Keywords:
lateral lumbar disc herniation, condoliase, intradiscal injection, conservative treatment

Spine Surg Relat Res 2021; 5(6): 437-441
dx.doi.org/10.22603/ssrr.2020-0127

Lateral lumbar disc herniation (LLDH) accounts for 7%-12% of all lumbar disc herniations1-3 and is more likely to occur in middle-aged to older adults4. It is typically resistant to conservative therapy and often requires surgery due to compression on the dorsal root ganglion of the exiting nerve root2.

An agent that induces chemical dissolution of the nucleus pulposus using condoliase (Hernicore4, Kaken Pharmaceutical Co.)5 was recently approved as a novel intradiscal treatment for LDH6,7. However, there is little information about its effectiveness in LLDH.

Case 1

A 77-year-old man with a history of unstable angina who was taking aspirin presented to our hospital complaining of one month of severe pain radiating to his left anterior thigh. The patient had a decreased left patellar tendon reflex. Manual muscle testing and sensations of the lower limbs were normal. The femoral nerve stretch test (FNST) was positive on the left. The Japanese Orthopaedic Association (JOA) score was 15/29.

In the sagittal section of the T1 weighted MRI, the left L3 nerve root was poorly visualized in the left L3/4 foramen due to a herniation (Fig. 1A). A horizontal section of T2 weighted MRI showed lateral disc herniation from inside to outside the left foramen at L3/4 (Fig. 1B). The degree of affected-disc degeneration was Grade IV, according to Pfirrmann classification8 (Fig. 1C). Standing radiography revealed that the L3/4 disc height was maintained (Fig. 1D). A CT after myelodiscography showed contrast media inflow to a left extraforaminal herniation at L3/4, but no intraforaminal or extraforaminal bony stenosis (Fig. 1E).

Due to the poor analgesic effect of oral drugs and selective nerve root blocks, we recommended surgery. However, the patient refused due to his heart condition and advanced age. Therefore, we injected 1.25 U condoliase (Fig. 2A). The pain improved within one week. One month after treatment, the patient did not need oral analgesics. An MRI three months after treatment showed the herniation had slightly decreased in size, and the left L3 nerve root was visualized (Fig. 2B, C). On standing radiography, the L3/4 disc height was slightly diminished (Fig. 2D). The JOA score had improved to 29/29 points.

Case 2

A 69-year-old man had lingering left lower extremity paralysis after the surgical resection of a middle thoracic intradural extramedullary tumor. He began experiencing radiating severe pain on the right anterior thigh three weeks after surgery. He was taking rivaroxaban for postoperative deep vein thrombosis. Although myelopathy was persistent, FNST was positive on the right. The JOA score was 14/29.

In the sagittal section of the T1 weighted MRI, the left L3 nerve root was poorly visualized in the left L3/4 fora-
Figure 1. Before treatment of Case 1.

In the sagittal section of the T1 weighted MRI, the left L3 nerve root was poorly visualized in the left L3/4 foramen due to a herniation (A, arrowhead). A horizontal section of T2 weighted MRI showed lateral disc herniation from inside to outside the left foramen at L3/4 (B, arrowhead). In the mid-sagittal section of a T2 weighted MRI, the degree of affected-disc degeneration was Grade IV, according to Pfirrmann classification (C, arrowhead). Standing radiography revealed that the L3/4 disc height was maintained (D, arrowhead). A CT after myelodiscography showed inflow of contrast media into a left extraforaminal herniation at L3/4, but no intraforaminal or extraforaminal bony stenosis (E, arrowhead).

men due to a herniation (Fig. 3A). In the horizontal section of the T2 weighted MRI showed right extraforaminal disc herniation with high signal intensity at L3/4 (Fig. 3B). The degree of affected-disc degeneration was Grade III, according to Pfirrmann classification (Fig. 3C). Standing radiography showed that the L3/4 disc height was maintained (Fig. 3D). A plain CT did not show osteophytes (Fig. 3E).

Due to the poor analgesic effect of oral drugs and selective nerve root blocks, the patient was unable to proceed with rehabilitation. Similar to case 1, 1.25 U condoliase was injected (Fig. 4A).

The pain had gradually decreased and had almost disappeared after 10 days. An MRI performed four months after treatment showed that the herniation had slightly decreased in size, and the right L3 nerve root could be visualized (Fig. 4B, C). On standing radiography, the L3/4 disc height was slightly diminished (Fig. 4D). The JOA score had improved to 21/29 points.

Condoliase injected into an intervertebral disc specifically dissolves glycosaminoglycans, which constitute proteoglycans, the main component of the nucleus pulposus. This restricts the proteoglycans’ water-holding capacity, reducing pressure inside the intervertebral disc, lowering the pressure on the nerve root from the hernia, and improving lower extremity and low back pain. A previous study observed significant analgesic effects, improved lumbar function, and improved quality of life compared to a placebo in cases of protrusion-type or subligamentous-type lumbar disc hernia-
In the prone position, a 12 cm spinal needle was inserted from the right-lateral side under fluoroscopy and advanced to the center of the L3/4 disc, where 1.25 U condoliase dissolved in 1.2 mL of physiological saline was injected (A). A lumbar MRI three months after treatment showed that the left extraforaminal herniation at L3/4 had slightly decreased in size in the horizontal section of a T2 weighted image (B, arrowhead) and the left L3 nerve root in the L3/4 foramen was visualized in sagittal section of T1 weighted image (C, arrowhead). On standing radiography, the L3/4 disc height was slightly diminished (D, arrowhead).

7) Another study concluded that condoliase injections seem to be most effective for transligamentous type and herniation with high signal change on the T2 weighted image9. They also indicated that there was no significant difference in affected-disc degeneration between efficacious and inefficacious group9.

This study is the first report on condoliase injections for LLDH. In both cases, conservative therapy with oral medications and selective nerve root block were not successful. However, intradiscal condoliase injections were effective, achieving an analgesic effect soon after treatment and allowing elderly patients to avoid surgery. In case 1, although the affected-disc degeneration had progressed, the disc height was maintained. Therefore, there seemed to be contained nucleus pulposus component in the herniated disc. In case 2, the disc herniation showed high signal change on the T2 weighted image, which is the better condition for condoliase injection therapy9.

Although more findings from large case series or comparative studies are needed, this report suggests that intradiscal condoliase injection could be a useful, novel conservative treatment option for LLDH.

Conflicts of Interest: The authors declare that there are no relevant conflicts of interest.

Sources of Funding: None.

Author Contributions: Toru Funayama wrote and prepared the manuscript, and all of the authors participated in the study design. All authors have read, reviewed, and approved the article.
