A *Catharanthus roseus* Fe(II)/α-ketoglutarate-dependent dioxygenase catalyzes a redox-neutral reaction responsible for vindolinine biosynthesis

Jasmine Ga May Eng¹, Mohammadamin Shamsavarani², Daniel Patrick Smith¹, Josef Hájíček³, Vincenzo De Luca⁴ & Yang Qu¹,²✉

The Madagascar’s periwinkle is the model plant for studies of plant specialized metabolism and monoterpenoid indole alkaloids (MIAs), and an important source for the anticancer medicine vinblastine. The elucidation of entire 28-step biosynthesis of vinblastine allowed further investigations for the formation of other remarkably complex bioactive MIAs. In this study, we describe the discovery and characterization of vindolinine synthase, a Fe(II)/α-ketoglutarate-dependent (Fe/2OG) dioxygenase, that diverts assembly of tabersonine to vinblastine toward the formation of three alternatively cyclized MIAs: 19S-vindolinine, 19R-vindolinine, and venalstonine. Vindolinine synthase catalyzes a highly unusual, redox-neutral reaction to form a radical from dehydrosecodine, which is further cyclized by hydrolase 2 to form the three MIA isomers. We further show the biosynthesis of vindolinine epimers from tabersonine using hydrolase 2 catalyzed reverse cycloaddition. While the occurrence of vindolinines is rare in nature, the more widely found venalstonine derivatives are likely formed from similar redox-neutral reactions by homologous Fe/2OG dioxygenases.
Monoterpenoid indole alkaloids (MIAs) are among the most complex and diverse alkaloids in nature with more than 3000 reported structures. These impressive natural products offer a vast array of bioactivities, exemplified by the anticancer drugs vindinastine and camptothecin, the anti-hypertensive ajmalicine, and the analgesic mitragynine. Among the MIA producing species, *Catharanthus roseus* (Madagascar’s periwinkle) has become the model plant for studying specialized MIA metabolism with extensive studies on the biochemistry, MIA pathway regulation, cellular compartmentation, and lately metabolic engineering of MIAs. Recently, the complete 28-step biosynthesis of vindinastine has been fully characterized, illustrating a remarkably complicated yet highly coordinated biosynthetic pathway and laying the foundation for the discovery of other medicinal MIA pathways and their engineering.

The formation of vindinastine requires coupling of the two most abundant *C. roseus* MIAs catharanthine (iboga type) and vindinastine (aspidosperma type) by a peroxidase. The spatial separation of these two MIAs is likely a reason for the low abundance of vinblastine in the plants. While the assembly of catharanthine and vindinastine has been fully elucidated, biosynthesis of the 3rd most abundant MIAs in *C. roseus*, namely vindolinines (19R) and its diastereomer epivindolinine (19S) (Fig. 1), have yet to be elucidated. In this study, we describe the discovery and characterization of vindolinine synthase (VNS), a Fe(II)/α-ketoglutarate-dependent (Fe/2OG) dioxygenase responsible for the formation of both epimers. Using the co-substrates α-ketoglutarate, O2, and the highly unstable intermediate dehydrosecodine generated by the dihydroprecondylocarpine acetate synthase (DPAS), or geissoschizine synthase (GS), VNS catalyzes an unusual, redox-neutral reaction to generate a radical intermediate that is further cyclized by *C. roseus* hydroxylase 2/tabersonine synthase (HL2/TabS) or hydrolase 4 (HL4) to generate the two diastereomeric vindolinines and a third isomer venalstonine that accumulate in various ratios in *C. roseus*. This discovery highlights the malleability and plasticity of MIA biosynthesis, one of the key drivers for the MIA diversity, and showcases the reaction versatility of Fe/2OG dioxygenases by presenting a rare, redox neutral reaction with respect to the MIA substrate and product formed.

**Results**

Vindolinines are the third most abundant MIAs in *C. roseus* leaves next to vindinastine and catharanthine. Previous results showed that MIAs are selectively extracted by dipping intact *C. roseus* leaves in chloroform followed by extracting the remaining MIAs by submerging leaves in methanol. This simple technique effectively extracted catharanthine, 19S-vindolinine, 19R-vindolinine, and perivine and ajmalicine in the chloroform, while most of the vindolinine, venalstonine (demethoxyvindolinine), and serpentine were extracted after submitting chloroform treated leaves with methanol. The identity of the two vindolinine epimers were confirmed by comparing to a commercial standard for 19R-vindolinine and Nuclear Magnetic Resonance (NMR) analyses of 19S-vindolinine purified from *C. roseus* leaf chloroform extract (Supplementary Fig. 1, Supplementary Table 1). The vindolinines are structurally related with the aspidosperma type MIA tabersonine, but differ by the addition of C2-C19 bridge and reduction of the C2-C16 double bonds (Fig. 1). They also differ from each other by the C19 stereochemistry, resulting in 0.4 ppm chemical shift difference for H18 (Supplementary Fig. 1). In addition to the two vindolinines, we were also able to detect and purify venalstonine from the same chloroform extract and confirmed its identity by NMR (Supplementary Fig. 2, Supplementary Table 1) and liquid chromatography-tandem mass spectrometry (LC-MS/MS) (Supplementary Fig. 3). Compared to the vindolinines, venalstonine instead contains a C2-C18 bridge that lacks a stereocenter on C18 or C19. The MS/MS product ion scans showed similar fragmentation patterns, as well as a signature daughter ion of mass 320 (loss of O2) unique to the vindolinine epimers and venalstonine (Supplementary Fig. 3). All three MIAs also showed typical UV absorption spectra as anticipated from a dihydroindole chromophore (Supplementary Fig. 3).

By extracting whole ground tissues with methanol, the major MIAs in *C. roseus* leaves and flowers were quantified using a number of standards in the plant variety “Little Delicata” and in another popular variety “Pacific White”. The results showed that while the vindolinine epimers were the third-most abundant MIAs in leaves of both varieties next to vindinastine and catharanthine, they were the most abundant MIAs in flowers of Little Delicata and the second most abundant after vindinastine/ vindorosine in flowers of Pacifica White (Supplementary Table 2).

![Fig. 1 The biosynthetic pathways from O-acetylstemmadenine for the three most abundant MIAs in *Catharanthus roseus* leaves: catharanthine, vindinastine, and vindolinine epimers (19R-vindolinine, 19S-vindolinine) as well as venalstonine. ASO: O-acetylstemmadenine oxidase, DPAS: dihydroprecondylocarpine acetate synthase, HL1: hydroxylase 1, HL2: hydroxylase 2, VNS: vindolinine synthase. HL1 and HL2 have also been named catharanthine synthase and tabersonine synthase, respectively.](image-url)
Identification of the Fe(II)/α-ketoglutarate-dependent dioxygenase VNS in C. roseus leaf epidermal transcriptome. The biosynthesis of MIAs in C. roseus leaves is largely located in the leaf epidermis. Loganic acid produced in the leaf internal phloem associated parenchyma (IPAP) cells is transported to the leaf epidermis, where it is further O-methylated and oxidatively cleaved to form the key iridoid secoligand. The secoligand is coupled to tryptamine, generated by decarboxylation of tryptophan, to form strictosidine, the central precursor to almost all 3,000 MIAs. A number of enzymes are responsible for converting strictosidine to two late intermediates catharanthine and tabersonine in the leaf epidermis, where the latter continues to be decorated to form desacetoxyvindoline before it is exported to leaf laticifers and idioblasts. The last two steps of vindoline formation in these two cell types requires an oxidation by desacetoxyvindoline 4-hydroxylase (D4H), the only known Fe/2OG dioxygenase in all MIA biosynthesis and 4-O-acetylation catalyzed by deacetylvinodline O-acetyltransferase (DAT).

The structural connection between vindolines and tabersonine and their presence in the leaf chloroform extract suggest the biosynthesis is likely located in leaf epidermis. The occurrence of vindolines is rare in nature and they are only reported in two other Apocynaceae species, Vinca erecta and Melodinus balansae. This suggests that the enzyme(s) involved must not be commonly shared among other MIA producing species. It is possible that the unstable dehydrosecodine intermediate generated during the ring-opening of O-acetylprecondylocarpane (OAP) required for the formation of tabersonine and catharanthine (Fig.1) may also be a precursor for the biosynthesis of vindolines. With this information, we searched genes from a Transcription PCR (qRT-PCR) supported that VNS expression EST numbers, a rough reassociation with previous studies. Speciﬁcally, we looked for genes that are unique to C. roseus and not found in three other MIA producing species Amsonia hubrichtii, Vinca minor and Tabernaemontana elegans that produce aspidosperma MIAs but not vindolines. This search resulted in the identification of a Fe/2OG dioxygenase VNS (Genbank OL677442) that is highly represented in the C. roseus leaf epidermis dataset (Expressed Sequence Tag (EST) number of 83) while showing no amino acid sequence identity of more than 50% to dioxygenases in the other three species. For comparison, other known epidermal vinblastine pathway enzymes secoligand synthase (SLS) and geissoschizine oxidase (GO) have relative EST numbers, a rough reflection of gene expression levels, of 54 and 38, respectively in this dataset. Quantitative Reverse Transcription PCR (qRT-PCR) supported that VNS expression is enriched in leaf epidermis total RNAs extracted by the carborundum abrasion technique compared to those from whole leaf tissues, which was also detected in all organs of C. roseus including flowers, roots, and stems (Supplementary Fig. 4).

Sequence alignment of VNS with other known Fe/2OG dioxygenases showed that VNS contains the HXDXH catalytic motif involved in α-ketoglutarate binding in these enzymes (Supplementary Fig. 4). In a phylogeny analysis, the mostly related gene is a Fe/2OG dioxygenase from Vinca minor with 48% amino acid identity (Supplementary Fig. 5).

Virus induced gene silencing (VIGS) confirmed VNS involvement in vindoline biosynthesis. Next, we performed VIGS experiments to investigate the in vivo VNS function in C. roseus. The leaves of VNS-silenced plants contained 95% lower levels of 19R- and 19S-vindoline compared to empty vector (EV) controls, as a result of silencing VNS transcript levels by 93% (Fig. 2a-c). A small reduction and increase of catharanthine and vindoline levels, respectively, were observed in VIGS plants compared to the EV controls (Fig. 2a). While these small changes may not be easily explained without further analyses, the drastic reduction of the vindoline levels strongly suggested that VNS is involved in 19S/R-vindoline production in planta.

Vindolines are formed from the same dehydrosecodine intermediate to the iboga and aspidosperma MIAs. To further investigate VNS function, we transiently expressed VNS and other MIA biosynthetic enzymes in Nicotiana benthamiana (tobacco) leaves, which provided required enzyme co-factors and facilitated multiplex gene expression studies. The substrate geissoschizine was produced as described previously, and O-acetylsomemanneline (OAS) was semi-puriﬁed from a C. roseus mutant of O-acetylsomemanneline oxidase (ASO), which accumulated almost exclusively OAS instead of catharanthine and vindoline. Transient expression of ASO, DPAS, and HL2 in tobacco and OAS substrate feeding led to the expected formation of tabersonine (Supplementary Figure 6). In these reactions, reduction of OAP leads to the simultaneous OAP deacetylation and the formation of the ring-opened dehydrosecodine, which is further cyclized by HL2 to form tabersonine as shown in previous studies. Next, the addition of VNS to the expression cocktail diverted the highly reactive dehydrosecodine intermediate towards the formation of 19R- and 19S-vindoline, since the transient expression of ASO, DPAS, VNS and HL2 in tobacco and OAS substrate feeding led to the formation of 19R- and 19S-vindoline instead of tabersonine (Supplementary Fig. 6). Surprisingly, a third product venalstonine formed in the feeding assays, which extended the VNS product spectrum. It is also worth noting that VNS activity was almost abolished when it was His-tagged at C-terminus (Supplementary Fig. 6).
Fig. 2 Vindolinine synthase (VNS) is responsible for the biosynthesis of 19 S/R-vindoline and venalstonine in vivo and in vitro. a Virus-induced gene silencing (VIGS) resulted in 95% reduction in the levels of the 19R-vindoline and 19S-vindoline in C. roseus leaf compared to the empty vector (EV) controls. b In the VIGS plants, the VNS transcripts were reduced by 93% compared to the EV controls. c Representative LC-MS chromatogram showing the reduction of vindoline 19-epimers in VIGS plants (m/z 337). d Tabersonine was biosynthesized when O-acetylprecondylocarpine (OAP) is incubated with dihydroprecondylocarpine acetate synthase (DPAS) plus Hydrolase 2 (HL2) recombinant enzymes. Addition of VNS to DPAS and HL2 recombinant enzymes converted OAP to 19R-vindoline, 19S-vindoline, and venalstonine at the expense of tabersonine. The following multiple reaction monitoring (MRM) ion transitions were used for detection: m/z 337->320 (vindoline 19-epimers and venalstonine); m/z 337->144 (catharanthine, vindoline 19-epimers, and venalstonine); m/z 337->168 (tabersonine). The alkaloid MS spectra used for selecting these parameters are found in Supplementary figure 3. In VIGS experiments, the data was generated by taking the mean values from 5 VIGS and 5 EV control plants. The error bars indicate the standard deviation. Unpaired two-tailed Student’s t-test was used for statistical analyses in VIGS experiments. For total vindolinine, the p value was 0.0001; for catharanthine, the p value was 0.0373; for vindoline, the p value was 0.0756; for ajmalicine, the p value was 0.110. The p value for relative VNS expression between EV and VIGS plants was 0.00007.

Table 1 Vindolinine synthase (VNS) requires both α-ketoglutarate and ascorbate for activity in vitro.

| α-ketoglutarate (mM) | Ascorbate (mM) | FeSO₄ (μM) | VNS pre-incubated with 2 μM FeSO₄ | Relative activity (%) |
|----------------------|----------------|------------|----------------------------------|----------------------|
| 0                    | 7.5            | 0          | YES                              | 0                    |
| 0.2                   |                |            |                                  | 104                  |
| 0.5                   |                |            |                                  | 100*                 |

*Standard reaction condition used in this study. Relative activity is defined as the relative amounts of vindoline epimers and venalstonine produced in other conditions when compared to the standard reaction in 19r reaction time.

venalstonine), which explains the rather equal production of the vindoline 19-epimers. Instead of hydroxylating C19, the VNS Fe(III)-OH center may abstract the hydroxyl from water to generate H₂O₂, while the hydrogen from water bonds to C16 (Fig. 9).

By replacing the H₂O in the reaction with D₂O, we observed the incorporation of one deuterium from D₂O into the vindolinines and venalstonine since the m/z values of these three (m/z 337) were all increased by 1 (m/z 338) (Fig. 3c, Supplementary Fig. 9). The rather high percentage (23%, Fig. 3c) of m/z 338 species in 100% H₂O reaction is likely caused by the low mass resolution (0.7 amu) of the LC-MS/MS instrument used in this study. In comparison, the mass of tabersonine (m/z 337) formed in D₂O solution remained unchanged (Supplementary Fig. 9), supporting the well-accepted cycloaddition mechanism and no involvement of water. To investigate the generation of H₂O₂ or •OH radical after VNS reaction since ascorbate is readily oxidized by these species to a number of products including the more stable threonate34. While ascorbate was spontaneously and rapidly oxidized to threonate in aerobic solution even without VNS, we observed a statistically significant increase of threonate formation in VNS catalyzed reactions (Supplementary Fig. 9), suggesting that ascorbate is the final electron donor in VNS reaction.

We further investigated the VNS reaction without the cyclase HL2, and two further reduced, isomeric (m/z 339) products were observed with only DPAS and VNS when reacted with OAP (Fig. 3d, Supplementary Fig. 10). To examine these two reduced
products, we hydrogenated the 14,15-double bonds of 19 S/R-vindolinines with palladium and H₂ and produced the 19 S/R-14,15-dihydropseudodine, which turned out to be identical with the enzymatically produced m/z 339 species in LC-MS/MS (Supplementary Fig. 10).

The VNS-catalyzed isomerization reaction is further investigated using the reverse reaction, specifically by reacting (-)-tabersonine and (-)-vincadifformine (14,15-dihydrotabersonine) with HL2 and VNS. The results showed that HL2 was able to catalyze the reverse reaction to produce the ring-opened secodine type intermediates (Fig. 3b, e, Supplementary Fig. 11). The highly reactive intermediate dehydropseudodine and secodine generated by HL2 were converted by the forward, VNS-HL2 mediated reaction to 19 S/R-vindolinines/venalstonine and 19 S/R-14,15-dihydropseudodine respectively using (-)-tabersonine and (-)-vincadifformine (Fig. 3e, Supplementary Fig. 11). These results also suggested that the VNS reaction does not involve an initial oxidation followed by an enzyme-mediated reduction, because no reductase was presented. In addition, VNS also accepted the indole-hydroxylated substrate 11-hydroxy-dehydrosecodine, since the reaction of 11-hydroxytabersonine with HL2 and VNS produced the 19 S/R-11-hydroxydehydrosecodine and 11-hydroxyvenalstonine with expected mass, although the enzymes instead showed a strong preference for producing the 19S-epimer.
(Supplementary Fig. 11). Using the same HL2/VNS reaction, no products were formed when the substrates were 19-hydroxyvincaflorimine (minovincine), 15-hydroxyvincaflorimine, or 14,15-epoxytabersonine (lochnerine). However, it is not clear whether these non-indole substitutions are not accepted by HL2 or VNS, since HL2 reverse reaction precedes that of VNS. Finally, we repeated the HL2-catalyzed reverse-cycloaddition reaction of (-)-tabersonine by including HL1 in the reaction mixture, which resulted in the conversion of (−)-tabersonine to catharanthine (Fig. 3b, Supplementary Fig. 11). Albeit barely detected by LC-MS/MS, we were able to convert trace amounts of catharanthine to vindoline epimers by reacting catharanthine with HL1, HL2, and VNS (Supplementary Fig. 11).

**Discussion**

Fe/2OG dioxygenases are a large family of oxidases found in all three kingdoms of life. Some are well known for their critical roles in primary metabolism such as proline hydroxylases involved in collagen modification, histone demethylases involved in gene activation, and the oxidases in the biosynthesis of plant hormone gibberellins. Several of them are also known in other specialized metabolism reactions, where oxidation and oxidative rearrangement is key to the diversification of chemical structures and their bioactivities. In these reactions, one oxygen atom of O₂ is inserted into the co-substrate α-ketoglutarate, and the other is usually inserted in the primary substrate resulting in a single hydroxylation. If the hydroxylation is on a carbon bound to a heteroatom (N/O), the hydroxylation usually leads to the demethylation/deacylation. In many cases, the Fe(III)-OH may also abstract a second hydrogen from an adjacent carbon/hydroxyl, and the resulting di-radical connect and form a double bond or a new ring on the substrate. Some Fe/2OG dioxygenases have further evolved to catalyze halogenation. In typical Fe/2OG dioxygenases, the iron is coordinated by a facial triad comprised of two histidines and an acidic Glu/Asp residue. However, in Fe/2OG halogenases, the acidic residue is replaced with an Ala/Gly residue, allowing the coordination of a large halogen anion, which results in substrate substitution with the halogen radical rather than the hydroxyl radical.

Among all known Fe/2OG dioxygenases with diverse activities, the redox-neutral reaction by VNS with respect to the substrate dehydrosecodine (C₂₁H₂₄N₂O₄) and the isomeric product vindolinines (C₂₁H₂₄N₂O₄) is highly unusual. There are only few redox-neutral reactions by Fe/2OG dioxygenases reported in nature. A well-studied example is the carbapenam synthase (CarC) catalyzed epimerization of (3S,5S)-carbapenam to (3S,5S)-carbapenam in the biosynthesis of several β-lactam antibiotics from the bacterium *Pectobacterium carotovorum*. Specifically, the Fe(IV) = O in CarC abstracts a hydrogen from the substrate, then a tyrosine residue of CarC donates a hydrogen to the radical on the opposite plane of the substrate leading to the epimerization. In CarC, the Fe(III)-OH is not reduced during the reaction, therefore the enzyme is limited to a single turnover. A second example is the AndA catalyzed rearrangement/epimerization in the biosynthesis of the triterpenoid Anditomin in the fungus *Aspergillus variecolor*. In this reaction, AndA generates a substrate radical, which triggers a set of ring re-arrangements and eventually forms andiconin, an isomer of the substrate pre-anilidol C. It is worth noting that both the bacterial CarC and the fungal AndA are able to catalyze a regular oxidation reaction in the same biosynthetic pathways using a different substrate, which in both cases forms a double bond.

In *C. roseus*, O-acetylstemonadine (OAS) is first oxidized to O-acetylprecondylocarpine (OAP). The following NADPH-dependent reduction leads to spontaneous deacetylation and ring-opening, forming dehydrosecodine and its iminium, which are cyclized by a number of α/β-hydrolases into various MIA skeletons (Fig. 1)⁵,⁶,⁷,30,31. VNS is not active against OAP or tabersonine. It is only active when OAP is reduced by DPAS or when tabersonine is reversely converted by HL2. This evidence suggest that the VNS substrate is most likely dehydrosecodine. When dehydrosecodine is cyclized directly by HL2, it forms the isomeric tabersonine as all studies have suggested so far. VNS reaction instead diverted this conversion to produce three isomeric, alternatively cyclized products without oxidation. VNS showed typical Fe/2OG dioxygenases motifs and does strictly require a-ketoglutarate, the co-substrate that receives an oxygen atom from splitting of O₂ in all known cases. It is surprising that the other oxygen atom is not incorporated in any MIA products, nor have the MIA products been oxidized in any way or lost a carbon because of this oxidation.

In the reverse reaction catalyzed by HL2 and VNS, vindolinines and venalstonine were formed without any reductase. The results suggest that VNS does not oxidize the MIA substrate, which is similar to the reactions catalyzed by CarC and AndA. A possible explanation for the destiny of the other oxygen atom of O₂ is that it is used to oxidize water to H₂O₂, which is reduced by ascorbate to generate threonate and water⁶. This is supported by the incorporation of a deuterium in the vindoline epimers and venalstonine from D₂O. It is also possible that ascorbate instead is oxidized by VNS’s Fe(III)-OH to form dehydroascorbate, which spontaneously continues to be hydrolysed and oxidized to threonate. In this process, ascorbate donates a hydrogen to C16 of the vindoline epimers and venalstonine, and a second hydrogen to Fe(III)-OH, which reduces it to Fe(II)-H₂O. Since ascorbate is in constant exchange of protons with water, this hypothesis can also explain the incorporation of a deuterium from D₂O. The absolute requirement of ascorbate in VNS reaction also supports this hypothesis. In both scenarios, ascorbate acts as the final electron donor and reductant, which is supported by the small but statistically significant increase of threonate production when VNS was involved (Supplementary Fig. 9). Nonetheless, the role of ascorbate in many other Fe/2OG dioxygenase reactions remains unclear, and we cannot rule out other possible reaction mechanisms.

It is interesting to observe the spontaneous cyclization of VNS product in the absence of the cyclase HL2. In this case, the 14,15-double bond is further reduced by DPAS activity to form 14,15-dihydrovindolinines. This agrees with the previous observation that dehydrosecodine iminium spontaneously cyclizes and gets reduced to vindacidiflorimine in the absence of a hydrolase. The formation of 14,15-dihydrovindolinines is therefore explained.

The vindoline epimers are the third most abundant MIA in *C. roseus*, the model plants for plant specialized metabolism, after catharanthine and vindoline. Silencing VNS in *C. roseus* resulted in more than 95% reduction of vindolinines, which is a strong support for its role in planta. Vindolinines are only reported in three MIA producing species, *C. roseus*, *Vinca erecta* and *Melodinus balansae*. There are no publicly available transcripts of the latter two species, but we suspect that similar dioxygenases may be responsible for vindoline biosynthesis in them. By searching in the National Center for Biotechnology Information (NCBI) total nonredundant protein database and the several sequenced transcripts of MIA producing species that have not been reported for vindolinines, we could not find a VNS homolog of more than 50% amino acid identity, which suggest that VNS evolved specifically within a few genera of Apocynaceae family. A further genomc investigation may answer whether other Apocynaceae plants encode a VNS homolog in the genome, which is likely not expressed or expressed with low levels in the plants due to the absence of vindolinines. Compared to the
restricted distribution of 19R- and 19S-vindoline, derivatives of venalstonine are found in many more Apocenaceae species including the genera of Kopsia, Melodinus, Pleiocarpa, Aspidosperma, and Alstonia. Based on VNS’s ability to produce small amounts of venalstonine, it is possible that the biosynthesis of more widespread venalstonine derivatives involves similar Fe/2O2 dioxygenases that catalyze this unusual, redox-neutral isoperoxidation. VNSs were harvested from TLC. Venalstonine (Rf 0.61) contaminated with vindoline was afforded total alkaloids. The alkaloids were separated by thin layer chromatography using N-acetyl-2-amino-4-one (NLCS, silica gel 60 G F254, Sigma Aldrich) and the solvent ethyl acetate: methanol 4:1 (v/v). The 19-vindoline (1 mg, Rf 0.32) and 19-vindoline (1 mg, Rf 0.36) were harvested from TLC. Venalstonine (Rf 0.61) contaminated with vindoline was further separated by TLC with pure methanol, which afforded less than 0.1 mg venalstonine (Rf 0.43). The remaining MIA standards used in this study were described previously5,6,39.

NMR and LC-MS/MS. The NMR spectra was recorded using a Varian Unity 400 MHz spectrometer with CDCl3, referenced at 7.26 ppm or acetone (6.39 ppm). The reference spectra of venalstonine were kindly provided by Prof. Kam Toh Seok at the University of Malaya, Malaysia to help identify venalstonine of low sensitivity. The 19-vindoline (1 mg, Rf 0.36) was harvested from TLC. Venalstonine (Rf 0.61) contaminated with vindoline was further separated by TLC with pure methanol, which afforded less than 0.1 mg venalstonine (Rf 0.43). The remaining MIA standards used in this study were described previously5,6,39.

Gene cloning. VNS was amplified from C. roseus total cDNA with primers set 1/ (1/3) and 2/ (1/3). The PCR reactions generated VNS gene fragments with and without a stop codon, which is cloned into the tobacco expression vectors pEAAQ-HT-DEST2 and -DEST3 for expression with a N-terminal Histag and a C-terminal Histag by virus- mediated transformation of Agrobacterium tumefaciens (strain GV3101).

Tobacco transient expression of multiple genes. The tobacco transient expression experiments were performed as previously described6. Overnight culture (28 °C) of A. tumefaciens (strain LBA4404) cells harboring various pEAQ-HT-DEST vectors were harvested by centrifugation and resuspended in infiltration buffer (10 mM MES pH 5.6, 10 mM MgCl2, 0.2 mM acetylsyringone) to OD600 = 1.5, which was cultured at 28 °C for 2.5 h. The suspensions for expressing different genes were mixed in equal volume and infiltrated to Nicotiana benthamiana leaves with a syringe. The tobacco plants were cultivated in a greenhouse at 26 °C (16/8 h photoperiod) for four days for protein expression and leaves were then infiltrated with 5–10 μg of alkaloid substrates in 10 mM Tris-HCl buffer at pH 8.0 and left overnight. The leaves were extracted with methanol, and the extracts were used for LC-MS/MS analyses.

Purification of recombinant VNS from E. coli. Overnight culture of E. coli strain BL21-DE3 harboring pET30b–VNS construct was used to inoculate 400 ml LB media shaking at 37 °C. When the culture OD600 reached 0.3, the cells were induced with 1 mM IPTG at 37 °C for 2.5 h. The pelletled cells were sonicated in ice cold buffer (Tris HCl pH 7.5, 100 mM NaCl, 1% (w/v) gycerol), and the soluble protein fraction obtained by centrifugation at 10,000 × g for 1 h at 4 °C. VNS with N-terminal 6×HisTag was affinity purified by binding to a Ni-NTA resin and pure VNS was eluted with 250 mM imidazole in the same buffer. Finally, the proteins were desalted to remove imidazole using a PD10 column (GE Health Sciences) into the same buffer and stored at −80 °C.

In vitro assay. A typical in vitro assay (100 μL) included 50 mM HEPES buffer pH 7.5, 1 mM NADPH, 0.5 mM a-ketoglutarate, 7.5 mM ascorbate, 5 μg O-acetyl-ylprecondylocarpine (OAP) or other alkaloid substrates, and 2 μg each enzyme (DPAS, VNS, Hs). For GS, 50 μg proteins were used instead. FeSO4 (2–10 μM) may be used. The reaction was started at 30 °C for 1 h, and stopped by adding equal volume of methanol. The reactions were further analyzed by LC-MS/MS. For all hydrolases-catalyzed reversed reactions, the reaction took place at 30 °C overnight. For reactions to determine threonate productions, the reactions (50 μL) included 20 mM Tris-HCl buffer pH 7.5, 1 mM NADPH, 0.5 mM a-ketoglutarate, 0.5 mM ascorbate, 5 μg O-acetyl-ylprecondylocarpine (OAP), 1 μg DPAS, 5 μg VNS, and 2 μg Hs. The reactions were started by adding DPAS and took place at 30 °C for 30 min, then they were terminated by mixing with 200 μL 75% (v/v) methanol.

Vindoline hydrogenation. The purified 19S- and 19R-vindolines (0.2 mg) were dissolved separately in 1 ml methanol in a small sample vial with trace amount of H2 to shield from light. The 19S-vindoline was added with solid Pd on C (Sigma Aldrich) loading 10 wt% with 10% H2 in Ar. The reaction was stirred at room temperature overnight under H2 to afford the 14,15-dihydro-vindoline 19-epimers, respectively.
Data availability

The raw data for Fig. 3 a, b, Supplementary Fig. 4, 9 e, and Supplementary table 2 are provided in the source data file. MS/MS and UV absorption data are provided in Supplementary fig.3. NMR data are provided in Supplementary fig. 1 and 2, and Supplementary table 1. Other data in this study are available from the corresponding author upon request. Source data are provided with this paper.
