the charge density wave. This justifies the use of the half filled case for the general analysis in the next
section, which is numerically less costly due to particle-hole symmetry. Analogous DMFT characterizations also hold for magnetic phases, in particular for the “sibling” crossover from a Slater to an Heisenberg antiferromagnet, as explicitly shown by recent DMFT and DCA results.

In this work the attractive Hubbard is not introduced as a microscopic description of any realistic material, but as a simple tool for the detection of preformed pairs. However, the energetic analysis we just summarized was suggested as a possible explanation of the spectral weight changes observed in the optical conductivity on the cuprates. Evidently any attempt in this direction must include at least qualitatively the effect of strong repulsive correlations, which mainly control the doping dependence of the cuprate phase diagram. Thus, if one wanted to use Eq. (1) with \( U = -\lambda < 0 \) for a rough investigation of these specific features in the cuprate physics, one should account for the doping dependence of the quasiparticle properties. This can be achieved by renormalizing the kinetic term by means of the quasiparticle weight \( Z \), while leaving at first approximation the effective attractive interaction unchanged:

\[
H = -Z \sum_{\langle i,j \rangle, \sigma} c_{i \sigma} c_{j \sigma} - \lambda \sum_i n_{i \uparrow} n_{i \downarrow} - \mu \sum_i (n_{i \uparrow} + n_{i \downarrow})
\]

(2)

Here the effective bandwidth \( D^* = 2Zt \) decreases as we reduce the hole doping and vanishes at the Mott transition \( Z \rightarrow 0 \) as \( x \rightarrow 0 \), while the attractive interaction \( \lambda \) is taken as a constant. Such a simple assumption is explicitly realized, e.g., in realistic modeling of the strongly correlated superconductivity in fullerenes. As for the energetic balance this amounts to a rescaling in the previous plot, whose effects are reported in the inset of Fig. 4. The results of this a “more physical” approach to the problem do not change the qualitative picture, making, however, the energetic balance between the BCS and the BEC regimes overall more symmetric.

III. DMFT RESULTS IN PRESENCE OF A FORCING FIELD

In this section we will apply a “theoretical probe” to investigate the preformed pair physics: We will study the superconducting response induced by a finite forcing pairing field, also beyond the linear response regime. We will compute by means of DMFT the \( s \)-wave superconducting order parameter \( \Delta = \frac{1}{N} \sum_i (c_{i \uparrow} c_{i \downarrow}) \) as a function of the external field \( \eta \) at different interaction couplings \( (U) \) and inverse temperatures \( (\beta = 1/T) \).

As a first step, we follow the evolution of \( \Delta(\eta) \) in the attractive case \( (U < 0) \) across the critical temperature at weak and strong coupling regimes (according to the classification of Sec. [1]). This evolution shows the expected appearance of a finite \( \Delta \) for \( \eta = 0 \) below \( T_c \) and the divergence of the slope of \( \Delta(\eta) \) for \( \eta \rightarrow 0^+ \) (which coincides with the linear-response pairing susceptibility) approaching \( T_c \) from above (see Fig. 2).

\[
\frac{d^2 \Delta(\eta)}{d\eta^2} < 0 \ \forall \ \eta > 0.
\]

(3)

We note that this general property is totally unaffected by the specific behavior of the linear response regime.
(slope for $\eta \to 0^+$), whose quantitative change as a function of $U$ mostly reflects a different proximity to $T_c$, which is maximum at intermediate coupling \( U \approx 2.25 \) very close to the reported value of $U/D = -2.225$. This is exemplified in Fig. 3 where we perform the same analysis but for a local pairing field $\eta_{loc}$ and detecting the local order parameter. Here the small-$\eta$ slope, being proportional to the local pairing susceptibility, is unaffected by the proximity to the second order phase transition, and it monotonically approaches the atomic limit result. Nevertheless, the curvature of the second derivative is the same as the one of the uniform-field case.

In order to understand the physical meaning of Eq. (3), and to exploit it for a preformed-pairs probing beyond our work, we provide a comparative DMFT study of the opposite situation, where our external pairing field $\eta$ contrasts the underlying spontaneously ordered phase of the system at low $T$. This can be realized repeating the same analysis for the repulsive ($U > 0$) Hubbard model. The corresponding results are shown in Fig. 3 (right panel), where -as before- the $s$-wave superconducting order parameter is plotted as a function of the pairing field $\eta$ for the same high temperature ($\beta = 7D^{-1}$). The DMFT behavior of $\Delta(\eta)$ shows quantitative and qualitative differences between the attractive and the repulsive case. The first difference concerns the linear response to the pairing field, which is progressively suppressed by increasing the strength of the repulsive interaction.

Yet, this difference should be considered -from our perspective- only quantitative: Since the linear response is crucially affected by the proximity to the second order phase transition, it always becomes progressively smaller going farther away from the transition (e.g., for the attractive case by increasing $T$, or for the repulsive case by increasing $U$). Hence, its absolute value is not per se informative about the presence of preformed pairs in the system.

The behavior of the second derivative of $\Delta(\eta)$, instead, is qualitatively richer than in the attractive case (Fig. 3): For small values of $\eta$, the second derivative has a positive sign (i.e., $\Delta(\eta)$ is a convex function), up to an inflection point $\eta^*$ (marked by a vertical arrow in the picture). For $\eta > \eta^*$ the curvature becomes negative and $\Delta(\eta)$ becomes concave, approaching eventually the regime value $\Delta = 0.5$.

As a first, heuristic interpretation of this difference, we observe that the appearance of a region with a convex curvature at low $\eta$ reflects the defiance of the $(U > 0)$ system against the formation of the $s$-wave pairs induced by the field. Very large fields instead simply override the repulsive interaction leading to the formation of pairs. This implies a quite general “rule-of-thumb”: If, by applying a finite pairing field $\eta$ to a system of interest, one observes an initial convex curvature of the corresponding superconducting response, the presence of an underlying preformed pair physics (with the same symmetry of the pairing field) can be ruled out. In fact, on the basis of our model results, an inspection of sign changes of the second derivative of $\Delta(\eta)$ should provide a good test for detecting the absence of preformed pair physics. This “rule-of-thumb”, which represents one of the main outcomes of our study, will be applied to the more realistic $d$-wave pairing in the pseudogap regime of the Hubbard model in Sec. V.

Before proceeding, however, we should recall that only the first derivative of $\Delta(\eta)$ (and, rigorously, only in the limiting case of $\eta \to 0^+$) has a standard interpretation within the linear response theory. Hence, we need to formalize our heuristic understanding of the curvature of $\Delta(\eta)$ more precisely. This will be done in the next section by investigating explicitly, in relevant limiting cases, the relation between the nature of the ground state of the system and its “defying” response to the pairing field.
IV. ANALYSIS OF LIMITING CASES

Aiming at extracting the physical information encoded in the second derivative of the superconducting order parameter, we perform an investigation of the simplest limiting cases, i.e., non interacting ($U = 0$), atomic limit ($t = 0$) and the two-site model, where a full analytical treatment is possible.

We start with the non-interacting case which can be diagonalized in momentum space:

$$H = \sum_{\mathbf{k} \sigma} c_{\mathbf{k} \sigma}^\dagger c_{\mathbf{k} \sigma} - \eta \sum_{\mathbf{k}} (c_{\mathbf{k} \uparrow}^\dagger c_{-\mathbf{k} \downarrow} + c_{-\mathbf{k} \uparrow} c_{\mathbf{k} \downarrow})$$

where $c_{\mathbf{k}}$ represents the free-particle energy dispersion. Because of the presence of the static field $\eta$, one immediately recognizes the formal analogy with the BCS mean-field. After few algebraic steps (see Appendix A), one obtains

$$\Delta(\eta) = \frac{\eta}{\pi D^2} \int_{-D}^D \frac{d\epsilon}{\sqrt{\epsilon^2 + \eta^2}} \tanh \left( \frac{\beta \sqrt{\epsilon^2 + \eta^2}}{2} \right).$$

While this integral can be computed numerically, it is insightful to study its behavior in the zero and high-temperature regimes for a small pairing field ($\eta \ll 1$ and $\beta \sqrt{\eta^2 + \epsilon^2} \ll 1$). In the first case, we have

$$\Delta(\eta) \bigg|_{T=0} = \frac{2\eta}{\pi} \left[ \int_0^{-\eta} \frac{d\epsilon}{\sqrt{\epsilon^2 + \eta^2}} + \int_\eta^1 \frac{d\epsilon}{\sqrt{\epsilon^2 + \eta^2}} \right] \\
\approx \frac{2\eta}{\pi} \left[ \frac{\eta^2}{2} + \log(2) - \log(\eta) \right].$$

Hence, at $T = U = 0$, the first derivative exhibits a positive logarithmic divergence as $\eta \to 0$, which is readily understood by looking at the non-interacting problem in the limit of vanishing interaction ($U/D \to 0$). Since $T_c$ decreases exponentially as $U \to 0$ [3], the non-interacting pair susceptibility at $U = 0$ must diverge exactly at $T = 0$. In the opposite, high-temperature regime, the expansion of the Fermi function as $\beta \sqrt{\eta^2 + \epsilon^2} \ll 1$ yields:

$$\Delta(\eta) \simeq \frac{\beta}{4} \eta - \frac{\beta^2 \eta^2}{4\pi} \int_0^1 d\epsilon \sqrt{1 - \epsilon^2} \sqrt{\epsilon^2 + \eta^2}. $$

As the second integral is always positive, we obtain an overall negative value of the second derivative of $\Delta$, which vanishes only for $\eta \to 0$. The study of the non-interacting case is not fully conclusive in itself, but it already indicates that a negative curvature of $\Delta(\eta)$ does not provide an unambiguous indication of an underlying preformed pair physics, certainly absent in our model for $U = 0$. Further insights can be gained by considering the atomic limit ($t = 0$) of Eq. (1). Here, the superconducting order parameter assumes the following expression (see Appendix B):

$$\Delta(\eta) = \frac{\eta}{2} \frac{\sinh(\beta \epsilon)}{\cosh(\beta \epsilon) + e^{\beta \mu}},$$

where $\epsilon = \sqrt{\mu^2 + \eta^2}$. In particular, Eq. (8) further simplifies at half-filling:

$$\Delta_{\text{att}}(\eta) = \frac{1}{2} \frac{\sinh(\beta \eta)}{\cosh(\beta \eta) + e^{-\beta \mu}},$$

$$\Delta_{\text{rep}}(\eta) = \frac{1}{2} \frac{\sinh(\beta \eta)}{\cosh(\beta \eta) + e^{\beta \mu}} ,$$

whose dependence on $\eta$, at different temperatures is plotted in Fig. 5 both for the attractive and the repulsive case. By exploiting a (rather rough) resemblance of the $\Delta(\eta)$ curves to the corresponding DMFT results of Fig. 3, we progress in clarifying the physical meaning of the second derivative of $\Delta(\eta)$. In particular, let us now focus on the repulsive atomic case, whose $\Delta(\eta)$ displays an inflection point at $\eta^* = U/2$, in a somewhat similar fashion to the DMFT results. We observe that the inflection point $\eta^*$ is exactly associated with a corresponding change of the ground state. By diagonalizing the Hamiltonian (see Appendix B), a crossing of energy levels occurs exactly at $\eta^* = U/2$: For $\eta < \eta^*$ the lowest energy eigenvalue is achieved in the (degenerate) subspace $\{ | \uparrow \rangle, | \downarrow \rangle \}$ describing an (isolated) magnetic moment, while for $\eta > \eta^*$, the ground state becomes $| \uparrow \rangle + | \downarrow \rangle$, i.e., a doubly/empty occupied state. Hence, the curvature of the superconducting response, as a function of the pairing field provides direct information about the ground state properties of the system and, in particular, about the presence or the absence of pairs.

The simplest way to verify to what extent these results hold, also for finite electron hopping, is to consider a two-site model. Here the Hilbert space is spanned by 16 basis vectors and the matrix can be readily diagonalized (see Appendix C), allowing to exactly compute the groundstate vector and $\Delta$ (Fig. 6) as a function of $\eta$. 

FIG. 4. Local superconducting $s$-wave order parameter $\Delta = \frac{1}{N} \sum_i \langle c_{i \uparrow} c_{i \downarrow} \rangle$ as a function of the local forcing pairing field $\eta_{\text{loc}}$ in the attractive Hubbard model. The black line provides the analytic behavior in the Atomic limit case at $U = -7$ and $\beta = 7$ [see Eq. (9)].
FIG. 5. Analytic behavior in the atomic limit of the superconducting order parameter \( \Delta = \frac{1}{N} \sum_i \langle c_i \downarrow c_i \uparrow \rangle \) with respect to the forcing pairing field \( \eta \) in the attractive (upper panel) and in the repulsive (lower panel) Hubbard model for \( U = -7 \) (and \( U = 7 \) in the repulsive case) and different temperature values (See Eqs. 9 and 10).

FIG. 6. Superconducting order parameter \( \Delta(\eta) = \frac{1}{N} \sum_i \langle c_i \downarrow c_i \uparrow \rangle \) as a function of \( \eta \): comparison between the DMFT results at \( \beta = 7 \) and the two sites results for \( T = 0 \) (Green line) and \( \beta = 7D^{-1} \) (Red line).

The agreement with DMFT obviously improves with respect to the atomic limit and an inflection point at \( \eta^* \) remains well visible. The broadening around the inflection point is no longer just a mere effect of the temperature as in the atomic case, but it results from the interplay between the magnetic moment and pair formation tendencies of the ground state. Such interplay is -evidently- affected by the hopping term, as it also happens for the DMFT results. Also in this case we relate \( \Delta(\eta) \), and specifically, the value of its inflection point \( \eta^* \), to the corresponding evolution of the system's ground state. For the latter, in presence of the pairing field \( \eta \), we obtain

\[
|\text{GS}\rangle = \alpha \left( \frac{|\uparrow, \downarrow\rangle - |\downarrow, \uparrow\rangle}{\sqrt{2}} \right) + \beta \left( \frac{|\uparrow, \downarrow\rangle + |0, \uparrow\rangle}{\sqrt{2}} \right) + \gamma \left( \frac{|0, \uparrow\rangle + |\uparrow, \uparrow\rangle}{\sqrt{2}} \right) \quad (11)
\]

where the coefficients \( \alpha, \beta, \gamma \) vary continuously as a function of the field \( \eta \) and the interaction strength \( U \). The first term of Eq. (11) represents a singlet-state over the two sites while the two remaining terms feature empty and doubly occupations. Intuitively, the singlet state could be linked to the presence of localized magnetic moment (with antiferromagnetic tendency) in the ground state, while the other states contain localized ("preformed") pairs.

The explicit dependence of the squared amplitude of \( \alpha, \beta, \gamma \) is shown in Fig. 7 as a function of the pairing field and for different values of the interaction \( U \): The coefficients show a smooth evolution as a function of \( \eta \) which becomes sharper by increasing the interaction, before recovering the step function of the atomic limit for \( U \to \infty \). For any given value of \( U \), \( |\alpha|^2 \) monotonically increases with \( \eta \), while \( |\beta|^2 \) and \( |\gamma|^2 \) decrease, reflecting the progressively enhanced weight of “pairs” (doubly occupied sites) induced by the pairing field.

By reporting the corresponding values of the inflection point \( \eta^* \) (as extracted by the data of Fig. 6) we find that \( \eta^* \) occurs in correspondence of the value of \( |\alpha|^2 = 0.5 \) (marked by dashed line in the figure) in the intermediate and strong coupling regimes (\( U = 3 \) and \( U = 7 \)). This reflects the fact that, also in the two-site model, the sign change of the second derivative of \( \Delta(\eta) \) marks a change of the prevalent character of the ground state. This is dominated by localized magnetic moments (\( |\alpha|^2 > 0.5 > |\beta|^2 + |\gamma|^2 \) for \( \eta < \eta^* \), i.e., where the curvature of \( \Delta(\eta) \) is convex. On the other hand, local ("preformed") pairs prevail (\( |\alpha|^2 < 0.5 < |\beta|^2 + |\gamma|^2 \) for \( \eta > \eta^* \), i.e., where a concave curvature of \( \Delta(\eta) \) occurs. Our microscopic analysis confirms thus the link between the curvature of \( \Delta(\eta) \) with the tendency of the system to contrast or to favor the driven superconducting state.

From a quantitative perspective, one should note that in the weak coupling regime (\( U = 1 \), Fig. 7(a)), the
FIG. 7. Ground state coefficients $|\alpha|^2$ (blue line), $|\beta|^2$ (green line) and $|\gamma|^2$ (red line) of the two-sites model (Eq. (11)) for different $U$ values as a function of the forcing field $\eta$.

FIG. 8. Values of the coefficients $|\alpha|^2$, $|\beta|^2$ and $|\gamma|^2$ of Eq. (11) at $\eta^*$ as a function of $U$.

inflection point $\eta^*$ is slightly before the coefficient $|\alpha|^2$ crosses the value 0.5, i.e., at $\eta = \eta^*$ one finds an $|\alpha|^2$ slightly larger than 0.5. While this weak-coupling feature might be a specific result of the two-site model, its presence, however, does not compromise the validity of our interpretation. This can be better understood looking at the Fig. 9 where the physics of the two-site model with pairing field is eventually summarized. Here, in a phase diagram $U$ vs. $\eta$ (drawn at a fixed $T = 1/7D$), the values of $\eta^*$, and of the loci where $|\alpha|^2 = 0.5$ are reported. Moreover, in the spirit of Sec. II, different region of the phase-diagram could be defined, and classified in terms of the kinetic/potential energy gain/losses induced by the application of the (finite) pairing field:

$$
(H_K)_{\eta} - (H_K)_{\eta=0} = -2\alpha\beta + \frac{2}{U} \left(1 + \frac{4}{U^2}\right)^{1/2}
$$

$$
(H_{pot})_{\eta} - (H_{pot})_{\eta=0} = -U\alpha^2 - 4\eta\beta\gamma
$$

$$
+ \frac{U}{2} \left[1 + \left(1 + \frac{4}{U^2}\right)^{-1/2}\right]
$$

FIG. 9. $U$ vs. $\eta$ plane showing the different regimes obtained from an energy balance analysis in the two-site model. The blue, violet and red regions indicate respectively the weak, intermediate and strong coupling regimes. The $\eta^*$ behavior at different $U$ values is shown by the red line.

The energetic balance analysis of Fig. 9 confirms, hence, that the correspondence between $\eta^*$ and the change of nature in the ground state of the two-site model is rather solid in the whole intermediate and “BEC” coupling regime (relevant for the preformed pair physics) with minor deviations occurring in the “BCS” regime. Moreover, we observe that in the “BCS” region for $\eta = \eta^*$, $|\alpha|^2$ is slightly larger than 0.5, indicating that a convex (=positive) curvature of $\Delta(\eta)$ is definitely incompatible with any preformed pair physics in the ground state (See Fig. 8). We finally note that such criterion of “absence”, usable to rigorously exclude the presence of preformed pairs, is also compatible with the analysis of the concave (=negative) curvature of $\Delta(\eta)$ in the non-interacting case, discussed at the beginning of the section.
V. IMPLICATIONS FOR OTHER STUDIES

By analyzing systematically the superconducting response ($\Delta$) of simple models to an external $s$-wave pairing field ($\eta$), we have demonstrated that, whenever $\Delta(\eta)$ displays a convex curvature in the low-field limit, we can safely exclude preformed Cooper pairs. In this section, we discuss the relevance of this “rule-of-thumb” criterion to a wider range of systems. Through a unitary transformation, the pairing field and the superconducting order parameter in the attractive Hubbard model map onto the magnetic field and the magnetic moments in the corresponding repulsive counterpart. This means that our findings apply also for the case where preformed magnetic moments are driven by an external magnetic field. This generalization of our results is particularly promising, because a measure of the magnetization as a function of the magnetic field is obviously not a pure theoretical probe and it can be directly applied in various experiments (at least for the ferromagnetic case).

Since the presence and the role of preformed magnetic moments remain a debated issue for several correlated materials, ranging from simple metals like Fe and Ni to alloys (FeAl) and iron-pnictides and chalcopyrides, the novel, clear-cut criterion proposed in this work may find widespread application in future experimental and theoretical studies of these materials.

One may also envisage further applications of our results as an idealized description of pump-probe experiments on superconductors. There, a transient state with an optical response, which is at least compatible with a superconductor, can be created by impulsive excitations inducing coherent phonon deformations, while leaving the temperature of the electrons unchanged. Comparing experiments against our idealized calculations, one could analyze to which extent the impulsive excitation can be interpreted as an external field driving superconductivity (obviously in our calculations the driven superconductivity is static, as the external field does not depend on time).

One of the most natural applications of our results is, however, the possible presence of preformed $d$-wave pairs in the pseudogap phase of the two-dimensional Hubbard model. Indeed a closely related theoretical analysis has already been performed using the Dynamical Cluster Approximation (DCA), an extension of DMFT where the single impurity is replaced by a cluster of $N_c$ sites. An external $d$-wave pairing field was applied and the resulting $d$-wave superconducting response $\Delta_k$ was then computed. Without driving fields, for $N_c = 8$ and $U > 1.5D$ (with $D = 4t$) the superconducting phase is replaced by the pseudogap state, where a strong spectral weight suppression is found at the antinodal point, without any superconducting long-range order. Clearly, the identification of the physical origin of this phase is also crucial to understand the debated underlying physics of the high-temperature superconductors. In this respect, the two main alternative interpretations describe the pseudogap either as the result of intrinsic interaction effects (spin fluctuations, Mott physics or other) or as the signature of preformed $d$-wave pairs. The results of Ref. [19] are reproduced in Fig. 10, which shows $\Delta_k(\eta_k)|_{k=(0,\pi)}$ as a function of the external $d$-wave pairing field $\eta = \eta_d$. On the basis of these calculations, the authors concluded that the superconducting response to a $d$-wave forcing field was “weak enough” to exclude a preformed pair origin of the pseudogap state in DCA. This statement is certainly reasonable, but it still lacks of formal strength as it is not based on some precise criterion.

A closer look to the data of Fig. 10 shows that, besides an expected progressive suppression of the linear response moving away from the critical regime, one observes a sign change of the second derivative of $\Delta_k(\eta_k)$, which starts displaying a convex curvature for small fields at $U = 1.6D$. Hence, according to our criterion, we can now safely conclude that, once the system is sufficiently far from the superconducting instability, there are no well defined preformed pairs which couple with the external pairing field in a parameter region where the pseudogap is observed in DCA. This excludes a preformed-pair origin of the pseudogap and it is rather suggestive of a major role played by the strong antiferromagnetic correlations or by non-local Mott physics. It is worth to mention that the claim of a lack of preformed pairs of Ref. [19] made more rigorous by the present analysis, is not necessarily in contradiction with the claim, based on a different DCA study of significant $d$-wave pairing fluctuations also far from $T_c$. The latter result indeed refers to short-ranged fluctuations both in space and time, while the (static) forcing-field analysis focuses on long-lived pairs. Indeed these results are perfectly compatible in view of the more recent study of Ref. [22], where it has been shown that well-defined spin-fluctuations, emerging as the predominant pseudogap mechanism according to our analysis of the data of Ref. [19], show up as short range/short lived pairing fluctuating modes, if viewed from the perspective of the particle-particle scattering channel.

VI. CONCLUSIONS

This work has been devoted to the definition of an operative criterion to confirm or exclude the existence of preformed pairs in a non-superconducting state. This goal has been achieved by a systematic DMFT study of the response to an external $s$-wave pairing forcing field $\eta$ in the controlled situation of a single band (attractive and repulsive) Hubbard model. For strong attractive interactions we are indeed certain of the existence of preformed pair region, while the repulsive model does not host any $s$-wave pair.

By comparing the different regimes, we identified a clear-cut “rule-of-thumb” criterion for excluding a preformed pair physics: The latter are certainly absent, if the second derivative of $\Delta(\eta)$ is positive in a finite region of $\eta$ from 0 to a finite value $\eta^*$ (i.e., $\Delta(\eta)$ is a convex function at small fields). This happens because the con-
FIG. 10. [DCA data reproduced from Ref. [19] d-wave superconducting order parameter induced by the corresponding d-wave pairing field $\eta_d$: in a DCA calculation for a 2D Hubbard model at $\beta D = 240$ the order parameter $\Delta_k$ is evaluated in the sector $k = (0, \pi)$ and plotted as a function of $\eta_d$ at doping $\delta = 0$ for interaction strengths indicated. The dashed lines, marking the slope of the (linear) response at $\eta_d \to 0^+$, make more easily noticeable the curvature change of $\Delta(\eta_d)$ occurring for the data set at $U = 1.6D$.

The curvature of $\Delta(\eta)$ reflects the “reluctance” of the systems to respond to the pairing field. In other words, the positive second derivative indicates that the applied forcing field is not intense enough to revert the dominant nature of the ground state, which opposes to the order induced by the probing field. Only if $\eta$ is enough large to exceed any intrinsic property of the model, the curvature changes sign and becomes concave, leading, eventually, to a saturation to the maximum pairing amplitude. This behavior testifies the absence of any intrinsic preformed pairing.

On the other hand, an overall concave curvature of $\Delta(\eta)$ is a necessary condition for the existence of preformed pairs, but it is not a sufficient condition. Therefore, the latter should be supplemented with further physical information, such as, e.g., the energetic balance underlying superconductivity, as we also discuss in Sec. II of this paper.

Our results have potential impact for several different aspects. Our “rule-of-thumb” can be indeed applied, as showed in the previous section, for improving the interpretation of cutting edge DCA calculations relevant for the cuprate physics, and -in particular- to exclude on a rigorous basis that the pseudogap state of DCA is originated by preformed pair fluctuations. Indeed, a related analysis has been proposed in Ref. [19], where, however, the physical interpretation of the results was mostly heuristic.

Moreover, it is quite natural to extend the conclusions of our analysis (and, in particular, our criterion) to cases of other, more physical, forcing fields: This would be, e.g., the case of a (finite) magnetic field exploited to detect preformed magnetic moments via the evolution of the magnetization as a function of magnetic field beyond linear response. Evidently, the latter analysis allows also for direct experimental realizations.

Finally, we notice that the study of regimes of external perturbation field, far away from the linear response, might provide important complementary information to interpret more challenging non-equilibrium phenomena. Comparing our results with pump-probe experiments where transient superconductivity is realized by coherently exciting phonon modes, we could study whether, and to which extent, these non-equilibrium phenomena can be interpreted in terms of a light-driven pairing field which favors pair formation.

APPENDIX

Appendix A: Non interacting case

The half-filled non-interacting problem under a isotropic pairing forcing field $\eta$ can be easily solved in $\mathbf{k}$-space. Here, the Hamiltonian assumes the following form:

$$ H = \sum_{\mathbf{k}\sigma} \epsilon_{\mathbf{k}\sigma} c_{\mathbf{k}\sigma}^\dagger c_{\mathbf{k}\sigma} - \eta \sum_{\mathbf{k}} \left( c_{\mathbf{k}\uparrow}^\dagger c_{-\mathbf{k}\downarrow} + c_{-\mathbf{k}\uparrow} c_{\mathbf{k}\downarrow}^\dagger \right) , $$

where $\epsilon_{\mathbf{k}}$ represents the free particle energy dispersion. This Hamiltonian can be exactly diagonalized by exploiting the Bogoliubov transformations \cite{4}, which read:

$$ \begin{align*}
\gamma_{\mathbf{k}\uparrow}^\dagger &= u_{\mathbf{k}} c_{\mathbf{k}\sigma}^\dagger - v_{\mathbf{k}} c_{-\mathbf{k}\sigma} \\
\gamma_{\mathbf{k}\downarrow} &= u_{\mathbf{k}} c_{-\mathbf{k}\sigma} + v_{\mathbf{k}} c_{\mathbf{k}\sigma}^\dagger
\end{align*} \quad (14)$$

where:

$$ \begin{align*}
u_{\mathbf{k}}^2 &= \frac{1}{2} \left( 1 + \frac{\epsilon_{\mathbf{k}}}{E_{\mathbf{k}}} \right) \\
v_{\mathbf{k}}^2 &= \frac{1}{2} \left( 1 - \frac{\epsilon_{\mathbf{k}}}{E_{\mathbf{k}}} \right) \quad (15)
\end{align*} $$

and $E_{\mathbf{k}} = \sqrt{\epsilon_{\mathbf{k}}^2 + \eta^2}$.

In order to evaluate the superconducting order parameter in real space, one has to perform the expectation value of the annihilation “pair operator” $b_\mathbf{k} = c_{-\mathbf{k}\downarrow}^\dagger c_{\mathbf{k}\uparrow}$ and sum over the Brillouin Zone:

$$ \langle b_\mathbf{k} \rangle = \langle c_{-\mathbf{k}\downarrow}^\dagger c_{\mathbf{k}\uparrow} \rangle = u_{\mathbf{k}}^* v_{\mathbf{k}} \left( 1 - \langle \gamma_{\mathbf{k}\uparrow}^\dagger \gamma_{\mathbf{k}\uparrow} \rangle - \langle \gamma_{\mathbf{k}\downarrow}^\dagger \gamma_{\mathbf{k}\downarrow} \rangle \right) = u_{\mathbf{k}}^* v_{\mathbf{k}} \left( 1 - 2 f(E_{\mathbf{k}}) \right) \quad , (16) $$

where $f(E_{\mathbf{k}})$ represents the usual Fermi-Dirac thermal distribution for fermion-like excitations with energy $E_{\mathbf{k}}$. Hence, we finally end up with the following expression for the superconducting order parameter:

$$ \Delta = \sum_{\mathbf{k}} u_{\mathbf{k}}^* v_{\mathbf{k}} \left( 1 - 2 f(E_{\mathbf{k}}) \right) = \sum_{\mathbf{k}} \frac{\eta}{2 \epsilon_{\mathbf{k}}} \left( 1 - 2 f(E_{\mathbf{k}}) \right) = \frac{\eta}{2} \int_{-\infty}^{\infty} \frac{d\epsilon}{\epsilon} D(\epsilon) (1 - 2 f(\epsilon)) \quad . (17) $$

Explicitly substituting the DOS of the Bethe-lattice and the Fermi-Dirac thermal distribution, one gets Eq. \cite{3}.

Appendix B: Atomic limit

In this section we explicitly derive the expression for the superconducting order parameter $\Delta$ in the atomic limit. We proceed in two steps: first we perform the unitary transformation to map the attractive Hubbard model onto the repulsive one, secondly we project the system onto the new principal axes and evaluate the expectation value $\langle c_i^\dagger c_j \rangle$ in the starting (attractive) system. Note that the analogous procedure can be adopted for the repulsive case just by swapping the $U$ sign.

Let us start from the attractive Hubbard model Hamiltonian, properly readjusted to emphasize the particle-hole symmetry:

$$ H_{attr} = U \sum_i \left( n_{i\uparrow} - \frac{1}{2} \right) \left( n_{i\downarrow} - \frac{1}{2} \right) - \left( \mu - \frac{U}{2} \right) \sum_i (n_{i\uparrow} + n_{i\downarrow}) - \eta \sum_i (c_{i\uparrow}^\dagger c_{i\downarrow}^\dagger + h.c) \quad . (18) $$

Here $U < 0$ and $\mu$ is the shifted chemical potential (note $\mu = U/2$ at half-filling). By performing the unitary transformation to map the attractive Hubbard model onto the repulsive one\cite{3}

$$ \begin{align*}
c_{i\uparrow} &\rightarrow (-1)^n c_{i\downarrow}^\dagger \\
c_{i\downarrow} &\rightarrow c_{i\uparrow}^\dagger
\end{align*} \quad , (19) $$

we end up with the corresponding repulsive Hubbard Hamiltonian:

$$ H_{rep} = |U| \sum_i n_{i\uparrow} n_{i\downarrow} - \frac{|U|}{2} \sum_i (n_{i\uparrow} + n_{i\downarrow}) - \left( \mu + \frac{|U|}{2} \right) \sum_i (n_{i\uparrow} - n_{i\downarrow}) - \eta \sum_i (-1)^n (c_{i\uparrow}^\dagger c_{i\downarrow} + c_{i\downarrow}^\dagger c_{i\uparrow}) \quad . (20) $$
Notice that Eq. (20) is nothing but a half-filled repulsive system with two external magnetic fields applied onto the $z$ and the $x$ axes. Since the first two terms are invariant under axes rotation, it is convenient to perform a unitary transformation of the operators, projecting the system along the principal axes in the $(x,z)$ plane.

Diagonalizing the last two terms in the 4-state Hilbert space for the single site and making the proper transformations, we end up with the following expression:

$$H_{\text{rep}} = |U| \sum_i n_{i\uparrow} n_{i\downarrow} - \frac{|U|}{2} \sum_i (n_{i\uparrow} + n_{i\downarrow}) + \epsilon \sum_i (n_{i\uparrow} - n_{i\downarrow}),$$

where $\epsilon = \sqrt{(\mu + \frac{|U|}{2})^2 + \eta^2}$ is the effective magnetic field resulting from the $\mu$ and $\eta$ terms.

In order to evaluate the superconducting order parameter $\Delta$, we need to map the pairing operator $c_{i\downarrow}c_{i\uparrow}$ onto the corresponding repulsive system by projecting it along the principal axes. We obtain:

$$\langle c_{i\downarrow}c_{i\uparrow} \rangle \rightarrow \frac{1}{4\eta e^2} \left[ -\frac{\epsilon - \frac{|U|}{2} - \mu}{a^2} \langle c_{i\uparrow}^\dagger c_{i\uparrow} \rangle + \frac{\epsilon + \frac{|U|}{2} + \mu}{b^2} \langle c_{i\downarrow}^\dagger c_{i\downarrow} \rangle \right],$$

where $a/b = \left( \eta^2 + \left( \mu \pm \frac{|U|}{2} \pm \epsilon \right) \right)^{-1/2}$.

Evaluating explicitly the expectation values in Eq. (22) one obtains:

$$\Delta(\eta) = \frac{\eta}{2} \frac{e^{-\beta \frac{|U|}{2}}}{\cosh(\beta \eta) + e^{-\beta \frac{|U|}{2}}}$$

which reduces to the simpler expression in the half-filling case:

$$\Delta_{\text{att}}(\eta) = \frac{1}{2} \frac{\sinh(\beta \eta)}{\cosh(\beta \eta) + e^{-\beta \frac{|U|}{2}}}. \quad (24)$$

Since this expression is typically applicable for large values of $|U|$, one can notice that the order parameter exhibits a weak dependence on the interacting constant. This also sets a minimum value for the slope in the limit $|U| \to +\infty$ at finite temperature:

$$\lim_{|U|\to+\infty} \left. \frac{\partial \Delta_{\text{att}}}{\partial \eta} \right|_{\eta=0} = \frac{\beta}{2}. \quad (25)$$

A study on the second derivative $\partial^2 \Delta_{\text{att}}/\partial \eta^2$ shows that, for all $\eta > 0$, the superconducting order parameter exhibits a negative curvature in the attractive Hubbard model, as shown in Fig. 5 (upper panel). The corresponding behavior for $U > 0$ is shown in Fig. 5 (lower panel).

**Ground state**

As a final atomic limit analysis in the repulsive case, we can look at the ground state evolution as a function of the external pairing field. The local, repulsive Hamiltonian has the following form:

$$H_{\text{rep}}^i = U n_{i\uparrow} n_{i\downarrow} - \frac{U}{2} (n_{i\uparrow} + n_{i\downarrow}) - \eta (c_{i\downarrow}^\dagger c_{i\uparrow} + c_{i\uparrow}^\dagger c_{i\downarrow}^\dagger)$$

where, for sake of simplicity, we reduced at half-filling.

By diagonalizing the $4 \times 4$ block matrix, we find three different eigenvalues: $-U/2$ (two-fold degenerate), $\pm \eta$. Therefore, as soon as $\eta \to U/2$, the ground state of the system abruptly changes from the degenerate subspace to the eigenstate associated with $-\eta$, namely:

$$| - \eta \rangle = \frac{|\uparrow\downarrow\rangle + |\downarrow\uparrow\rangle}{\sqrt{2}} \quad (27)$$
Appendix C: Two-site model

In this section we target the solution of the repulsive Hubbard model taking into account just two sites. The two sites Hamiltonian reads:

\[ H = -t \sum_{\sigma} (c_{1\sigma}^\dagger c_{2\sigma} + c_{2\sigma}^\dagger c_{1\sigma}) + U \sum_{i=1,2} (n_i^\uparrow - \frac{1}{2})(n_i^\downarrow - \frac{1}{2}) - \eta \sum_{i=1,2} (c_{i\uparrow}^\dagger c_{i\downarrow}^\dagger + c_{i\downarrow} c_{i\uparrow}) \]  

(28)

Where \( t \) is the hopping integral, \( U > 0 \) is the interaction parameter and \( \eta \) represents the external pairing field. Since we are working in the grandcanonical ensemble, the Hilbert space is spanned by 16 basis vectors, namely:

\[ \{ | \uparrow, \downarrow \rangle, | \downarrow, \uparrow \rangle, | \uparrow \uparrow, 0 \rangle, | 0, \uparrow \downarrow \rangle, | \uparrow \downarrow, 0 \rangle, | 0, \downarrow \uparrow \rangle \} \Rightarrow \text{ssp n = 1} \]  

(29)

\[ \{ | \uparrow, 0 \rangle, | \downarrow, 0 \rangle, | 0, \uparrow \rangle, | 0, \downarrow \rangle \} \Rightarrow \text{ssp n = 0.5} \]  

(30)

\[ \{ | \uparrow \uparrow, \downarrow \rangle, | \downarrow \uparrow, \uparrow \rangle, | \uparrow \downarrow, \uparrow \rangle, | \downarrow \uparrow, \downarrow \rangle \} \Rightarrow \text{ssp n = 1.5} \]  

(31)

\[ \{ | \uparrow, \uparrow \rangle \} \Rightarrow \text{ssp n = 2} \]  

(32)

\[ \{ | 0, 0 \rangle \} \Rightarrow \text{ssp n = 0} \]  

(33)

where each line indicates a specific subspace (ssp) characterized by an electron density \( n \). By exploiting the symmetries of the system one can identify for which states the Hamiltonian is diagonal:

\[ \{ | \uparrow \downarrow, 0 \rangle - | 0, \uparrow \downarrow \rangle, | 0, 0 \rangle - | \uparrow \downarrow, \uparrow \rangle \} \Rightarrow E_1 = 0 \]  

(34)

\[ \{ | \uparrow, \uparrow \rangle, | \downarrow, \downarrow \rangle, | \uparrow \downarrow, \uparrow \rangle + | \downarrow \uparrow, \downarrow \rangle \} \Rightarrow E_2 = -U \]  

(35)

While projecting the Hamiltonian on the 3 dimensional subspace \( \{ | 0, 0 \rangle + | \uparrow \downarrow, \uparrow \rangle, | \uparrow \downarrow, 0 \rangle - | \downarrow \uparrow, \downarrow \rangle \} \) gives the following matrix:

\[ M = \begin{pmatrix} -U & -2t & 0 \\ -2t & 0 & -2\eta \\ 0 & -2\eta & 0 \end{pmatrix} \]  

(36)

One can demonstrate that this matrix has three distinguished real eigenvalues \( (E_3, E_4 \text{ and } E_5) \) even if an explicit simple expression cannot be found analytically. Nevertheless, we are able to compute numerically eigenvalues and eigenvectors as a function of the interaction \( U \) and the pairing field \( \eta \). The remaining states with an odd average number of particles span two equivalent 4-dimensional subspaces (one for each spin channel) whose Hamiltonian projection reads:

\[ M_1 = \begin{pmatrix} -\frac{U}{2} & -t & -\eta & 0 \\ -t & -\frac{U}{2} & 0 & -\eta \\ -\eta & 0 & -\frac{U}{2} & t \\ 0 & -\eta & t & -\frac{U}{2} \end{pmatrix} \]  

(37)

So we obtain the two eigenvalues \( E_6 \) and \( E_7 \) (each one four times degenerate) and the associated eigenvectors. Fig. 11 shows the seven eigenvalues as a function of \( \eta \) at different interaction values. Hence, it is possible to identify the state associated with \( E_5 \) to be the ground state of the system for any \( U \) and \( \eta \) values.

This state lives in the subspace described by matrix \( M \) and can be written as follows:

\[ |\text{GS} \rangle = \alpha \left( \frac{| \uparrow \downarrow, 0 \rangle - | 0, \uparrow \downarrow \rangle}{\sqrt{2}} \right) + \beta \left( \frac{| \uparrow \downarrow, 0 \rangle + | 0, \uparrow \downarrow \rangle}{\sqrt{2}} \right) + \gamma \left( \frac{| 0, 0 \rangle + | \uparrow \downarrow, \uparrow \rangle}{\sqrt{2}} \right) \]  

(38)

Superconducting response at \( T \neq 0 \)

The superconducting order parameter at finite temperature in the two sites model is readily computed as

\[ \Delta = \frac{1}{2} \sum_i \frac{1}{Z} \text{Tr} e^{-\beta H} c_{i\downarrow}^\dagger c_{i\uparrow} = \frac{1}{2} \sum \alpha \sum_n e^{-\beta \epsilon_n} \langle \bar{n} | c_{i\downarrow} n \rangle \langle \langle \bar{n} | c_{i\uparrow} \rangle \rangle^* \]  

\[ = \frac{1}{Z} \left\{ e^{-\beta E_0} (m_1 p_1 + m_2 p_2) + e^{-\beta E_1} (m_3 p_3 + m_4 p_4) + e^{-\beta E_4} (\beta_1 \gamma_1 + \beta_2 \gamma_2) + e^{-\beta E_5} (\beta_3 \gamma_3) \right\} \]  

(39)
where the coefficients $m_i$ and $p_i$ ($i = \{1, 4\}$) are related to the eigenstates of $M_1$. Namely:

\begin{align}
|E_6⟩ &= l_{1(2)}|\uparrow, 0⟩ + m_{1(2)}|0, \uparrow⟩ + p_{1(2)}|\uparrow⟩ \downarrow, \uparrow⟩ \\
|E_7⟩ &= l_{3(4)}|\uparrow, 0⟩ + m_{3(4)}|0, \uparrow⟩ + n_{3(4)}|\uparrow⟩ \downarrow, \uparrow⟩ + p_{3(4)}|\uparrow⟩ \downarrow, \uparrow⟩
\end{align}

And the partition function is given by:

\[
Z = 3 e^{\beta U} + 2 + e^{-\beta E_3} + e^{-\beta E_4} + 4 e^{-\beta E_5} + 4 e^{-\beta E_6} + 4 e^{-\beta E_7}.
\]

Fig. 6 shows the comparison between equation (39) and the DMFT result for the superconducting order parameter.
