(Dated: March 23, 2022)

Transport in ultrathin graphite grown on silicon carbide is dominated by the electron-doped epitaxial layer at the interface. Weak anti-localization in 2D samples manifests itself as a broad cusp-like depression in the longitudinal resistance for magnetic fields $10 \text{ mT} < B < 5 \text{ T}$. An extremely sharp weak-localization resistance peak at $B = 0$ is also observed. These features quantitatively agree with graphene weak-(anti)localization theory implying the chiral electronic character of the samples. Scattering contributions from the trapped charges in the substrate and from trigonal warping due to the graphite layer on top are tentatively identified. The Shubnikov-de Haas oscillations are remarkably small and show an anomalous Berry’s phase.

The extraordinary transport properties of carbon nanotubes \cite{1}, graphene \cite{2,3,4} and graphene ribbons \cite{5} make this an exciting and promising new material for nanoelectronics. Epitaxial graphene (EG) grown on silicon carbide substrates can be patterned using standard lithography methods and is robust and reproducible. Their transport properties reflect those previously observed in deposited microscopic single graphene sheets from exfoliated graphite. In both cases, the special transport properties have their origin in the chiral nature of the charge carriers, causing reduced backscattering \cite{6} and an anomalous quantum Hall effect \cite{7,8}. Chirality is due to the equivalence of the A and B sublattices of graphene, which produces two inequivalent Dirac cones at opposite corners of the Brillouin zone at $K$ and $K'$. Consequently, the wave functions have an additional isospin quantum label. On a specific cone the isospins of oppositely directed electrons are also reversed. Hence, isospin conserving (IC) scattering processes \textit{i.e.} long-range scatterers that do not distinguish between A and B atoms cannot backscatter the charge carriers, reducing the resistance caused by those scatterers. The effect diminishes in a magnetic field, resulting in a positive magnetoresistance. This weak anti-localization (WAL) effect is a signature of the isospin. It stands in contrast to the usual the weak localization (WL) effect, characterized by a negative magnetoresistance, which occurs in these materials at point defects that locally break the sublattice degeneracy, thereby causing intervalley scattering \textit{i.e.} from one Dirac cone to the other. Note that due to the A-B stacking in graphite, the sublattice degeneracy is lifted so that WAL is neither expected nor observed.

We show here evidence for WAL in two-dimensional thin graphitic layers grown on single crystal silicon carbide. The effect is quantitatively in agreement with recent graphene WAL theory demonstrating the isospin character of the charge carriers in epitaxial graphene \cite{9}. In patterned, quasi one-dimensional epitaxial graphene structures we recently demonstrated quantum confinement effects, exceptionally high mobilities and evidence for an anomalous Berry’s phase \cite{3}. Transport is dominated by the interface layer, which due to the built-in electric field, is charged with an electron density $n = 3.4 \times 10^{12} \text{ cm}^{-2}$.

In two-dimensional graphene, depending on the relative magnitude of the intervalley scattering time $\tau_{iv}$ and the phase coherence time $\tau_{\phi}$, either WL or WAL has been predicted \cite{9}. The phase interference correction to the resistance depends on the nature of the disorder \cite{6,10}. In Ref. \cite{10}, McCann \textit{et al.} point out that WAL is suppressed by any scattering mechanism that changes isospin, as well as the warping term in the Hamiltonian.

For epitaxial graphene samples in this study, elastic scattering favorable for WAL can be caused by remote charges like the counterions in the substrate. On the other hand, atomically sharp disorder \textit{i.e.} local defects and edges) causes intervalley scattering, and gives rise to WL. Finally, trigonal warping tends to suppress the WAL. Trigonal warping can be caused by the interlayer interactions of a graphene sheet on top of the EG layer. Hence scattering from each of the three components of the EG system is expected to contribute to the MR.

In the case that IC scattering dominates, the correction to the sheet magnetoresistance can be expressed as \cite{9}:

\begin{equation}
\Delta \rho(B) = -\frac{e^2 \rho_s^2}{\pi \hbar} \left[ F\left(\frac{2\tau_{\phi}}{\tau_B}\right) - F\left(\frac{2}{\tau_B(\tau_{\phi}^{-1} + 2\tau_{iv}^{-1})}\right) \right. \\
\left. - 2F\left(\frac{2}{\tau_B(\tau_{\phi}^{-1} + \tau_{iv}^{-1} + \tau_{w}^{-1})}\right)\right]
\end{equation}

\begin{equation}
F(z) = \ln z + \Psi\left(\frac{1}{2} + \frac{1}{z}\right).
\end{equation}

In contrast, the correction to the magnetoresistance in conventional 2D metals due to the weak-localization is
The amplitude of the WL peak at $B = 0$ depends on $\tau_w$. Another important implication is that WAL can manifest itself in relatively high magnetic fields ($i.e.$, where mainly short return trajectories contribute to the interference correction), even in the presence of significant intervalley scattering. Qualitatively, in that case the long tail of the negative MR will ultimately give way to a positive MR at high fields. In other words, the MR behavior is described very well by Eq. (1). Both the high field behavior of the MR, which is dominated by WAL for $B > 20$ mT, and the low field behavior, for which the peak is absent, is subtracted from the temperature dependent part of the MR, the $50$ K data ($\Delta R^* (B, T) = R(B, T) - R(B, 50K)$).}

The graphene layer is of high crystalline quality and protected from the environment by the graphite over layer. Ultra-thin graphite layers were made by thermal decomposition of single-crystal silicon carbide on the $000\bar{1}$ face. Unlike graphite, which consists of A-B stacked graphene planes, our samples show evidence for azimuthal orientational disorder as seen in low energy electron diffraction and grazing incidence X-ray diffraction. The graphene symmetry is preserved. Graphite layers were patterned to produce a standard Hall bar $100 \mu m \times 1000 \mu m$ in size. The wired samples were placed into a He$^4$ cryostat providing temperatures down to 1.4 K. Standard four-point measurements were carried out using a lock-in amplifier. A magnetic field was applied perpendicular to the graphene layer. Applying a magnetic field parallel to the graphene layer diminished the magnetoresistance to 1.5 $\%$ of its perpendicular-field value. This establishes an upper limit to the angular dispersion of the normal EG layer of $\delta \theta \leq 0.015$. A detailed analysis on the WL peak in a perpendicular and parallel magnetic fields gives a smaller upper limit : $\delta \theta \leq 0.006$. The transport electron density $3.8 \times 10^{12} \text{cm}^{-2}$ was determined from the Shubnikov-de Haas (SdH) oscillations. The low field Hall slope is $137 \Omega/T$, corresponding to a Hall electron density of $n_H = 4.6 \times 10^{12} \text{cm}^{-2}$, which agrees with the density from SdH oscillations.

In contrast to 1D samples, in 2D films, edge scattering is significantly reduced and universal conductance fluctuations are absent. The WL is strongly suppressed and a positive MR in the intermediate field region is observed. These properties are reflected in the model developed by McCann et al. (Eq. (1)).

We have studied two samples and both displayed similar behavior. Fig. 1 shows the low-field resistance ($B < 35$ mT) of one sample for temperatures ranging from 1.4 K to 50 K, which consists of a temperature dependent peak around zero field and a temperature independent parabolic component. As conventional, to bring out the temperature dependent part of the MR, the 50 K data (for which the peak is absent) is subtracted from the lower temperature data $R^*(B, T) = R(B, T) - R(B, 50K)$ and then the temperature dependent MR is calculated by $\Delta R^* = R^*(B, T) - R^*(0, T)$. An extremely sharp WL peak at $B = 0$ (upper-right inset of Fig. 2) indicates a long phase coherence length (see below). As expected, the amplitude of the WL peak decreases while its width increases with increasing temperature as a result of the reduction of the phase coherence length. An attempt to fit the WL peak using conventional WL theory is shown in Fig. 2. Here a scaling factor $\alpha \sim 0.3$ was introduced to obtain a reasonable fit about $B = 0$. This factor suggests that the WL is suppressed.

However an important deviation in $\Delta R^*$ from conventional WL theory is observed at fields above 20 mT where $\Delta R^*$ increases with increasing field up to $B = 4$ T. This temperature dependent positive MR is a clear signature of WAL as discussed above. Moreover, the entire MR behavior is described very well by Eq. (1). Both the high field behavior of the MR, which is dominated by WAL for $B > 20$ mT, and the low field behavior, for
temperature, which, in 2D, is an indication that the dom-

A scaling factor $\alpha \sim 0.3$ is introduced in order to fit data,
caused by a short scattering time $\tau$ because $\tau \sim 0.26$ ps, is longer than those in Ref. [2], where SdH oscillations even evolved into a quantum Hall effect. More striking is that the SdH amplitudes in 2D samples are much smaller than the SdH amplitudes in 1D samples (c.f. Ref. [3]). We find that the amplitudes are approximately inversely proportional to the sample width. This observation leads to the interesting speculation that in graphene scattering from atomically sharp defects enhances the SdH oscillation amplitudes, and consequently, that such local defects are also required to produce the integer quantum Hall effect. Apparently in our 2D samples the defect density of intervalley scatterers in the bulk is too low to produce large SdH oscillations or an integer quantum Hall effect.

In summary, epitaxial graphene exhibits a number of graphene properties. The isospin degeneracy that causes both weak anti-localization as well as the anomalous Berry’s phase is a graphene property that is not present in graphite. It appears that the 2D bulk scattering in EG causes WAL and is dominated by valley symmetry conserving processes, consistent with scattering from long range potentials arising from charges in the substrate. WL appears to be primarily caused by isospin symmetry breaking scattering, for example from edges. Trigonal warping scattering due to the graphite layer on top of the EG could explain the reduction of the WAL. The extremely small SdH amplitudes (which preclude the quantum Hall effect) may be directly related to the scattering processes in the 2D bulk EG.

[15] Electron-electron interaction can also lead to a temperature dependent positive MR, provided the magnetic field is large enough so that either $g \mu_B B > k_B T$ or $hD/l_{cy}^2 > k_B T$ is satisfied, here $l_{cy}$ is the cyclotron radius. The positive MR observed in our experiment starts from 20 mT. To see any effect of $e$-$e$ interaction at this field, we have to go to a temperature below 30 mK, according to the above condition. Consequently, the effect of $e$-$e$ interaction can be ruled out.

[17] A strong suppression of WL in graphene deposited on a SiO$_2$ substrate has recently been reported by Morozov et al. and attributed to corrugations of graphene sheets, which shift $K_{\pm}$ points. The shift $\Delta K$ is equivalent to a time reversal symmetry breaking gauge field, which suppresses WL. This curvature induced shift has been well studied in carbon nanotubes (Phys. Rev. Lett. 78, 1932 (1997)). For a graphene sheet with a curvature radius of $R$, $\Delta K = a_0/16R^2$, where $a_0$ is the bond length. For graphene: $v_F = 3a_\sigma g_0/2\hbar$, hence $\Delta K = \frac{3}{2} \frac{a_\sigma g_0}{h v_F}$. It is the same formula used by Morozov et al. where $a_0/R$ is replaced by $\nabla Z$. For a sample with a height fluctuation of order $h$ over a length $d$, $R \sim d^2/8h$, the gauge field $A = \hbar \Delta K e = 4\hbar a_\sigma h^2/ed^4$. The flux through the ripple $\Phi = \oint A \cdot dl$. This results in $\Phi_0 \sim 2a_0 h^2/\Phi_0$, where $\Phi_0$ is the flux quantum. In our sample, the angular dispersion of the normal to the graphene is 0.006. Even if $d \approx a_0$, the flux resulting from the distortion is
\( \Phi/\Phi_0 \sim 10^{-5} \), which produces a WL effect that is orders of magnitude too small to explain our data.
