Recent progress has revealed that quantum systems with multiple position-dependent couplings, e.g., giant atoms, can exhibit some unconventional phenomena, such as non-exponential decay. However, their potential applications are still open questions. In this paper, we propose a giant-cavity-based quantum sensor for the first time, whose performance can be greatly enhanced compared to traditional cavity-based sensors. In our proposal, two cavities are coupled to a dissipative reservoir at multiple points while they couple to a gain reservoir in a single-point way. To detect an unknown parameter entering the sensor, a waveguide is coupled to one of the cavities where detecting fields can pass through for homodyne detection. We find that multiple position-dependent couplings can induce an inherent non-reciprocal coupling between the cavities, which can enhance the performance of sensors. Compared to the results in the work of Lau and Clerk, (Nat Commun, 2018, 9: 4,320), our output noise can remain at the shot noise level, which is about one order of magnitude lower. In addition, the signal-to-noise ratio per photon is also enhanced by about one order of magnitude. These results showed that the multiple-point coupling structure is beneficial to existing quantum devices.

Keywords: giant cavities, quantum sensors, SNR (signal-to-noise ratio), non-Markovian quantum systems, quantum metrology, waveguide quantum electrodynamics, homodyne detection, position-dependent coupling

1 INTRODUCTION

High-precision measurement of physical quantities lies in the core of metrology, e.g., gravitational wave detection [1, 2], nano-particle detection [3–6], thermal sensing [7], navigation [8, 9], and magnetometers [10–12]. Towards fundamental detection limits in weak-signal measurements, non-reciprocity [13] has become a powerful resource [14]. Since reciprocity is hard to break due to Lorentz theorem [15], many methods have been proposed for inducing non-reciprocity, for example, biasing with odd-symmetric quantities under time reversal [16], steering systems into exceptional points [17,18], constructing directional couplings [19], employing asymmetric or non-linear elements [20–29], or breaking the time-invariance of systems [30, 31].

Recent progress on quantum systems with multiple-point couplings (e.g., giant atoms [32–48]) provides a new possibility to acquire non-reciprocity. For example, when several giant atoms couple to a common reservoir, an indirect coupling among atoms can be built up via the shared reservoir. This indirect coupling depends on the arrangements of atoms and the relative phase between coupling points [36]. Therefore, one can construct an effective directional coupling between atoms...
by tuning the relative phase and adjusting the arrangements. It should be noticed that the non-reciprocity realized in this way is an inherent property of the system and it can be totally tuned by the relative phase, such that this method of acquiring non-reciprocity requires no other non-linear elements such as Faraday rotators [20, 21] or Josephson parametric converters [26, 28], and thus, it is easy to be integrated into an on-chip structure and flexible in experiments.

In this study, we propose a quantum sensor consisting of two giant cavities, where two coupled cavities couple to reservoirs at multiple points. We find that an inherent non-reciprocal coupling between cavities can be built up through a shared reservoir. Compared with the small-cavity-based structures in [14], i.e., cavities couple to reservoirs at a single point, the signal-to-noise ratio in our proposal can be improved by one order of magnitude. The study is organized as follows. In Section 2, we propose the theoretical model of the quantum sensor, including the Hamiltonian and equations of motion. Following the standard frame [14], we propose the performance indicator of sensors in Section 3, including signal, output noise, and signal-to-noise ratio per photon. The comparison with the sensor made up of small cavities is shown in Section 4. Finally, further discussion and conclusion are given in Section 5.

2 MODEL OF GAINT-CAVITY-BASED QUANTUM SENSOR

2.1 Hamiltonian

Generally speaking, a quantum sensor means the sensor utilizing quantum resources, such as quantum devices, quantum states, quantum effects, etc. [49, 50]. In [14], a paradigm in designing quantum sensors is proposed that several coupled cavities couple to a gain reservoir and a dissipative reservoir at a single point. Illuminated by this paradigm, the sensor we considered consists of a coupled double-cavity interacting with two reservoirs. The first cavity is coupled to a dissipative reservoir at $x_1$ and $x_2$, and the second cavity is coupled to it at $x_3$ and $x_4$, as shown in Figure 1. On the contrary, a gain reservoir couples to both cavities at the same point. In addition, a classical pump with an amplitude $B_{in}$ is injected into the readout waveguide which only couples to the cavity 1, and its reflected field $B_{out}$ is measured by homodyne detection. This model can be realized by superconducting quantum circuits, i.e., two LC resonators couple to three waveguides, where one of the waveguides is used for readout and the others are used as reservoirs. According to the model, the total Hamiltonian reads

$$H_{tot} = H_0 + H_d + H_f,$$  \hfill (1)

where

$$H_0 = \sum_{l, j=1}^{2} H_{ij}[\alpha]a_l^\dagger a_j + \int d\kappa \omega_{\kappa, \lambda} b_\lambda^\dagger b_\lambda + \int d\kappa \omega_{\kappa, \lambda} c_\lambda^\dagger c_\lambda$$

$$+ \int d\kappa \omega_{\kappa, \lambda} d_\lambda^\dagger d_\lambda,$$ \hfill (2a)

$$H_d = \sqrt{k}(\beta e^{-i\omega t} a_1^\dagger + H.c.) + \sqrt{k} \int d\kappa \sqrt{2\pi} (a_1b_\lambda + H.c.),$$ \hfill (2b)

$$H_f = \sum_{l=1}^{2} \int d\kappa (Y_{ij}a_l^\dagger c_\lambda^\dagger + H.c.)$$

$$+ \int d\kappa (Z_{ij}(e^{i\kappa x_1} + e^{i\kappa x_2})a_1^\dagger d_\lambda + Z_{ij}(e^{i\kappa x_3} + e^{i\kappa x_4})a_2^\dagger d_\lambda + H.c.).$$ \hfill (2c)

Equation 2a describes the free Hamiltonian of the two cavities, the readout waveguide, the gain and dissipative reservoirs with bosonic annihilation operators $a_l$, $b_\lambda$, $c_\lambda$, and $d_\lambda$, respectively. Here, we have assumed that the perturbation $\varepsilon$ is small enough such that $H_{ij}[\varepsilon]$ has a linear form $^1$ [14, 51] $H_{ij}[\varepsilon] = H_{ij}^0 + \varepsilon V_{ij}$, where $H_{ij}^0$ is the unperturbed part of the coupled cavities and $V_{ij}$ denotes the coupling of perturbation $\varepsilon$ on the cavities. The first term in Eq. 2b represents a classical pump $\beta$ with a driving frequency $\omega_t$ and a coupling strength $k$ that enters cavity 1 through the readout waveguide. The second term denotes the interaction between cavity 1 and the readout waveguide, which yields a noise input $B_{in}$ to the cavity, as shown later. Eq. 2c describes couplings between the cavities and the reservoirs with strengths $Y_{ij}$ and $Z_{ij}$, respectively. Notably, the position-dependent phase $e^{i\kappa x_m}$, $(m = 1, 2, 3, 4)$ with a wave vector $k$ is introduced by the multi-point couplings.

2.2 Langevin Equations

For the sake of sensing, we analyze how the output varies when the perturbation $\varepsilon$ acts on the sensor, which can be done with the quantum Langevin equation. Before we proceed, we assume that

$^1$Since the perturbation is small enough, such that it can be expanded as a small quantity and kept to the first order.
the coupling points are equally spaced, i.e., \( d = x_2 - x_1 = x_3 - x_2 = x_4 - x_3 \). For simplicity, we let \( x_1 = 0 \). Also, the linear dispersion relation holds in the dissipative reservoir, i.e., \( \omega_{dk} = v_c k \) with \( v_c \) being the group velocity \([48, 52, 53] \).

With the abovementioned assumptions, the equations of motion for two cavities take the form

\[
\hat{a}_1[t] = F_{11} [\varepsilon] \hat{a}_1[t] + 2\pi |Z_1| \hat{a}_1[t - \tau] e^{i\omega \tau} + F_{12} [\varepsilon] \hat{a}_2[t] - M_1^{\text{in}} [t],
\]

\[
\hat{a}_2[t] = F_{22} [\varepsilon] \hat{a}_2[t] + 2\pi |Z_2| \hat{a}_2[t - \tau] e^{i\omega \tau} + F_{21} [\varepsilon] \hat{a}_1[t] - M_2^{\text{in}} [t],
\]

where

\[
F_{11} [\varepsilon] = i\omega - iH_{11} [\varepsilon] + n|Y_1|^2 - 2\pi |Z_1|^2 - \frac{\kappa}{2},
\]

\[
F_{22} [\varepsilon] = i\omega - iH_{22} [\varepsilon] + n|Y_2|^2 - 2\pi |Z_2|^2,
\]

\[
F_{12} [\varepsilon] = -iH_{12} [\varepsilon] + n|Y_2|^2,
\]

\[
F_{21} [\varepsilon] = -iH_{21} [\varepsilon] + n|Y_1|^2,
\]

\[
F_{11}^{\text{in}} [t] = 2\pi n Z_1^2 e^{i\omega \tau} (\hat{a}_1[t - \tau] + \hat{a}_2[t - 2\tau] e^{i\omega \tau} + \hat{a}_1[t - 3\tau] e^{i\omega \tau}),
\]

\[
\hat{M}_1^{\text{in}} [t] = i\sqrt{2\pi} Z_1^2 \hat{C}_1^{\text{in}}[t] - i\sqrt{2\pi} Z_1 \hat{D}_1^{\text{in}}[t] + \hat{M}_1[t - \tau] e^{i\omega \tau},
\]

\[
\hat{M}_2^{\text{in}} [t] = i\sqrt{2\pi} Z_2^2 \hat{C}_2^{\text{in}}[t] - i\sqrt{2\pi} Z_2 \hat{D}_2^{\text{in}}[t] + \hat{M}_2[t - \tau] e^{i\omega \tau},
\]

are the inputs for the readout waveguide, gain, and dissipative reservoirs, respectively. In addition, the input-output relation for the field in the readout waveguide is given by

\[
\hat{B}_{\text{out}}[t] = (\hat{B}_{\text{in}}[t] + \beta) - i\sqrt{\kappa} \hat{a}_1[t],
\]

where

\[
\hat{B}_{\text{out}}[t] = B_{\text{out}}[t] e^{i\omega t} = \frac{1}{\sqrt{2\pi}} \int dk \ b_k [t] e^{i\omega k} e^{i\omega \tau} dt,
\]

is the output field in the waveguide at a final time \( t_\tau \).

Using Fourier transformation, the delayed differential Eqs. 3a, 3b can be solved as

\[
\left( \tilde{a}_1[\omega; \varepsilon] \right) = \left( \omega - \omega - iH[\varepsilon] - \pi IgY + 2\pi iDZ + \frac{i\kappa}{2} \right)^{-1} \tilde{M}_{\text{in}}[\omega],
\]

\[
\left( \tilde{a}_2[\omega; \varepsilon] \right) = \frac{\chi[\omega; \varepsilon]}{i\kappa} \tilde{M}_{\text{in}}[\omega],
\]

with \( \kappa = \kappa \left( \begin{array}{ccc} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{array} \right) \).

\[
G_Y = \frac{\left( Y_1 Y_1 Y_2^* \right)}{\left( Y_2 Y_2 Y_1^* \right)} = \left( Y_1 Y_2^* \right),
\]

and

\[
D_Z = \frac{\left( Z_1 Z_1 \left( e^{i\omega \tau} + e^{-i\omega \tau} \right) + e^{i\omega \tau} + e^{-i\omega \tau} \right)}{\left( Z_2 Z_2 \left( e^{i\omega \tau} + e^{-i\omega \tau} \right) \right)}
\]

are the inputs for the readout waveguide, gain, and dissipative reservoirs, respectively. In addition, the input-output relation for the field in the readout waveguide is given by

\[
\hat{B}_{\text{out}}[t] = (\hat{B}_{\text{in}}[t] + \beta) - i\sqrt{\kappa} \hat{a}_1[t],
\]

where

\[
\hat{B}_{\text{out}}[t] = B_{\text{out}}[t] e^{i\omega t} = \frac{1}{\sqrt{2\pi}} \int dk \ b_k [t] e^{i\omega k} e^{i\omega \tau} dt,
\]

is the output field in the waveguide at a final time \( t_\tau \).

Using Fourier transformation, the delayed differential Eqs. 3a, 3b can be solved as

\[
\left( \tilde{a}_1[\omega; \varepsilon] \right) = \left( \omega - \omega - iH[\varepsilon] - \pi IgY + 2\pi iDZ + \frac{i\kappa}{2} \right)^{-1} \tilde{M}_{\text{in}}[\omega],
\]

\[
\left( \tilde{a}_2[\omega; \varepsilon] \right) = \frac{\chi[\omega; \varepsilon]}{i\kappa} \tilde{M}_{\text{in}}[\omega],
\]

with \( \kappa = \kappa \left( \begin{array}{ccc} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{array} \right) \).

\[
G_Y = \frac{\left( Y_1 Y_1 Y_2^* \right)}{\left( Y_2 Y_2 Y_1^* \right)} = \left( Y_1 Y_2^* \right),
\]

and

\[
D_Z = \frac{\left( Z_1 Z_1 \left( e^{i\omega \tau} + e^{-i\omega \tau} \right) + e^{i\omega \tau} + e^{-i\omega \tau} \right)}{\left( Z_2 Z_2 \left( e^{i\omega \tau} + e^{-i\omega \tau} \right) \right)}
\]

are the inputs for the readout waveguide, gain, and dissipative reservoirs, respectively. In addition, the input-output relation for the field in the readout waveguide is given by

\[
\hat{B}_{\text{out}}[t] = (\hat{B}_{\text{in}}[t] + \beta) - i\sqrt{\kappa} \hat{a}_1[t],
\]

where

\[
\hat{B}_{\text{out}}[t] = B_{\text{out}}[t] e^{i\omega t} = \frac{1}{\sqrt{2\pi}} \int dk \ b_k [t] e^{i\omega k} e^{i\omega \tau} dt,
\]

is the output field in the waveguide at a final time \( t_\tau \).

Using Fourier transformation, the delayed differential Eqs. 3a, 3b can be solved as

\[
\left( \tilde{a}_1[\omega; \varepsilon] \right) = \left( \omega - \omega - iH[\varepsilon] - \pi IgY + 2\pi iDZ + \frac{i\kappa}{2} \right)^{-1} \tilde{M}_{\text{in}}[\omega],
\]

\[
\left( \tilde{a}_2[\omega; \varepsilon] \right) = \frac{\chi[\omega; \varepsilon]}{i\kappa} \tilde{M}_{\text{in}}[\omega],
\]
unknown parameter affects the output of the detecting field. Different from the existing sensors, the dynamics of our sensor involve non-reciprocity induced by time-delayed terms which would improve the performance of the sensor.

3 PERFORMANCE EVALUATION OF THE SENSOR

3.1 Homodyne Detection
As we have introduced, our sensor employs homodyne detection to extract the perturbation, where the photon current of the output field

\[ I(t) = \sqrt{\kappa/2} (e^{i\theta} B_{\text{out}}(t) + H.c.) \]  

(13)

is measured. All the information of \( \varepsilon \) is contained in the real part of \( e^{i\theta} B_{\text{out}}(t) \). Note that the current is measured in a steady-state of the system such that we can evaluate the response of the system to the perturbation at the zero frequency; i.e., \( \omega = 0 \). Also, for small \( \varepsilon \), the expectation value of the output is assumed to be in a linear response to \( \varepsilon \) [14], i.e.,

\[ \langle B_{\text{out}}[0] \rangle_\varepsilon = \langle B_{\text{out}}[0] \rangle_0 + \lambda \varepsilon, \]

(14)

where \( \langle \rangle_\varepsilon \) denotes taking expectations at \( \varepsilon = \varepsilon \). Using this relation, the response coefficient \( \lambda \) reads

\[ \lambda = \lim_{\varepsilon \to 0} \frac{\langle B_{\text{out}}[0] \rangle_\varepsilon - \langle B_{\text{out}}[0] \rangle_0}{\varepsilon} = -2\pi b\delta(0) \frac{d\chi_{11}^2(0; \varepsilon)}{d\varepsilon}|_{\varepsilon=0} \]

\[ = \frac{2\pi i b \delta(0)}{\kappa} (\chi V \chi^\dagger)_{11}, \]

(15)

whose phase \( \varphi = -\arg \lambda \) determines the angle in Eq. 13.

3.2 Signal, Noise, and Signal-to-Noise Ratio per Photon
To estimate the performance of the sensor, we further define a measurement operator \( m[\omega] \) as the windowed Fourier transformation of current \( I[t] \), i.e.,

\[ m[\omega] = \frac{1}{\sqrt{T}} \int_{-T/2}^{T/2} dt I[t] e^{-i\omega t}, \]

(16)

where the segment \( T \) should be much greater than \( 1/\kappa \) such that the sensor can reach the steady states during the measurement window. Under this condition, the integral limits can be extended to \( \pm \infty \). Notably, this definition of \( m[\omega] \) makes it have a unit of \( A/\sqrt{Hz} \) [54].

The power associated with the signal can be defined as the square of the difference of measurement operator \( m[0] \) between the perturbed and unperturbed cases, i.e.,

\[ S = (\langle m[0] \rangle_\varepsilon - \langle m[0] \rangle_0)^2 = \frac{2\kappa\varepsilon^2}{T} |\lambda|^2. \]

(17)

In addition, the total average photon number induced by the classical input can be calculated as

\[ n_{\text{tot}} = \sum_{i=1}^2 \langle \dot{a}_i^\dagger[0; \varepsilon]\dot{a}_i[0; \varepsilon] \rangle_0 = \frac{\kappa b^2 |\beta|^2}{\kappa} (\chi^2 \chi^\dagger)_{11}, \]

(18)

where the mean-field approximation [55, 56] has been used. With this definition, the signal per photon can be expressed as

\[ \frac{S}{n_{\text{tot}}} = \frac{2\varepsilon^2}{T} |(\chi V \chi^\dagger)_{11}|^2, \]

(19)

where we let \( \chi = \chi[0; 0] \) for brevity.

Similarly, the total photon noise can be calculated as

\[ N = \langle m^2[0] \rangle_0 - \langle m[0] \rangle_0^2 = \frac{\kappa}{2T} \left( 1 + |\chi_{11}|^2 - (\chi_{11} + \chi_{12}) \right. \]

\[ + \left. \frac{2\pi}{\kappa} (\chi G Y \chi^\dagger)_{11} + \frac{2\pi}{\kappa} (1 + e^{i\omega \tau})^2 (\chi Z Z^\dagger \chi^\dagger)_{11} \right) \]

\[ = \frac{\kappa}{2T} \left( 1 + 2\varepsilon \cdot \theta[\varepsilon] + \frac{4\pi}{\kappa} (1 + \cos(\omega \tau))(1 + e^{i\omega \tau}) |\chi_{11}^\dagger | \right. \]

\[ + \left. L \chi_{12} e^{i\omega \tau} |\chi_{12}^\dagger |^2 \right), \]

(20)

where \( \bar{Z} = (Z_1 Z_2 e^{i\omega \tau}), \bar{\varepsilon} = |\chi_{11}^\dagger | - 1 > 1 \), the output noise must be greater than the simple shot noise. Or equivalently speaking, a linear amplification for signal also amplifies the noise. And the third term results from the dissipative noise of the dissipative reservoir.

Combining Eqs. 19, 20, one can obtain the signal-to-noise ratio (SNR) per photon

\[ \frac{S}{N_{\text{tot}}} = \frac{4\varepsilon^2}{\kappa} \left( 1 + 2\varepsilon \cdot \theta[\varepsilon] + \frac{4\pi}{\kappa} (1 + \cos(\omega \tau))(1 + e^{i\omega \tau}) |\chi_{11}^\dagger | \right. \]

\[ + \left. L \chi_{12} e^{i\omega \tau} |\chi_{12}^\dagger |^2 \right), \]

(21)

which is the sensitivity of the sensor. Notably, the state transfer matrix \( \chi \) is now independent in the perturbation \( \varepsilon \), which means that the SNR has a purely parabolic response to the changes of \( \varepsilon \) for a determined \( \chi \).

3.3 Corresponding Results for the Sensor Composed of Two Small Cavities
For comparison, we also consider the sensor made up of two small cavities that couple to the dissipative reservoir in a single-point way. This is a standard model of two-mode quantum
sensors [14, 51], which is used as a benchmark. In this case, the second line in interaction Hamiltonian Eq. 2c is rewritten as

$$H_{12}^D = \sum_{n=1}^{2} \int dk (Z_n a_n^d d_k + H.c.) \tag{22}$$

This induces a modification on Eq. 10

$$D_2^S = \frac{1}{2} \left( \frac{1}{Z_2^2} Z_2 Z_1^2 |Z_3|^2 \right) = \frac{1}{2} \left( \frac{1}{Z_2^*} Z_2^* Z_1^2 |Z_3|^2 \right) = \frac{1}{2} ZZ^* \tag{23}$$

and Eq. 11

$$\hat{N}^S_{in}[0] = \left( \sqrt{\kappa} \left( 2\pi \beta \theta [0] + \bar{B}_{in}[0] \right) + \sqrt{2\pi} \left( Y_1 Y_2 c^\dagger_{in}[0] \right) + \sqrt{2\pi} \left( Z_1 Z_2 D_{in}[0] \right) \right). \tag{24}$$

and the gain matrix $G_Y$ (9) remains the same. Hereafter, we use superscript $S$ to label the corresponding quantities of the sensor composed of small cavities.

An interesting fact is that, the third term in Eq. 20 then reduces to $\frac{2\pi}{\gamma} (Z_1 X_{14}^S + Z_3 X_{14}^S)$ in this case, which is an unavoidable and untunable noise. However, in our proposal, one can adjust $\omega_L$ or $\tau$ to eliminate the dissipative noise such that the output noise $N$ can remain at a lower level.

### 4 NUMERICAL COMPARISON OF GIANT VS. SMALL SENSORS

To numerically estimate the performance of the sensor, we set the Hamiltonians $H^D [0]$ and $V$ as

$$H^D = \begin{pmatrix} \omega_1 & J \\ J & \omega_2 \end{pmatrix} \quad \text{and} \quad V = \begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix}, \tag{25}$$

which describes a common linear coupled-cavity system. For simplicity, we consider that both $Y_1$ and $Z_i$ are real. With these specific matrices, one can easily rewrite the state transfer matrix as

$$\chi = ik \left( \begin{pmatrix} \Delta - \frac{\omega_1}{2} + \frac{\omega_2}{2} & \frac{\Delta - \frac{\omega_1}{2} - \Delta + \frac{\omega_2}{2}}{2} \end{pmatrix} + i\gamma \left( 1 + e^{i(\Delta + \phi)} \right) \right), \tag{26}$$

$$\chi^S = ik \left( \begin{pmatrix} \Delta - \frac{\omega_1}{2} + \frac{\omega_2}{2} & \frac{\Delta - \frac{\omega_1}{2} - \Delta + \frac{\omega_2}{2}}{2} \end{pmatrix} + i\gamma \left( 1 + e^{i(\Delta + \phi)} \right) \right)^{-1}, \tag{27}$$

where $\Delta = \omega_L - \omega_1$ and $\Delta_{12} = \omega_2 - \omega_1$ are detunings, $\Gamma = 2\pi \gamma S$ and $\gamma = 2\pi \Gamma_1^S$ denote the decay rates of the cavities to the reservoirs, and $\phi = \omega_1 \tau$ is a fixed phase. For numerical simulations, we set $\Delta_{12} = 0$ and $J = \Gamma = 0.1 \kappa$, which describes a good cavity in the weak coupling regime [57].

We first plot the frequency responses of the relative signal per photon, noise, and SNR per photon of the sensor made up of two small cavities, as shown in Figure 2. We find that both the signal per photon and the noise reach the maximum value at the resonant point, as shown in Figure 2A,B, but does not the SNR per photon, as shown in Figure 2C. To characterize the influences of the loss $\gamma$, we replot the above quantities as the functions of $\gamma$ at the resonant point $\Delta = 0$, as shown in Figure 3. Hereafter, we only consider the responses at the resonant point. As the loss $\gamma$ increases, both the signal per photon and the noise gradually increase until reaching their maximum values at $\gamma = 0.65 \kappa$ and then decrease, shown as the blue and red lines in Figure 3A. Especially, one can find that the output noise $N^S$ is always greater than the shot noise in the whole intervals of $\gamma$, which means that the shot noise is a fundamental limit of the output noise. Notably, this result also applies to the sensor made up of giant cavities, and we will discuss it later. Indeed, by rewriting Eq. 20 with the replacements $\chi \rightarrow \chi^S$ and $Z \rightarrow Z_S$, it becomes

$$N^S = \frac{\kappa}{\Delta} \left( 1 + 2\pi : \theta [Z] + 2\pi \xi (\xi_{11}^S + \xi_{12}^S) \right),$$

where $\xi = \frac{1}{\gamma} \left( \xi_{11}^S - 1 \right)^2 - 1$. One can find that the last two terms respectively representing the reflective gain and the dissipative loss are always greater than or equal to zero, as shown in Figure 3B. Another point that need to be noticed is a sudden change of SNR per photon occurs when $\gamma = \Gamma$, as shown in the inset of Figure 3A. The reason behind this can be found in the inset of Figure 3B, where the reflective gain becomes zero at this point. This is because $|\xi_{11}^S - 1|^2 < 1$ when $\gamma > \Gamma$, such that the reflective gain is cut off by the Heaviside function, and thus the output noise includes a non-zero dissipative loss only. This
result indicates that the dissipative loss is an inevitable and unadjustable noise in a small-cavity-based proposal.

With the previous results, we now turn to the sensor made up of two giant cavities. In contrast to the case we discussed in the last section, the dissipative matrix $D_2$ additionally introduces a degree of freedom of the fixed phase $\phi$ ($\Delta\tau$ is zero at the resonant point), such that the relative signal per photon, noise, and SNR per photon have a response to $\phi$, as shown Figure 4 where we also use the same parameters in plotting. Both the signal per photon and the noise experience a process of first increasing and then decreasing as the phase $\phi$ increases, as shown in Figure 4A,B. An interesting point is that, thanks to the phase $\phi$, the output noise can remain at the shot noise level, e.g., $N = 1.12$ at $\phi = 0.76\pi$ when $\gamma = 0.5\Gamma$ (Blue line), $N = 1.03$ at $\phi = 0.84\pi$ when $\gamma = \Gamma$ (Red line) and $N = 1.00$ at $\phi = 0.89\pi$ when $\gamma = 2\Gamma$ (Green line), which are about one order of magnitude smaller than $N^0$, as shown in the inset in Figure 4B. In Figure 4C, it shows that SNR per photon increases as the loss $\gamma$ increases when $\phi \in [\pi, 2\pi]$, but indeed, SNR per photon reaches its maximum value at $\gamma = 2\Gamma$.\(^2\) As we mentioned in the last section, the shot noise is the fundamental limit of the output noise for any sensor. This result also applies to our giant-cavity-based proposal, as shown in Figure 5. The reflective gain and dissipative loss cannot simultaneously be zero although they can be zero by adjusting the phase $\phi$, which also explains why the noise is always greater than the shot noise in Figure 4B.

A clear comparison with the sensor made up of the small cavities is plotted in Figure 6. As Figure 6A shows, the signal per photon of giant-cavity proposal $S/n_{tot}$ can be about one order of magnitude greater than that of small-cavity proposal $S^n/n_{tot}$, especially when $\gamma = 2\Gamma$ (green line). An interesting point is that $\text{Re}(N)$ is almost always smaller than $N^0$ in the entire

---

\(^2\)We have simulated SNR with $\gamma \in \{0.25\Gamma, 0.5\Gamma, \Gamma, 2\Gamma, 4\Gamma, 8\Gamma, 16\Gamma\}$ and found SNR per photon is maximum at $\gamma = 2\Gamma$. For the sake of keeping the picture simple and clear, we do not show other curves in Figure 4C.
interval $[0, 2\pi]$ when $\gamma = \Gamma$, as shown as the red line in Figure 6B. This means that our proposal can effectively decrease the output noise by adjusting the parameter $\phi$, compared to Ref. [14]. In addition, from the green and blue lines in Figure 6A,B, one can find that both the ratio of signal per photon $S/n_{\text{out}}$ and the ratio of noise $R/n_{\text{out}}$ are greater than 1 at some certain values of $\phi$, which means both the signal per photon and the noise of the giant-cavity proposal are enhanced compared to the small-cavity proposal. Indeed, this enhancement is led by the non-reciprocal coupling. As we mentioned in Section 2.2, the non-reciprocal coupling means that the cavity 1 can affect the excitation of the cavity 2 via the shared reservoir but not vice-versa, and thus both the signal per photon and the output noise are amplified by this non-reciprocity since the readout waveguide is coupled to the cavity 1. The mathematical reason lies in that the non-reciprocal state transfer matrix $\tilde{\chi}$ effectively amplifies the element $\tilde{\chi}_{12}$ but decrease the element $\tilde{\chi}_{21}$ when $\phi \neq (2k + 1)\pi$. Physically, such the amplification and decrease means that the incident photons are transmitted back to cavity 1 rather than stored in cavity 2, with the help of the directional interaction $a_2 \rightarrow a_1$. For the signal per photon, this process is equivalent to amplifying the signal $S$ but decreasing the total photon number $n_{\text{tot}}$. For the output noise $R/N$, this process amplifies the dissipative loss. One can examine the above results by substituting Eqs. 25-27 into Eqs. 19, 20. Furthermore, although both the signal $S$ per photon and the output noise $R/N$ are enhanced in the interval $[\pi, 1.5\pi]$ when $\gamma = 2\Gamma$ (green lines in Figure 6A,B, respectively), the SNR per photon is much greater than those with other $\gamma$, as shown as the green line in Figure 6C. These results show that the giant-cavity structure is a powerful resource in designing quantum sensors.

5 CONCLUSION AND FUTURE WORKS

In conclusion, we proposed a quantum sensor consisting of two giant cavities. By coupling cavities to a dissipative reservoir at multiple points, a non-reciprocal interaction can be engineered between the cavities and the common reservoir, which requires no non-linear elements. Compared to the standard two-mode quantum sensor [14], the output noise can remain at the shot noise level, which is reduced by about one order of magnitude. And the signal-to-noise ratio per photon is also enhanced by

![Figure 5](image-url) (Color online) Reflective gain (A) and dissipative loss (B) as the functions of $\phi$. Parameters in plotting are: $\Delta = \Delta_{12} = 0$, $J = \Gamma = 0.1\Gamma$. Both reflective gain and dissipative loss can be zero at some certain $\phi$ but they cannot be zero simultaneously, which is the reason why the noise is always greater than the shot noise in Figure 4B.

![Figure 6](image-url) (Color online) The ratios of signal per photon (A), output noise (B) and SNR per photon (C) between sensors made up of giant and small cavities. Parameters in plotting are: $\Delta = \Delta_{12} = 0$ and $J = \Gamma = 0.1\Gamma$. For some certain intervals, e.g., $[\pi, 1.5\pi]$, the signals $S/n_{\text{tot}}$ are greater than $S^\text{tot}/n_{\text{tot}}$. Especially, when $\gamma = 2\Gamma$, $S/n_{\text{tot}}$ is about one order magnitude enhanced compared to $S^\text{tot}/n_{\text{tot}}$. In particularly, when $\gamma = \Gamma$, $S/n_{\text{tot}}$ can be almost smaller than $S^\text{tot}/n_{\text{tot}}$ globally. With proper gain and loss, e.g., $\gamma = 2\Gamma$, $S/(R/N) n_{\text{tot}}$ is about one order magnitude greater than $S^\text{tot}/(R/N) n_{\text{tot}}$. These results show that the giant-cavity structure is a powerful resource in designing quantum sensors.
about one order of magnitude. These results show that the giant-cavity-based sensor can effectively improve sensing precision.

A future direction is to consider how the non-Markovian effect affects the sensing performance. Since we only consider the cases at the resonant point, such that the non-Markovian effect depending on $\Delta t$ is neglected. However, this degree of freedom plays important roles in the deep non-Markovian regime $\tau \gg 1/\kappa$ [35], e.g., it induces a non-exponential decay [37] and a multi-peak excitation spectrum [48]. Therefore, how these non-Markovian effects affect the sensing performance is an open question to be explored in the future, especially when a coherent feedback is applied to control the system [58–62]. A possible method to investigate the influences of the non-Markovian effect is utilizing the quantum simulation platform [63].
