Baryon Number-Induced Chern-Simons Couplings of Vector and Axial-Vector Mesons in Holographic QCD

Sophia K. Domokos and Jeffrey A. Harvey

(Dated: April 2007)

We show that holographic models of QCD predict the presence of a Chern-Simons coupling between vector and axial-vector mesons at finite baryon density. In the AdS/CFT dictionary, the coefficient of this coupling is proportional to the baryon number density, and is fixed uniquely in the five-dimensional holographic dual by anomalies in the flavor currents. For the lightest mesons, the coupling mixes transverse $\rho$ and $a_1$ polarization states. At sufficiently large baryon number densities, it produces an instability, which causes the $\rho$ and $a_1$ mesons to condense in a state breaking both rotational and translational invariance.

INTRODUCTION

Models which use the gravity/gauge correspondence to treat strongly-coupled QCD as a five-dimensional theory of gravity have progressed dramatically in recent years. Particularly at high energies, these theories differ significantly from QCD – yet those models which incorporate light quarks and chiral symmetry-breaking of the form observed in QCD do capture much of the important low-energy structure of the theory, and give rise to a spectrum of mesons whose masses, decay constants, and couplings match those of QCD to within 20%.

The gravity/gauge approach includes both top-down models of QCD arising from $D$-brane constructions in string theory, and bottom-up phenomenological models, which attempt to capture the essential dynamics using a simple choice of five-dimensional metric ($AdS_5$) and a minimal field content consisting of a scalar $X$ and gauge fields $A^a_L$ and $A^a_R$. These fields are holographically dual to the quark bilinear $\bar{q}q$, and to the $SU(N_f)_L \times SU(N_f)_R$ flavor currents $q_L \gamma^{\mu} F^{\mu}_{RL}$ and $\bar{q}_R \gamma^{\mu} F^{\mu}_{LR}$ of QCD, respectively.

These holographic models can be used to study QCD at finite baryon density. In this paper we focus on a novel effect, in which a Chern-Simons term leads to a spectrum of mesons whose masses, decay constants, and couplings match those of QCD to within 20%.

In AdS/CFT calculations, boundary contributions to the action must be treated with care. In the full AdS space, the only boundary is in the UV (at $z = 0$). UV-divergent contributions to the action and to other quantities are canceled by counterterms. For details see (10, 11).

In the model at hand, the IR boundary at $z = z_m$ may contribute to the action. We follow the approach of (6, 7) by (1) dropping IR boundary terms, and (2) taking parameters normally fixed by IR boundary conditions on the classical solution as input parameters of the model.

We generalize the gauge symmetry to $U(N_f)_L \times U(N_f)_R$ and add a Chern-Simons term which gives the correct holographic description of the QCD flavor anomalies. The Chern-Simons term does not depend on the metric and on general grounds will be present in any holographic dual description of QCD. The $U(1)$ axial symmetry in QCD is anomalous, but in the spirit of the large $N_c$ approximation we treat it as an exact symmetry of QCD with massless quarks. Including the anomaly would not affect our conclusions.

The Lagrangian is thus

$$ S = \int d^4x dz \sqrt{g} tr \left[ |D X|^2 + 3 |X|^2 - \frac{1}{4g_s^2} (F_L^2 + F_R^2) \right] + CS \ . $$

The Chern-Simons term is given by

$$ S_{CS} = \frac{N_c}{24\pi^2} \int [\omega_5(A_L) - \omega_5(A_R)] \ . $$

where $d\omega_5 = tr F^5$, $N_c$ is the number of colors, and $A_{L,R} = A_{L,R} t^a + A_{L,R}^a t^a$ where $t^a$ are the generators of $SU(N_f)_L \times SU(N_f)_R$ normalized so that $tr t^a t^b = \delta^{ab}/2$ and $t_1 = 1/\sqrt{2N_f}$ is the generator of the $U(1)$ subalgebra of $U(N_f)$. In what follows, we take $N_f = 2$ so that $a = 1, 2, 3$. We will often work with the vector and axial-vector fields $V = (A_L + A_R)/2$ and $A = (A_L - A_R)/2$.

THE MODEL

We work in a slice of $AdS_5$ with metric

$$ ds^2 = \frac{1}{z^2} (-dz^2 + dx^\mu dx_\mu) \ , \ \ 0 < z \leq z_m \ . $$

The fifth coordinate, $z$, is dual to the energy scale of QCD. We generate confinement by imposing an IR cutoff $z_m$, and specifying the IR boundary conditions on the fields. The UV behavior, meanwhile, is governed by $z \rightarrow 0$.

CLASSICAL BACKGROUND

We expand around a nontrivial solution to the classical equations of motion for the scalar $X$. Following (6, 7) we
find the scalar background

\[ X_0(z) = \left( \frac{1}{2} M z + \frac{1}{2} \Sigma z^3 \right) = \frac{v(z)}{2} \]  

(4)

where the coefficient \( M \) of the non-normalizable term is proportional to the quark mass matrix, and \( \Sigma \) is the \( \hat{q} \hat{q} \) expectation value. We take both \( M \) and \( \Sigma \) to be diagonal: \( M = m_q \mathbf{1} \) and \( \Sigma = \sigma \mathbf{1} \). As shown in [6, 7], we can fix the five-dimensional coupling \( g_5 \) by comparison with the vector current two-point function in QCD at large Euclidean momentum. This leads to the identification

\[ g_5^2 = \frac{12\pi^2}{N_c}. \]  

(5)

The model is thus defined by three parameters: \( z_m, m_q \) and \( \sigma \). Note that including the \( U(1) \) gauge fields and Chern-Simons coupling does not mandate the addition of any new parameters. We use \( z_m = 1/(346 \text{ MeV}) \), \( m_q = 2.3 \text{ MeV} \) and \( \sigma = (308 \text{ MeV})^3 \), which correspond to values found through a global fit to seven observables (Model B) in [6].

A background with a static, constant quark density is described by a classical solution to the equation of motion for the time component of the \( U(1) \) vector gauge field \( \hat{V}_\mu \), which is dual to the quark number current. Solving the \( V_0 \) equation of motion at zero four-momentum yields

\[ \hat{V}_0(z) = A + \frac{1}{2} Bz^2. \]  

(6)

By the general philosophy of AdS/CFT, the coefficient of the non-normalizable term, \( A \), is proportional to the coefficient with which the operator dual to \( \hat{V}_0 \) enters the gauge theory Lagrangian. Since \( \hat{V}_\mu \) is dual to the quark number current, \( A \) must be proportional to the quark chemical potential. Meanwhile, the coefficient of the normalizable term, \( B \), is proportional to the expectation value of the operator dual to \( \hat{V}_0 \); the quark number density. We now obtain the normalizations of \( A \) and \( B \). The action evaluated for the background Eq. (6) is given by a boundary term:

\[ S = \frac{1}{2g_5^2} \int d^4x \frac{1}{z} \hat{V}_0 \partial_z \hat{V}_0 |_{z=0} = \frac{1}{2g_5^2} AB \int d^4x. \]  

(7)

At finite temperature and baryon number, the Euclidean action is equal to the grand canonical potential. Using Eq. (6), this implies that

\[ AB = \frac{24\pi^2}{N_c} n_q \mu_q \]  

(8)

with \( n_q \) the quark number density and \( \mu_q \) the quark chemical potential. To fix \( A \) we separate \( U(N_f)_L \times U(N_f)_R \) into \( U(1)_{L,R} \) and \( SU(N_f)_{L,R} \) components and note that the Chern-Simons term contains the coupling

\[ S = \frac{N_c}{24\pi^2} \int d^4xdz \epsilon^{MNPQ} (\hat{A}^L_0 \text{ Tr } F^{L}_{MN} F^{L}_{PQ} - \hat{A}^R_0 \text{ Tr } F^{R}_{MN} F^{R}_{PQ}) \]  

(9)

where the indices \( M, N, P, Q \) run over 1, 2, 3, \( z \) and the trace is over \( SU(N_f) \). Defining the \( SU(N_f)_{L,R} \) instanton numbers by

\[ n_{L,R} = \frac{1}{32\pi^2} \int d^3xdz \epsilon^{MNPQ} \text{ Tr } F^{L}_{MN} F^{L}_{PQ} \]  

(10)

and taking \( \hat{A}^L_0, \hat{A}^R_0 \) constant, this reduces to the coupling

\[ \frac{N_c}{2} \int dx^0 (\hat{A}^L_0 n_L - \hat{A}^R_0 n_R). \]  

(11)

Using the connection between instantons and Skyrmion configurations of the pion field carrying non-zero baryon number [12, 13, 14, 15, 16], we can interpret an instanton with \( n_L = -n_R = N_b \) as a state with baryon number \( N_b \). Eq. (11) then fixes \( A = \mu_0/N_c = \mu_q \) with \( \mu_q \) the quark chemical potential; Eq. (8) fixes \( B = 24\pi^2 n_q/N_c \).

### Quadratic Action

In vacuum, the spectrum of the theory consists of towers of scalar, vector, pseudoscalar, and axial-vector mesons given by mode-expanding the five-dimensional fields along the holographic \((z)\) direction, and integrating over \( z \). In this section, we identify the spectrum of excitations and their dispersion relations at non-zero baryon density by expanding the action to quadratic order around the background given by Eqs. (4, 6).

Pions arise as Nambu-Goldstone modes associated with the breaking of \( U(N_f)_L \times U(N_f)_R \) to \( U(N_f)_V \). We write \( X(x,z) = X_0(z) \exp(i2\pi^a x^a) \) and expand to quadratic order in \( \pi^a \). The four-dimensional pion field is obtained by writing \( \pi^a(x,z) = \pi^a(z) \psi(z) \pi^a(z) \). Similarly, the \( \rho^a \) and \( \omega^a \) mesons appear by writing \( \rho^a(x,z) = g_5 \rho^a_0(x) \psi_\rho(z) \), \( A^a_{\mu}(x,z) = g_5 \alpha^a_0(x) \psi_\alpha(z) \). The wave functions \( \psi(z) \), \( \psi_\rho(z) \), and \( \psi_\alpha(z) \) are solutions of the quadratic equations of motion for fields with four-momentum \( q^2 = m^2 \) and with boundary conditions \( \psi(0) = \partial_z \psi(z_m) = 0 \). For details see [6, 7].

Making the above substitutions and expanding to quadratic order yields the four-dimensional action

\[ S = \int d^4x \left[ \frac{1}{2} \partial_{\mu} \pi^a \partial^{\mu} \pi^a - \frac{1}{2} \partial_\mu \pi^a \partial^{\mu} \pi^a - \frac{1}{4} (\rho^a_{\mu\nu})^2 \right] \]  

\[ - \frac{1}{4} (\rho^a_{\mu\nu})^2 + \frac{1}{2} m^2 \rho^a_{\mu\nu} \rho^a_{\mu\nu} + \frac{1}{2} n^2 \rho^a_{\mu\nu} \rho^a_{\mu\nu} \]  

\[ \rho^a_{\mu\nu} = \partial_\mu \rho^a_{\rho} + \partial_{\rho} \rho^a_{\mu}, \]  

(12)
with \( \rho_{\mu\nu}, a_{\mu\nu} \) the field strengths for \( \rho_{\mu}, a_{\mu} \). The Chern-Simons term with coefficient \( \mu \) mixes the \( \rho \) and \( a_1 \) mesons. It arises from reduction of a term of the form \( \int dV \, Tr \, A \tilde{D} V \) in the expansion of Eq. \( \text{48} \).

As usual, to obtain Eq. \( \text{12} \) one must remove the mixing between \( a_1^\mu \) and \( \partial_{\mu} \pi^a \) by performing the transformation \( a_1^\mu \rightarrow a_1^\mu + \varepsilon \partial_{\mu} \pi^a \) and then rescaling the pion field to obtain a canonical kinetic energy term \( \text{17} \). This leads to a pion contribution to the Chern-Simons term. A total spatial derivative, it does not contribute to the equations of motion and may be dropped.

Since the \( \rho \) has \( J^{PC} = 1^{--} \) and the \( a_1 \) has \( J^{PC} = 1^{++} \), the Chern-Simons coupling is even under \( P \) and odd under \( C \). This is indeed consistent with a background having non-zero baryon number, which preserves \( P \) and violates \( C \): the coupling is rotationally invariant, but not Lorentz invariant due to the preferred rest frame of the baryons.

We can deduce the existence of the Chern-Simons coupling in four-dimensional terms as follows. The reduction of the five-dimensional Chern-Simons term \( \text{22} \) gives rise to the usual gauged WZW action \( \text{18, 19, 20} \), as well as a set of couplings which arise from inexact bulk terms. These include a \( \rho - a_1 - \omega \) coupling which, in the presence of a coherent \( \omega \) field in nuclear matter, gives rise to a coupling of the form given in Eq. \( \text{12} \). The \( \rho - a_1 - \omega \) coupling has been considered previously in a general discussion of chiral effective Lagrangians \( \text{22} \), and is implicit in the formulae of \( \text{22} \). Related terms appear in \( \text{21} \). In AdS/QCD, different forms of the gauged WZW action can be obtained by the addition of UV counterterms \( \text{21} \), but these will not cancel the Chern-Simons coupling and lead to explicit breaking of chiral symmetry beyond that given by the quark mass term in Eq. \( \text{4} \).

The mass of the \( \rho \) meson is given by \( m_\rho = 2.405/\sqrt{m} \), while \( m_{a_1} \) must be determined from a numerical solution of the equation of motion. Model B of \( \text{6} \) finds \( m_\rho = 832 \text{ MeV}, m_{a_1} = 1200 \text{ MeV} \), which should be compared to the experimental values \( m_\rho = 775.8 \pm 0.5 \text{ MeV} \) and \( m_{a_1} = 1230 \pm 40 \text{ MeV} \). The parameter \( \mu \) in the Chern-Simons coupling is given by

\[
\mu = 18 \pi^2 n_b z_m^2 I \tag{13}
\]

where \( I \) is the dimensionless overlap integral

\[
I = \frac{1}{z_m^2} \int_0^{z_m} dz z \psi_\rho(z) \psi_{a_1}(z) . \tag{14}
\]

Numerical evaluation of the integral gives \( I = 0.54 \). A typical baryon density in nuclear matter, \( n_b \) \( \simeq 0.16/(\text{fermi})^3 \), gives

\[
\mu \simeq 1.05 \text{ GeV} \left( \frac{n_b}{n_0} \right) . \tag{15}
\]

**PHENOMENOLOGICAL APPLICATIONS**

We now outline two potentially observable consequences of the Chern-Simons coupling between the \( \rho \) and \( a_1 \). Details will appear elsewhere.

**Mixing of transverse \( \rho \) and \( a_1 \) states**

We consider plane-wave solutions to the equations of motion resulting from Eq. \( \text{12} \), dropping the pion fields and focusing on the \( \rho \) and \( a_1 \) dispersion relation and polarization vectors. Without loss of generality, we consider propagation along \( x^3 \):

\[
\rho_\mu(x) = e^\rho_\mu(q)e^{-iq \cdot x}, \quad a_\mu(x) = e^a_\mu(q)e^{-iq \cdot x} \tag{16}
\]

with \( q = (q_0, 0, 0, q_3) \). For convenience, we suppress the \( SU(2) \) indices in the following. The components \( \rho_0, \rho_3, a_0, a_3 \) have standard dispersion relations, unaffected by the Chern-Simons coupling. The transverse components \( \rho_1, \rho_2, a_1, a_2 \) mix through a derivative coupling. The equations of motion yield the dispersion relation for the transverse polarizations

\[
q_0^2 - q_3^2 = \frac{1}{2}(m_\rho^2 + m_{a_1}^2) \pm \frac{1}{2} \sqrt{(m_\rho^2 - m_{a_1}^2)^2 + 16\mu^2 q_3^2} . \tag{17}
\]

The lower sign in Eq. \( \text{17} \) gives a state which is pure \( \rho \) as \( q_3 \rightarrow 0 \). At non-zero \( q_3 \), it is a mixture of transverse \( \rho \) and \( a_1 \) states with orthogonal polarization vectors:

\[
e_1^\rho = \frac{iM^2(q_3)}{2\mu q_3} e_2^\rho, \quad e_1^\rho = -\frac{iM^2(q_3)}{2\mu q_3} e_2^\rho \tag{18}
\]

where we have defined \( \Delta^2 = m_{a_1}^2 - m_\rho^2 \) and \( M^2(q_3) = (\sqrt{\Delta^4 + 16\mu^2 q_3^2} - \Delta^2)/2 \). The upper sign in Eq. \( \text{17} \) gives a pure \( a_1 \) state for \( q_3 = 0 \), while for non-zero \( q_3 \),

\[
e_1^\rho = -\frac{iM^2(q_3)}{2\mu q_3} e_2^\rho, \quad e_2^\rho = \frac{iM^2(q_3)}{2\mu q_3} e_1^\rho . \tag{19}
\]

For \( \mu \) greater than some momentum-dependent critical value, the dispersion relation Eq. \( \text{17} \) leads to tachyonic modes (modes having \( dq_3/dq_3 > 1 \)). For very large momenta, this critical value becomes

\[
\mu_{\text{crit}} = \sqrt{(m_\rho^2 + m_{a_1}^2)^2} \simeq 1.09 \text{ GeV} . \tag{20}
\]

For a range of \( \mu \) below \( \mu_{\text{crit}} \) the dispersion relation with the lower sign in Eq. \( \text{17} \) exhibits interesting anomalous behavior, the analysis of which is beyond the scope of this letter.

It would be interesting to explore signatures of these mixed polarization states in the quark-gluon plasma and in nuclear matter.
Vector Meson Condensation

To identify the tachyonic instability which occurs for $\mu > \mu_{\text{crit}}$, we start with the energy density corresponding to Eq. (12) for the diagonal component of the $\mu$ fields, $a^\mu = \alpha a^\alpha$, $\rho^a = \rho^0 a^3$. Completing the square and dropping the terms involving the electric components of the field strengths, which play no role in the instability, we find

$$\mathcal{H} = \frac{1}{2} (m_a^2 - \mu^2) \tilde{a} \cdot \tilde{a} + \frac{1}{2} \left( m_\rho^2 - \mu^2 \right) \tilde{\rho} \cdot \tilde{\rho} + \frac{1}{2} (\tilde{B}_a - \mu \tilde{\rho})^2 + \frac{1}{2} (\tilde{B}_\rho - \mu \tilde{\rho})^2$$

(21)

where $\tilde{B}_\rho = \tilde{\nabla} \times \tilde{\rho}$, $\tilde{B}_a = \tilde{\nabla} \times \tilde{a}$.

Applying the ansatz

$$\tilde{a} = v \cos(\mu x_3) \hat{x}_2, \quad \tilde{\rho} = v \sin(\mu x_3) \hat{x}_1$$

(22)

the last two terms in Eq. (21) vanish, while the average of the first two terms over $x_3$ is negative for $\mu^2 > \mu_{\text{crit}}^2$, leading to an instability to $v \neq 0$. Understanding the stabilization of the configuration Eq. (22) requires generalizing $\mathcal{H}$ to include higher order terms. Note that Eq. (22) breaks both rotational and translational symmetry, exhibiting a structure similar to the smectic phase of liquid crystals which includes an interesting set of topological defects.

The critical value Eq. (20) is remarkably close to the estimate Eq. (15) for $\mu$ at ordinary nuclear densities. If this model is accurate then there should be a condensate of vector and axial-vector mesons in nuclear matter with baryon densities at or slightly above $n_0^B$. In ordinary nuclei, there are finite size effects as well as other corrections to the $\rho$ and $a_1$ interactions which will have to be included to determine whether this condensate occurs. Neutron stars are more likely to produce such a condensate, as they are thought to contain matter at a density somewhat greater than $n_0^B$. The interplay between this condensate and other conjectured effects in nuclear matter, such as pion condensation and color superconductivity, deserves further study.
