Abstract
Let \( P = \{ p_1, p_2, ... \} \) be the set of all odd primes arranged in increasing order. A Goldbach partition of the even integer \( 2k > 4 \) is a way of writing it as a sum of two primes from \( P \) without regard to order. Let \( Q(2k) \) be the number of all Goldbach partitions of the number \( 2k \). Assume that \( 2k \) is selected uniformly at random from the interval \((4, 2n], n > 2\), and let \( Y_n = Q(2k) \) with probability \( 1/(n - 2) \). We prove that the random variable \( \frac{Y_n}{n/(\frac{1}{2} \log n)} \) converges weakly, as \( n \to \infty \), to a uniformly distributed random variable in the interval \((0, 1)\). The method of proof uses size-biasing and the Laplace transform continuity theorem.

Key words: Goldbach partition, limiting distribution

1 Introduction
Let \( P = \{ p_1, p_2, ... \} \) be the sequence of all odd primes arranged in increasing order. A Goldbach partition of the even integer \( 2k > 4 \) is a way of writing it as a sum of two primes \( p_i, p_j \in P \) without regard to order. The even integer \( 2k = p_i + p_j, i \geq j \), is called a Goldbach number. Let \( Q(2k) \) denote the number of the Goldbach partitions of the number \( 2k \). In 1742 C. Goldbach conjectured that \( Q(2k) \geq 1 \) for all \( k > 2 \). This problem still remains unsolved (for more details, see, e.g., [4; Section 2.8, p. 594], [8; Section 4.6] and [9; Chapter VI]). Let \( \Sigma_{2n} \) be the set of all Goldbach partitions of the even integers from the interval \((4, 2n], n > 2\). The cardinality of this set is obviously

\[
| \Sigma_{2n} | = \sum_{2 < k \leq n} Q(2k).
\]
In this paper, we consider two random experiments. In the first one, we select a partition uniformly at random from the set \( \Sigma_{2n} \), i.e., we assign the probability \( \frac{1}{|\Sigma_{2n}|} \) to each Goldbach partition of an even integer from the interval \((4, 2n]\). An important statistic (random variable) of this experiment is the Goldbach number \( 2G_n \in (4, 2n] \) partitioned by this random selection. Its probability mass function (pmf) is given by

\[
f_{G_n}(x) = \frac{Q(2k)}{|\Sigma_{2n}|} \quad \text{if} \quad x = 2k \in (4, 2n],
\]

and zero elsewhere.

**Remark 1.** It was established in [7] that

\[
|\Sigma_{2n}| \sim \frac{2n^2}{\log^2 n}, \quad n \to \infty.
\]

The proof is based on a classical Tauberian theorem due to Hardy-Littlewood-Karamata [3; Chapter 7]. Recently, in a private communication, Kaisa Matomäki [5] showed me a shorter and direct proof of (3) that uses only the Prime Number Theorem [4; Section 17.7] and partial summation.

In the second random experiment, we select an even number \( 2k \in (4, 2n] \) with probability \( \frac{1}{n-2} \). Let \( Y_n \) be the statistic, equal to the number \( Q(2k) \) of its Goldbach partitions. Obviously, the pmf of \( Y_n \) is

\[
f_{Y_n}(x) = \frac{1}{n-2} \quad \text{if} \quad x = Q(2k), \quad 2k \in (4, 2n],
\]

and zero elsewhere.

The main goal of this paper to study the limiting distribution of the random variable \( Y_n \). In Section 2 we show that \( Y_n \), appropriately normalized, converges weakly, as \( n \to \infty \), to a random variable that is uniformly distributed in the interval \((0, 1)\).

The method of proof uses size biasing and the Laplace transform continuity limit theorem [2; Chapter XIII, Section 1].

## 2 The Limiting Distribution of \( Y_n \)

The first step is to determine the asymptotic of the expected value of \( Y_n \). From (1), (3) and (4) it follows that

\[
\mathbb{E}(Y_n) = \frac{1}{n-2} \sum_{2 < k \leq n} Q(2k) \sim \frac{2n}{\log^2 n} = \frac{1}{2} b_n, \quad n \to \infty,
\]

where

\[
b_n = \frac{n}{(\frac{1}{2} \log n)^2}, \quad n > 2.
\]

Next, we will introduce the concept of size-biasing. The definition we present below is given in [1; Section 4.2]. Suppose that \( X \) is a non-negative random
variable with finite mean $\mu$ and distribution function $F$. The notation $X^*$ is used to denote a random variable with distribution function given by

$$F^*(dx) = \frac{x F(dx)}{\mu}, \quad x > 0. \quad (7)$$

The random variable $X^*$ and the distribution function $F^*$ are called size-biased versions of $X$ and $F$, respectively.

Our goal is to show that the size-biased version $Y_n^*$ of $Y_n$ is $G_n$. To see this, we set in the right-hand side of $(7)$ $x = Q(2k)$ ($2k \in (4, 2n]$) and $\mu = E(Y_n)$. Using $(5)$, $(4)$, $(2)$ and $(1)$, we obtain

$$f_{Y_n^*}(2k) = \frac{1}{n-2} \frac{Q(2k)}{E(Y_n)} = \frac{1}{n-2} \sum_{2<k \leq n} \frac{Q(2k)}{Q(2k)} = f_{G_n}(2k). \quad (8)$$

If we multiply both sides of $(8)$ by $e^{-2\lambda k/(2n)} = e^{-\lambda k/n}, \lambda > 0$, and sum up over $k \in (2, n]$, we observe that

$$\sum_{2<k \leq n} e^{2\lambda k/(2n)} \frac{1}{n-2} \frac{Q(2k)}{E(Y_n)} = \frac{E(Y_n e^{-\lambda X_n})}{E(Y_n)} = \frac{E(e^{-\lambda G_n/n})}{E(Y_n e^{-\lambda X_n})},$$

where $X_n$ denotes a random variable that assumes the values $2k/(2n) = k/n, k \in (2, n]$, with probability $1/(n-2)$. Hence, for fixed $n > 2$, we have

$$E(Y_n e^{-\lambda X_n}) = (E(Y_n))E(e^{-\lambda G_n/n}).$$

Let

$$Z_n = \frac{1}{b_n} Y_n, \quad n > 2, \quad (9)$$

where the scaling factor $1/b_n$ is defined by $(6)$. Clearly, $Z_n$ satisfies the same identity as $Y_n$. We have

$$E(Z_n e^{-\lambda X_n}) = (E(Z_n))E(e^{-\lambda G_n/n}), \quad n > 2. \quad (10)$$

We start our asymptotic analysis of $(10)$ with

$$\lim_{n \to \infty} E(Z_n) = \frac{1}{2}, \quad (11)$$

which follows from $(3)$ and $(4)$. The second factor in the right-hand side of $(10)$ is the Laplace transform of the random variable $G_n/n$. Its limiting distribution, as $n \to \infty$, was found in [7]. (The proof is based on the asymptotic equivalence $(3)$.) We state this result in the following separate lemma.

**Lemma 1** The sequence of random variables $\{G_n/n\}_{n \geq 2}$ converges weakly, as $n \to \infty$, to the random variable $U = \max\{U_1, U_2\}$, where $U_1$ and $U_2$ are two independent copies of a uniformly distributed random variable in the interval $(0, 1)$.
Remark 2. Clearly, the probability density function of the random variable $U$ equals $2x$, if $0 < x < 1$, and zero elsewhere. The $r$th moment of $U$ is
\[ \frac{2r}{r+2}, \quad r = 1, 2, \ldots \]
The Laplace transform of the random variable $U_1$ (uniformly distributed in the interval (0, 1)) is
\[ \phi(\lambda) = \frac{1 - e^{-\lambda}}{\lambda}, \quad \lambda > 0, \quad (12) \]
while the Laplace transform of $U$ is
\[ \frac{2}{\lambda^2}(1 - e^{-\lambda} - \lambda e^{-\lambda}) = -2\phi'(\lambda), \quad \lambda > 0. \]

Further, for any fixed $s > 0$, we integrate (10) with respect to $\lambda$ over the interval $(0, s)$. Applying Fubini’s theorem [2; Chapter IV, Section 3], we obtain
\[ \mathbb{E}\left(\frac{Z_n}{X_n}(1 - e^{-sX_n})\right) = \left(\mathbb{E}(Z_n)\right)\mathbb{E}\left(\frac{1 - e^{-sG_n/n}}{G_n/n}\right). \quad (13) \]
To find the limit of the right-hand side of (13), we combine the result of Lemma 1 with the continuity theorem for Laplace transforms (see, e.g., [2; Chapter XIII, Section 1]) and the Lebesgue dominated convergence theorem. Using the probability density function of the random variable $U$, (11) and (12), we deduce that
\[ \lim_{n \to \infty} \mathbb{E}\left(\frac{1 - e^{-sG_n/n}}{G_n/n}\right) = \frac{1}{2}\mathbb{E}\left(\frac{1 - e^{-sU}}{U}\right) = 1 - \varphi(s). \quad (14) \]
The random variable $X_n$ in the left-hand side of (13) has simple probabilistic interpretation: $nX_n$ equals an integer, chosen uniformly at random from the interval $(2, n]$. So, it converges weakly, as $n \to \infty$, to the random variable $U_1$ (uniformly distributed in the interval (0, 1)). Applying again the continuity theorem for Laplace transforms [2; Chapter XIII, Section 1], we have
\[ \lim_{n \to \infty} \mathbb{E}(e^{-sX_n}) = \varphi(s), \quad s > 0, \quad (15) \]
where $\varphi$ is given by (12). Moreover, (13) and (14) imply that
\[ \lim_{n \to \infty} \mathbb{E}\left(\frac{Z_n}{X_n}(1 - e^{-sX_n})\right) = 1 - \varphi(s). \quad (16) \]
Now, it is not difficult to show that $Z_n/X_n \to 1$ in probability, as $n \to \infty$. In fact, if this is not true, then there is a number $\epsilon \in (0, 1)$, such that, for infinitely many values of $n$, either $Z_n/X_n \leq 1 - \epsilon$ or $Z_n/X_n \geq 1 + \epsilon$ for these values of $n$ with probability tending to 1. Both inequalities contradict with (15) and (16) for these $n$. Hence, for any $\eta > 0$,
\[ \lim_{n \to \infty} \mathbb{P}\left(\left|\frac{Z_n}{X_n} - 1\right| \geq \eta\right) = 0, \]
which implies that $Z_n$ and $X_n$ have one and the same limiting distribution. Thus we obtain the following limit theorem.
Theorem 1 The sequence \( \{ Z_n = Y_n/b_n \}_{n \geq 2} \), with \( b_n \) given by (6), converges weakly, as \( n \to \infty \), to the random variable \( U_1 \), which is uniformly distributed in the interval \((0, 1)\).

Theorem 1 shows that the number of Goldbach partitions of even integers \( 2k \in (4, 2n] \) is typically of order

\[
ab_n = \frac{4an}{\log^2 n},
\]

where \( 0 < a < 1 \) (see (6)). This informal evidence in favor of the Goldbach’s conjecture does not give us any rigorous argument to prove it. Finally, we note that in number theory special interest is paid on asymptotic estimates for the probability \( P(Y_n = 0) \) (see, e.g., [9; Chapter VI]). For instance, Montgomery and Vaughan [6] have shown that, for sufficiently large \( n \), there exist a positive (effectively computable) constant \( \delta < 1 \), such that \( P(Y_n = 0) \leq (2n)^{-\delta} \).
