(March 25, 2022)

We introduce an integrated algorithm for full scale investigation of the earth regeneration effect of solar neutrinos with all three active neutrinos. We illustrate that the earth effect on low energy solar neutrinos \((E_\nu < 20 \text{ MeV})\) causes large variations in the survival probabilities for large values of the mixing angle \(\theta_{12}\) for a given value of \(\theta_{13}\). But it is maximal for small values of \(\theta_{13}\) and diminishes for large values at a given value of \(\theta_{12}\). The nadir angle dependence is sensitive to the value of \(E' \equiv E/\Delta_{12}\). As far as low energy solar neutrinos are concerned we notice that the earth effect is more pronounced for core penetration. We confirm that the earth effect leaves the SMA region almost intact regardless of \(\theta_{13}\) and that it is significant for high energy \(^8\text{B}\) and \(\text{hep}\) neutrinos in the LMA region. We also show that for large values of \(\theta_{13}\), the earth effect is significant for high energy neutrinos \((E' \gtrsim 10^9)\) and it can be large at any nadir angle.

I. INTRODUCTION

Neutrinos are produced abundantly from thermonuclear reactions taking place in the stellar core. They carry away most of the energy during the supernova explosion. Due to the extreme weakness of its interaction it escapes its cradle almost intact and provides us with most reliable clues to the internal physical environments of a star. Thus neutrino astronomy has been established as an important research field recently. The Standard Solar model (SSM) predicts the flux of the electron neutrino. The historic Homestake experiment \(^4\) for detecting solar neutrinos revealed the detected neutrinos fall far short of the SSM prediction.

Several mechanisms were proposed for the depletion of solar neutrinos. Pontecorvo \(^5\) proposed the idea of neutrino flavor oscillation earlier than any unification theories \(^6\). (see ref. \(^7\) for an interesting review). The possibility of solar neutrino flux reduction by vacuum oscillation was investigated earlier \(^8,9\). Subsequent experiments \(^10\) revealed that the solar neutrino deficit depends on the energy of the neutrino. Recently the idea of flavor oscillation combined with the Mikheyev-Smirnov-Wolfenstein (MSW) effect \(^14,15\) has been most popular. The MSW equations have been vigorously studied. For simple matter densities, some authors \(^16\) derived accurate analytic solutions for the two-neutrino MSW evolution equations. These solutions have been used for computing the neutrino survival probabilities with the approximation of the solar matter density by a mosaic of exponential functions. Direct numerical analysis was carried out also \(^21\). Two-flavor MSW solutions to the solar neutrino puzzle were fully analysed with high accuracy, including both the day/night effect and spectral information \(^22,23\).

Recent Super-Kamiokande experiment \(^24\) shows an evidence for oscillations of the atmospheric neutrinos \(^25,26\). The data are in good agreement with two-flavor \(\nu_\mu \leftrightarrow \nu_\tau\) oscillations. These results did establish that neutrinos oscillate and possess non-zero masses. Thus full three-flavor neutrino oscillation analysis is needed for more accurate estimation of neutrino masses and mixing angles. Even four neutrino solutions with the sterile neutrino have been suggested \(^29,30\).

It has been argued \(^23,25\) that under certain conditions the solution of the solar neutrino evolution equation in the two neutrino case can be extended to the three neutrino case with a slight modification. There have been many analytic works on three-flavor MSW solutions of the solar neutrino problem with simple linear and exponential matter densities \(^33,34\). Most three-flavor MSW fits to the solar neutrino experiments have been made within the above framework \(^34,41\). Recently exact solutions to the three neutrino MSW equations for such simple matter densities were derived \(^14,33\). Direct numerical analysis is always desirable but it has been hampered by the huge computational costs. Recently we presented an efficient numerical algorithm for direct computation of the solar neutrino survival probability with all three active neutrinos \(^49,50\).

* e-mail: jsk@postech.ac.kr
According to the PREM model [51], the earth consists of 10 layers of different matter densities and compositions. The PREM model gives the matter density in each earth layer as a polynomial in radius. It is around $\rho \sim 1.6 \sim 6.1$ mol/cm$^3$. In such matter densities, the MSW effect can be significant for neutrinos with certain energies. The earth regeneration effect for solar neutrinos was numerically analysed by many people within the two-flavor framework [2] [3]. Since numerical analysis takes a lot of computing time a few attempts to derive analytic formula were made. Approximating the matter density in each of the five simplified earth layers as an even degree quartic polynomial in radius, Lisi and Montanino [64] derived analytic solutions for the two-neutrino MSW equations. Other attempts were made for three neutrino MSW equations with a periodic step-function density profile [12] and with constant matter densities [60]. However, to the best of our knowledge, there are no direct numerical works on the earth regeneration effect for solar neutrinos was numerically analysed by many people within the two-flavor framework [52–63].

In this paper we present an integrated algorithm for analyzing the earth regeneration effect of solar neutrinos with all three active neutrinos considered. Integration of neutrino evolution equations can be done with any ordinary differential equation solver such as adaptive Runge-Kutta or Bulirsch-Stoer methods (see, e.g. [67]). The wavefunction of a neutrino passing through the earth oscillates rapidly with large amplitudes in certain ranges of energy and mixing parameters. The crux of the problem is how to take time averages out of these wildly oscillating wavefunctions. Two methods have been used in the two neutrino case. Baltz and Weneser [54] carefully analyzed the oscillatory behavior of the survival probabilities and derived a formula that uses instantaneous values of the two particular wavefunctions. Exploiting the symmetry of the transition probabilities, Smirnov [59] derived a formula that uses only one transition probability, $P(\nu_2 \to \nu_\alpha)$. Due to economy of the Smirnov’s formula it has been widely used. However, we could not extend the formula to the three neutrino case. There is no shortcut in this case and we need to integrate the evolution equation for three different initial conditions, we realized. We introduce a method to obtain time averages of survival probabilities of solar neutrinos after passing through the earth in the three neutrino case. Our method is numerical and thus quite general and can be used with any number of flavors.

This paper is organized as follows: In section 2 we review the basic formalism very briefly. In section 3 we introduce our method for taking averages of neutrino fluxes as they pass through the earth core. In section 4 we illustrate the complexity of the earth effect occurring at large mixing angles. We illustrate how it depends on neutrino energies, the mixing parameters, and the nadir angles. In section 5 we present how to make long term averages such as daily averages in different seasons and monthly and yearly averages. In section 6 we present sample contour plots for an interesting set of parameters.

II. BASIC FORMALISM

The state of a neutrino can be expressed either in the weak eigenstate basis $|\nu_\alpha\rangle$ or in the mass eigenstate basis $|\nu_i\rangle$. The unitary matrix $U$ transforms the mass eigenstates into the weak eigenstates,

$$\nu_\alpha = \sum_{i=1}^{3} U_{\alpha i} \nu_i, \quad \alpha = e, \mu, \tau. \quad (1)$$

The Particle Data Group [68] adopts the convention for the mixing matrix,

$$U = \begin{pmatrix} C_1 C_3 & S_1 C_3 & S_3 \\ -S_1 C_2 - C_1 S_3 S_2 & C_1 C_2 - S_1 S_3 S_2 & C_2 S_3 \\ S_1 S_2 - C_1 S_3 C_2 & -C_1 S_2 - S_1 S_3 C_2 & C_3 C_2 \end{pmatrix}, \quad (2)$$

where $C_i \equiv \cos \theta_i$ and $S_i \equiv \sin \theta_i$ and the three mixing angles $\theta_1 = \theta_{12}$, $\theta_2 = \theta_{23}$, and $\theta_3 = \theta_{13}$ roughly measure mixing between mass eigenstates (1-2), (2-3), and (1-3) respectively. We have neglected the CP violating phase, which is irrelevant in this problem.

It is convenient to express the state of a neutrino as a mixture of three active neutrinos in the weak eigenstate basis,

$$\Phi(t) = a_e |\nu_e\rangle + a_\mu |\nu_\mu\rangle + a_\tau |\nu_\tau\rangle. \quad (3)$$

The mass matrix is non-diagonal in the weak eigenstate basis. It is obtained from the diagonal mass matrix,

$$M_{ij} = \sum_k U_{ik}^\dagger m_k^2 U_{kj}. \quad (4)$$

The wavefunctions $a_\alpha(t)$ of a neutrino in a medium obey the evolution equations,
Then the state of a solar neutrino in a mixed state with probabilities, \( a_e(t) \), \( a_\mu(t) \), \( a_\tau(t) \), they pass through the earth for a given set of parameters, \( \Delta E \), three pure states, \( \Psi_e, \Psi_\mu, \Psi_\tau \), especially checked our results against those of \([66]\) and found good agreements. (see Fig. 1a). It would be extremely time-consuming to trace all these neutrinos individually as they pass through the earth. Instead we trace how three pure neutrinos, \( \Psi_e(t = 0) = (1, 0, 0, 0, 0, 0) \), \( \Psi_\mu(t = 0) = (0, 0, 1, 0, 0, 0) \) and \( \Psi_\tau(t = 0) = (0, 0, 0, 0, 1, 0) \) evolve as they pass through the earth for a given set of parameters, \( \Delta_{12}, \Delta_{23}, \theta_{12}, \theta_{13}, \theta_{23} \). We compile the wavefunctions for selected values of the energy \( E \) and the zenith angle \( \eta \). Then we set up a handy interpolation function to be used for computing the neutrino fluxes arriving at various experiments in any given period of time.

Let us denote the states of pure neutrinos after passing through the earth as,

\[
\begin{align*}
\Psi_e(t) &= a_e(t)|\nu_e\rangle + a_\mu(t)|\nu_\mu\rangle + a_\tau(t)|\nu_\tau\rangle, \\
\Psi_\mu(t) &= \beta_e(t)|\nu_e\rangle + \beta_\mu(t)|\nu_\mu\rangle + \beta_\tau(t)|\nu_\tau\rangle, \\
\Psi_\tau(t) &= \gamma_e(t)|\nu_e\rangle + \gamma_\mu(t)|\nu_\mu\rangle + \gamma_\tau(t)|\nu_\tau\rangle.
\end{align*}
\]

Then the state of a solar neutrino in a mixed state with probabilities, \( X_e^2, X_\mu^2, X_\tau^2 \) can be written as a linear sum of three pure states,

\[
\Psi_{SE}(t) = X_e \exp(i\phi_1)\Psi_e(t) + X_\mu \exp(i\phi_2)\Psi_\mu(t) + X_\tau\Psi_\tau(t),
\]

where we assumed some phases for solar neutrinos while keeping the phase of the \( \tau \) neutrino zero.

Let us denote the state of a solar neutrino arriving at the earth as,

\[
\Psi_S(t = 0) \equiv a_e|\nu_e\rangle + a_\mu|\nu_\mu\rangle + a_\tau|\nu_\tau\rangle.
\]

Then the probability of a solar neutrino to emerge as an electron neutrino after passing through the earth is written as

\[
P_{SE} = |\langle \nu_e|\Psi_{SE}\rangle|^2 = |a_e a_\alpha e + a_\mu a_\beta e + a_\tau a_\gamma e|^2
\]

\[
= |a_e|^2|a_\alpha e|^2 + |a_\mu|^2|a_\beta e|^2 + |a_\tau|^2|a_\gamma e|^2
\]

\[
+ [a_e a_\alpha e a_\mu^* a_\beta e + \text{c.c.}] + [a_\mu a_\beta e a_\tau^* a_\gamma e + \text{c.c.}] + [a_\tau a_\gamma e a_\alpha e a_\beta e + \text{c.c.}].
\]

In order to obtain the time average of \( P_{SE}(t) \) it is more convenient to use the mass eigenstate basis. Let us denote

\[
\begin{align*}
\Psi_{SE}(t) &= X_0 \exp(i\phi_1)\Psi_e(t) + X_1 \exp(i\phi_2)\Psi_\mu(t) + X_2\Psi_\tau(t), \\
\Psi_{SE}(t) &= X_0 \exp(i\phi_1)\Psi_e(t) + X_1 \exp(i\phi_2)\Psi_\mu(t) + X_2\Psi_\tau(t),
\end{align*}
\]
\[ \alpha_e(t) = s_1 e^{i \omega_1 t} + s_2 e^{i \omega_2 t} + s_3 e^{i \omega_3 t}, \]  
\[ \beta_e(t) = t_1 e^{i \omega_1 t} + t_2 e^{i \omega_2 t} + t_3 e^{i \omega_3 t}, \]  
\[ \gamma_e(t) = u_1 e^{i \omega_1 t} + u_2 e^{i \omega_2 t} + u_3 e^{i \omega_3 t}, \]

where \( s_i, t_i, u_i \) are independent of time. Then we have

\[ \alpha_e \alpha_e^* = s_1 s_1^* + s_2 s_2^* + s_3 s_3^* + \text{cross terms}, \]  
\[ \alpha_e \beta_e^* = s_1 t_1^* + s_2 t_2^* + s_3 t_3^* + \text{cross terms} \]

\[ = (s_1 R t_1 R + s_1 t_1 l) + i(s_1 l t_1 R - s_1 R t_1 l) + (s_2 R t_2 R + s_2 l t_2 l) + i(s_2 l t_2 R - s_2 R t_2 l) \]

\[ + (s_3 R t_3 R + s_3 l t_3 l) + i(s_3 l t_3 R - s_3 R t_3 l) + \text{cross terms} \]

\[ \equiv R_{\alpha \beta} + i I_{\alpha \beta} + \text{cross terms}, \]

where

\[ R_{\alpha \beta} = (s_1 R t_1 R + s_1 t_1 l) + (s_2 R t_2 R + s_2 l t_2 l) + (s_3 R t_3 R + s_3 l t_3 l), \]

\[ I_{\alpha \beta} = (s_1 l t_1 R - s_1 R t_1 l) + (s_2 l t_2 R - s_2 R t_2 l) + (s_3 l t_3 R - s_3 R t_3 l). \]

The cross terms cancel out upon time averaging.

It is convenient to express the amplitudes \( (a_e, a_{\mu}, a_\tau) \) in the weak eigenstate basis in terms of those in the mass eigenstate basis, \( (a_1, a_2, a_3) \),

\[ a_e(t) = U_{11} a_1(t) + U_{12} a_2(t) + U_{13} a_3(t), \]

\[ a_{\mu}(t) = U_{21} a_1(t) + U_{22} a_2(t) + U_{23} a_3(t), \]

\[ a_\tau(t) = U_{31} a_1(t) + U_{32} a_2(t) + U_{33} a_3(t). \]

Averaging over time, we obtain

\[ X_e^2 = \langle a_e a_e^* \rangle = U_{11}^2 |a_1|^2 + U_{12}^2 |a_2|^2 + U_{13}^2 |a_3|^2, \ldots. \]

We solve this equation for \( |a_i|^2 \). Then we can express \( \langle a_e a_{\mu}^* \rangle \) in terms of \( |a_i|^2 \). Let us denote

\[ \langle a_e a_{\mu}^* \rangle = U_{11} U_{21} a_1 a_1^* + U_{12} U_{22} a_2 a_2^* + U_{13} U_{23} a_3 a_3^* \equiv X_{e\mu} + i Y_{e\mu}. \]

We notice that the phases of \( a_i \) become irrelevant upon time-averaging. Now we get the time average

\[ \langle a_e a_\mu^* a_\mu^* + \text{c.c.} \rangle = \langle (R_{\alpha \beta} + i I_{\alpha \beta}) (X_{e\mu} + i Y_{e\mu}) + \text{c.c.} \rangle = 2(R_{\alpha \beta} X_{e\mu} - I_{\alpha \beta} Y_{e\mu}). \]

Similarly working on other terms and collecting all terms, we obtain the time averaged probability of a solar neutrino to emerge as an electron neutrino after passing the earth,

\[ \langle P_{SE} \rangle = |a_e|^2 |a_\mu|^2 + |a_\mu|^2 |a_\tau|^2 + |a_e|^2 |a_\tau|^2 + 2(R_{\alpha \beta} X_{e\mu} - I_{\alpha \beta} Y_{e\mu} + R_{\beta \gamma} X_{\mu\tau} - I_{\beta \gamma} Y_{\mu\tau} + R_{\gamma \alpha} X_{\tau\epsilon} - I_{\gamma \alpha} Y_{\tau\epsilon}). \]

In order to check our algorithm we reproduced some figures published in the literatures [14, 64] in the limit \( \theta_{13} \to 0 \) (see Fig. 1). Our figures agree with the results as illustrated in Fig. 4 of [14] in the range \( E < 10^8 \). Our figures completely agree with the results obtained by using the time averaged \( P_{SE} \langle \nu_2 \to \nu_e \rangle \) in Eqn. (1) of [14].

IV. SURVIVAL PROBABILITIES OF A SOLAR NEUTRINO WITH NON-ZERO \( \theta_{13} \)

We consider the effects of non-zero \( \theta_{13} \) on the electron neutrino survival probabilities of an electron neutrino created at the center of the Sun as a function of \( E' \equiv E/\Delta_{12} \) in MeV/eV². We illustrate two cases in Figs. 2. In Fig. 2a we consider the Small Mixing Angle (SMA) case using the set of parameter values, \( \sin^2(2\theta_{12}) = 4.40 \times 10^{-3}, \Delta_{12} = 6.31 \times 10^{-6} \text{ eV}^2 \). It consists of 3 plots corresponding to \( \theta_{13} = 5^\circ, 22.5^\circ, 45^\circ \). Fig. 2b corresponds to the Large Mixing Angle (LMA) case and \( \sin^2(2\theta_{12}) = 0.76, \Delta_{12} = 1.8 \times 10^{-5} \text{ eV}^2 \) was used. The upper limit of solar
neutrino energy, 20 MeV is indicated by the downward arrow. Each plot contains a curve for raw solar neutrino flux and five curves marked by Sn corresponding to five neutrino paths with nadir angles \( \eta = (m/10)(\pi/2) \).

Neutrinos undergo resonance conspicuously in those regions where the curves oscillate widely away from the raw curve. We notice that for nonzero values of the (1-3) mixing angle \( \theta_{13} \) double resonances occur, one in the range \( 10^6 \leq E' \leq 10^7 \) and the other in \( 10^8 \leq E' \leq 10^{10} \). The resonance in the low range is caused by non-zero \( \theta_{13} \) and its amplitude grows larger for large \( \theta_{12} \). The resonance in the high range is due to non-zero \( \theta_{13} \) and it is enhanced for large \( \theta_{13} \). The resonances occur for all nadir angles with almost equal strengths. It is noteworthy that for low energy solar neutrinos the earth effect is larger for smaller values of the nadir angle.

Fig. 2a reveals that in the SMA case the earth effect for low energy solar neutrinos \( (E < 20 \text{ MeV}) \) is minor for all values of \( \theta_{13} \). Fig. 2b exhibits that in the LMA case the earth effect is non-trivial for some high energy \( ^7\text{Be} \) and hep solar neutrinos. It is most significant for small values of \( \theta_{13} \) and diminishes for large \( \theta_{13} \).

Since it costs a lot of computation to trace neutrinos for each nadir angle we need to make a strategy for handling the angular effect. We exploit that for a given set of parameters, the neutrino wavefunctions are smooth functions of the nadir angle \( \eta \). We thus compute at a finite number of angles and then build an interpolation function. For the nadir angle, we choose \( \cos(\eta) \) as the sampling function. Thus we sample more frequently near \( \eta = 0 \) and scarcely near \( \eta = \pi/2 \). We selected 25 nadir angles between 0 and \( \pi/2 \). For low energy solar neutrinos the earth effect diminishes for \( \eta > \eta_c = 0.5779 \), the nadir angle grazing the boundary between the core and the mantle. Thus our sampling strategy works fine. An interpolation function made from these 25 \( \eta \) values will be fairly accurate to use.

We can now compute the states of pure neutrinos, \( \Psi_{\nu_e}(t), \Psi_{\mu}(t), \Psi_{\tau}(t) \) at discrete energies and nadir angles selected according to the importance sampling functions. In our previous works on solar neutrino flux \(^{14}\), we selected energy sampling points according to the convolution of the neutrino energy distribution functions as they are created in the solar core and the detector cross sections. In the present work we added 7 more energy sample points in the interval \( 0.23 \leq E \leq 0.737 \) MeV to account for the CNO neutrinos more faithfully.

V. LONG TERM AVERAGES: DAILY, MONTHLY AND YEARLY AVERAGES

We have compiled a large amount of raw solar neutrino fluxes for a reasonably large area in the parameter space, \((\Delta_{12}, \sin^2(2\theta_{12}))\) for selected values of \( \theta_{13} \), using the method described in \(^{19}\). Our results were partially reported without the earth effect in \(^{15}\). The results of our computations in the \( \theta_{13} \to 0 \) limit have been carefully checked against the results obtained with the analytic approximation formula such as the Petcov’s improved formula \(^{15}\). We agree with their results in the range of creation positions where their results are reliable as they claimed, in the sense that their formula give the flux values averaged over the creation positions whereas ours give the fluxes created at exact positions as illustrated in Fig. 5 of Ref. \(^{46}\). We also compared the survival probabilities of a neutrino created at the center of the Sun in the range of \( E' \) for various sets of mixing parameters. The agreement is to one part in 1000 in the worst case. Since our results are computed numerically we have equally accurate fluxes beyond their claimed range. For three neutrino cases, analytic formula for survival probabilities for simple densities have been derived only recently \(^{48}\). We have already confirmed that our subroutines reproduce the same results as those given in \(^{48}\).

Next we compute seasonal variations of daily averages. The nadir angle \( \eta \) of a neutrino path can be written \(^{64}\) as a function of the date of year \( \tau_d \) from the winter solstice, the time of day \( \tau_h \) from the midnight and the latitude \( \lambda \) as follows,

\[
\cos(\eta) = \cos(\lambda) \cos(\tau_h) \cos(\delta_S) - \sin(\lambda) \sin(\delta_S)
\]

where the Sun declination is given by \( \sin(\delta_S) = -\sin(i_E) \cos(\tau_d) \) and \( i_E = 0.4091 \) is the earth inclination.

We illustrate the survival probabilities for two interesting parameter sets in Figs. 3. The average was taken over every 12 minutes for 24 hours on three days, the winter solstice (dotted), the vernal equinox (dash-dotted) and the summer solstice (dashed). The raw solar neutrino flux is plotted with the solid curve. The latitude of Gran Sasso was used. The downward arrows mark the point of \( E = 20 \text{ MeV} \), the upper bound of the solar neutrino energy. Each set consists of 4 plots corresponding to \( \theta_{13} = 0^\circ, 1.5^\circ, 15^\circ, 22.5^\circ \). As we notice from Fig. 3a, in the small mixing angle case the electron neutrino survival probability is almost unaffected by the earth effect as in the two neutrino case, regardless of \( \theta_{13} \). Fig. 3b shows that in the large mixing angle case (we used \( \sin^2(2\theta_{12}) = 0.63, \Delta_{12} = 1.3 \times 10^{-5} \text{ eV}^2 \) in Fig. 3b) the earth effect is non-negligible for high energy neutrinos. The effect is maximal for \( \theta_{13} = 0 \) and diminishes as \( \theta_{13} \) is increased.

We are now equipped with all the routines that are needed to compute average fluxes in an extended period of time. Since we used the importance sampling method for selecting reasonably large number of creation positions and energies to set up an interpolation function that is particularly good in the important ranges, we can reproduce the fluxes with high accuracy for creation position and energy values within the those ranges.
We have computed a large number of states of pure neutrinos, $\Psi_e(t), \Psi_\mu(t), \Psi_\tau(t)$ at 100 discrete energies and 25 nadir angles. We used 40 energy sample points for $pp$ neutrinos in the interval $0.23 < E < 0.737$ MeV similarly picked as in [50] and the same 60 points as used in [49] in the interval $0.737 < E < 19$ MeV for boron and CNO neutrinos, for the same set of parameters $(\Delta_{12}, \sin^2(2\theta_{12}), \theta_{13})$. We handpicked three important energy points, $E = 0.384, 0.862, 1.442$ MeV for Be neutrinos and pep neutrinos respectively. Each integration of the neutrino evolution equations in the earth takes only a modest amount of computing time but the huge number of integrations requires a large amount of total computing time. We again have to resort to a parallel supercomputer. The parallelization can be done using the same method as described in [49].

Using these data we can compute the earth regeneration effect on the survival probability of an incident solar neutrino at any energy and any nadir angle for a selected set of mixing parameters. In this way we can compute the earth regenerated solar neutrino fluxes for a large region of the mixing parameter space with a modest number of energy samplings to yield an accurate estimate of event rates.

Some cautions are needed for setting up an interpolation function for creation positions and energies. We illustrate the solar neutrino survival probability as a function of creation position in Fig. 4, where we see a very sharply rising curve. We see a sharply dropping curve in Fig. 2a. Since we are using only a finite number of samples with different spacings we will encounter a sticky situation when the curves happen to turn sharply in the region where the sample spacing is wide. The popular cubic spline interpolation fails badly in this situation. One needs to use the exponential spline [12]. We used the FITPACK subroutines available in the GAMS library [70]. As Fig. 4 shows the interpolated curve is as good as the original one.

VI. SAMPLE CONTOUR PLOTS

We illustrate sample iso-SNU(FLUX) contour plots in the plane, $(\sin^2(2\theta_{12}) - \Delta_{12})$, for a set of mixing parameters, $\theta_{14} = 10^\circ$, $\Delta_{23} = 2.2 \times 10^{-3}$ eV$^2$, and $\theta_{23} = 43.5^\circ$ in Fig. 5. For a given set of $(\sin^2(2\theta_{12}), \Delta_{12})$ we had generated solar neutrinos according to the SSM model [13]. In order to compute the raw solar neutrino fluxes we used 36 creation positions and 60 energy samples for $pp$ neutrino and 60 creation positions and 60+7 energy samples for others. For the same set of mixing parameters $(\sin^2(2\theta_{12}), \Delta_{12})$ we had computed the states of three pure neutrinos, $\Psi_e(t), \Psi_\mu(t), \Psi_\tau(t)$ at 100 discrete energies and 25 nadir angles optimally selected as explained in section IV. For each solar neutrino created at position $r$ with energy $E$ we perform a sequence of time averaging operations leading to Eq. (22). In this way we build an interpolation function for $\langle P_{SE}(r, E, \eta) \rangle$ as a function of creation position $r$, energy $E$ and nadir angle $\eta$. We integrate the fluxes over the creation positions according to the relevant creation probability distribution functions and then build an interpolation function for $\langle P_{SE}(E, \eta) \rangle$ as a function of the energy and nadir angle. We can now take seasonal and yearly averages of this flux to get $\langle P_{SE}(E) \rangle$, which involves integration over $\eta$ with a definite latitude $\lambda$. Finally we take a convolution of $\langle P_{SE}(E) \rangle$ with the absorption cross sections $\sigma(E)$ to get the yearly average of event rate for a particular experiment.

In order to make iso-SNU(FLUX) contour plots, we used a $16 \times 21$ logarithmic mesh in the $(\sin^2(2\theta_{12}) - \Delta_{12})$ plane in the range $0.001 \leq \sin^2(2\theta_{12}) \leq 1$ and $1.58 \times 10^{-6} \leq \Delta_{12} \leq 1.58 \times 10^{-4}$ eV$^2$. We padded two extra values, $(0.85, 0.97)$, for $\sin^2(2\theta_{12})$ in order to examine the large $\theta_{12}$ region more carefully.

We made separate plots for each experiment [10] with appropriate latitude $\lambda$. As expected from previous figures, contours in the SMA region are almost intact but those in the small $\Delta_{12} < 10^{-5}$ eV$^2$ and large $\sin^2(2\theta_{12}) > 0.1$ region are distorted significantly by the earth effect. But for gallium detectors the curves are not distorted visibly in the considered region of parameter space. This is due to the fact that the major signal source for gallium detectors is the $pp$ neutrinos with very low energies, for which the earth regeneration effect is minimal. The overall earth effect for solar neutrinos is larger for small $\theta_{13}$ than for large $\theta_{13}$ as we see from Fig. 6.

VII. SUMMARY AND CONCLUSION

We introduced an integrated algorithm to deal with the earth regeneration effect of solar neutrinos with all three active neutrinos considered. Main ingredients of the algorithm are the time averaging algorithm with the use of mass eigenstates, the strategy for sampling energy and nadir angle, and the interpolation algorithm. Our algorithm is useful for full scale investigation of the earth effect.

We illustrated that the earth effect on low energy solar neutrinos causes large variations in the survival probabilities for large mixing angles $\theta_{12}$ at a given value of $\theta_{13}$. But it is maximal for small values of $\theta_{13}$ and diminishes for large values ($\sim 45^\circ$) at a given value of $\theta_{12}$. The nadir angle dependence is sensitive to the value of $E'$. As far as low energy solar neutrinos are concerned we notice that the earth effect is more pronounced for smaller nadir angles.
We have shown that for large values of $\theta_{13}$, the earth effect is significant for high energy accelerator or atmospheric neutrinos ($E' \gtrsim 10^9$) and it can be large at any nadir angle.

Fig. 3a Daily averages of solar neutrino fluxes (SMA case)

Solid curves are for raw flux, dotted ones for earth regenerated flux on the winter solstice, dashed ones on the summer solstice, dash-dotted ones on the equinox. All solar neutrinos are created at the center of the Sun. Downward arrows mark the 20 MeV upper limit of $E_\nu$. We used the mixing parameters: $\Delta m_{23}^2 = 2.2 \times 10^{-3} \text{ eV}^2$, $\theta_{23} = 43.5^\circ$. The values of $\theta_{13}$ are inscribed in the plots. For the SMA case: $\Delta m_{12}^2 = 6.31 \times 10^{-6} \text{ eV}^2$, $\sin^2(2\theta_{12}) = 4.36 \times 10^{-3}$. For the LMA case: $\Delta m_{12}^2 = 1.3 \times 10^{-5} \text{ eV}^2$, $\sin^2(2\theta_{12}) = 0.63$. 
Fig. 3b Daily averages of solar neutrino fluxes (LMA case)

Solid curves are for raw flux, dotted ones for earth regenerated flux on the winter solstice, dashed ones on the summer solstice, dash-dotted ones on the equinox. All solar neutrinos are created at the center of the Sun. Downward arrows mark the 20 MeV upper limit of $E_\nu$. We used the mixing parameters: $\Delta m^2_{32} = 2.2 \times 10^{-3}$ eV$^2$, $\theta_{23} = 43.5^\circ$. The values of $\theta_{13}$ are inscribed in the plots. For the SMA case: $\Delta m^2_{12} = 6.31 \times 10^{-8}$ eV$^2$, $\sin^2(2\theta_{12}) = 4.36 \times 10^{-3}$. For the LMA case: $\Delta m^2_{12} = 1.3 \times 10^{-5}$ eV$^2$, $\sin^2(2\theta_{12}) = 0.63$. 
Fig. 1 Comparison of earth regenerated solar neutrino fluxes:

(top) Fig. 1 of Ohlsson Ref. [66]; (middle) Fig. 3d of Baltz and Weneser (1987), Ref. [54] (bottom) Fig. 5d of Ref. [54]
The solid curve (DY) is for raw flux and the others marked by Sm are for the paths with the nadir angles $\eta = (m/10)\pi/2$. All solar neutrinos are created at the center of the Sun. Downward arrows mark the 20 MeV upper limit of $E_\nu$. We used the mixing parameters: $\Delta m_{12}^2 = 2.2 \times 10^{-3} \text{ eV}^2$, $\theta_{13} = 43.5^\circ$. The values of $\theta_{13}$ are inscribed in the plots. For the SMA case: $\Delta m_{12}^2 = 6.31 \times 10^{-6} \text{ eV}^2$, $\sin^2(2\theta_{12}) = 4.40 \times 10^{-3}$. For the LMA case: $\Delta m_{12}^2 = 1.8 \times 10^{-5} \text{ eV}^2$, $\sin^2(2\theta_{12}) = 0.76$. 

Fig. 2a Earth regenerated solar neutrino fluxes (SMA case)
The solid curve (DY) is for raw flux and the others marked by Sn are for the paths with the nadir angles \( \eta = (m/10)(\pi/2) \). All solar neutrinos are created at the center of the Sun. Downward arrows mark the 20 MeV upper limit of \( E_\nu \). We used the mixing parameters: \( \Delta m^2_{12} = 2.2 \times 10^{-3} \text{ eV}^2, \theta_{13} = 43.5^\circ \). The values of \( \theta_{13} \) are inscribed in the plots. For the SMA case: \( \Delta m^2_{12} = 6.31 \times 10^{-6} \text{ eV}^2, \sin^2(2\theta_{12}) = 4.40 \times 10^{-3} \). For the LMA case: \( \Delta m^2_{12} = 1.8 \times 10^{-5} \text{ eV}^2, \sin^2(2\theta_{12}) = 0.76 \).
Fig. 4 Survival probability of a solar neutrino as a function of creation position

Original data are marked by the solid curve, the cubic spline fit by the dashed and the exponential fit by the dotted.
Fig. 5. iso-SNU(FLUX) plots for solar neutrinos with the Cl, Ga, and Water detectors.

The upper-left figure is for Cl with SNU values 1.5, 2.56, 3.5, 4.5. The upper-right figure is for Water with FLUX values 1.5, 2.44, 3.5, 4.5. The lower-left figure is for GA with SNU values 5.65, 7.31.90. Each contour is represented by dotted, dashed, long-dashed and solid curves respectively. In all these three figures the thick curves are drawn with the earth regenerated fluxes while the thin curves with raw fluxes. In each plot the vertical axis refers to $\Delta m_{12}^2$ in eV$^2$ and the horizontal axis to $\sin^2(2\theta_{12})$. We used $\Delta m_{23}^2 = 2.2 \times 10^{-3}$ eV$^2$, $\theta_{23} = 43.5^\circ$, $\theta_{13} = 10^\circ$. 
Fig. 6. iso-SNU(FLUX) plots for solar neutrinos with the CI detectors.

Contours are for SNU values 1.5, 2.56, 3.5, 4.5. Each contour is represented by dotted, dashed, long-dashed and solid curves respectively. In all these four figures the thick curves are drawn with the earth regenerated fluxes while the thin curves with raw fluxes. In each plot the vertical axis refers to $m^2/2$ in eV$^2$ and the horizontal axis to $\sin^2(2\theta_{12})$. We used $\Delta m^2_{33} = 2.2 \times 10^{-3}$ eV$^2$, $\theta_{23} = 43.5^\circ$.
