Angiogenesis is fundamental to physiological and pathological processes. Despite intensive efforts, little is known about the intracellular circuits that regulate angiogenesis. The transcription factor Net is activated by phosphorylation induced by Ras, an indirect regulator of angiogenesis. Net is expressed at sites of vasculogenesis and angiogenesis during early mouse development, suggesting that it could have a role in blood vessel formation. We show here that down-regulation of Net inhibits angiogenesis and vascular endothelial growth factor (VEGF) expression in vivo, ex vivo, and in vitro. Ras-activated phosphorylated Net (P-Net) stimulates the mouse VEGF promoter through the −80 to −53 region that principally binds Sp1. P-Net and VEGF are coexpressed in angiogenic processes in wild-type mouse tissues and in human tumors. We conclude that Net is a regulator of angiogenesis that can switch to an activator following induction by pro-angiogenic molecules.

Received May 13, 2003; revised version accepted July 11, 2003.

The process of forming new blood vessels, angiogenesis, occurs throughout embryonic development and in all fetal organs. In adult mammals, angiogenesis is restricted to pathological situations including tumors and wound healing, and some natural processes such as the female reproductive cycle. Counterbalancing positive and negative factors regulate angiogenesis. During angiogenesis, growth factors, generated by surrounding normal or tumor cells, induce quiescent endothelial cells to proliferate and differentiate, to form new blood vessels that facilitate material exchange. An important unresolved question is which intracellular circuits regulate this “angiogenic switch” (Carmeliet and Jain 2000). One of the most potent positive factors is vascular endothelial growth factor (VEGF), an endothelial cell-specific mitogen that plays a central role in neovascularization [Ferrara and Davis-Smyth 1997]. The molecular mechanisms of the regulation of VEGF expression during this “switch” are still incompletely understood, but are known to involve hypoxia, growth factors, and transformation. Hypoxia induces VEGF expression through increased transcription mediated by hypoxia-inducible factor 1 [HIF-1; Forsythe et al. 1996]. A variety of growth factors and serum up-regulate VEGF in quiescent human keratinocytes, a process thought to be important in wound healing [Frank et al. 1995]. The Kaposi’s sarcoma-associated herpesvirus (KSHV/HHV8) stimulates angiogenesis. The G-protein-coupled receptor [KSHV–GPCR] encoded by open reading frame [ORF] 74 induces cell transformation, tumorigenicity, and a switch to an angiogenic phenotype mediated by VEGF [Bais et al. 1998]. Overexpression of the oncogenes Ras, v-Raf, and v-Src [Grugel et al. 1995; Mukhopadhyay et al. 1995; Rak et al. 1995] leads to increased expression of VEGF, which is thought to be important for tumor angiogenesis.

Growth factors and oncogenes such as Ras induce MAP kinase signaling cascades that transduce extracellular signals from ligand-activated cell surface receptors to the nucleus. MAP kinases phosphorylate nuclear effectors, such as members of the ets family of transcription factors [Sharrocks 2001]. In particular, MAP kinase phosphorylation enhances the ability of the three ternary complex factor [TCF] ets factors [Net, Elk-1, and Sap-1] to activate transcription of many immediate early response genes [Tresism 1994]. Despite considerable interest in the role of the TCFs in signaling, their physiological roles remain unclear.

Net [Elk-3/Sap-2/ERP] is a repressor of transcription...
that is converted to a positive regulator by Ras and Src signaling. Net is activated through phosphorylation of critical residues of the C-terminal [C] domain [Giovane et al. 1994, Maira et al. 1996, Cricqui-Filipe et al. 1999]. We have found that at early stages of mouse development, net RNA is expressed at sites of vasculogenesis and angiogenesis, raising the possibility that Net is involved in angiogenesis. Later, around birth and in the adult, net is widely expressed in different tissues and cell types [Ayadi et al. 2001a, data not shown]. Homozygous net mutant mice, which express a Net mutant protein that lacks the Ets DNA-binding domain [Net δ], develop a vascular defect. A large proportion of the mice die just after birth due to respiratory failure, resulting from the accumulation of chyle in the thoracic cage (chylothorax). The mice have dilated lymphatic vessels [lymphangiectasia] as early as embryonic day 16.5 [E16.5]. They express more cgr-1 in heart and pulmonary arteries at E18.5, suggesting that Net is a negative regulator of cgr-1 in vivo. However, we did not observe any obvious malformations of blood vessels in mutant embryos or adults [Ayadi et al. 2001b]. These results suggest that Net is implicated in vascular biology and raise the possibility that Net may have a positive role in angiogenesis in the adult. Consequently, we studied the contribution of Net to angiogenesis in wound healing, in several in vitro, ex vivo, and in vivo assays, in experimental tumors, and in different types of human tumors. Our results provide strong evidence that phosphorylated Net (P-Net) is a positive regulator of angiogenesis, at least in part through effects on VEGF expression.

Results

Net is required for angiogenesis and VEGF expression during skin wound healing

Angiogenesis plays a fundamental role in skin wound healing. Dense capillary plexuses as well as inflammatory cells and fibroblasts form the granulation tissue that replaces the temporary fibrin clot. The granulation tissue produces the VEGF that plays an important role in this process. At earlier stages, invading keratinocytes at the wound edge also produce VEGF [Martin 1997, Kishimoto et al. 2000]. We compared the rate of wound healing in netδ/δ and wild-type littermate adult mice. This experiment is possible because around 10% of netδ/δ mice survive beyond 4 wk of age [Ayadi et al. 2001b]. We generated full-thickness wounds on the dorsal skin, and then photographed and measured the size of the wounds at regular intervals. The wounds in netδ/δ mice heal significantly more slowly than in the wild type [Fig. 1A, B]. We studied blood vessel formation 6 d after wounding, an intermediate time at which the wounds were healing at a high rate, hyperplastic epidermis had migrated to cover the denuded wound surface, and the provisional fibrin matrix was partially replaced by granulation tissue. Blood vessels were detected by immunohistochemistry [IHC] with antibodies against CD31 [Fig. 1C]. Vessel density was considerably reduced in the netδ/δ mice at the edges and in the bed of the wounds. The proportion of the area occupied by vessels in different optical fields was examined in five pairs of wild-type and mutant mice. The proportion was 38% ± 3% in the wild type compared to 18% ± 4% in the netδ/δ mice [P < 0.01]. The number of vessels per mm² was 396 ± 33 in the wild type versus 182 ± 50 in netδ/δ mice [P < 0.005; see Materials and Methods]. These results show that there is decreased angiogenesis in the netδ/δ mice. We examined adjacent sections for VEGF expression. As expected, in the wild-type mice, VEGF was highly expressed by mononuclear cells [probably macrophages and wound fibroblasts] in the granulation tissue in the bed and at the edge of the wounds [Fig. 1D, arrows]. In contrast, VEGF expression was much lower in netδ/δ mice, with only a few cells expressing levels similar to the wild type [indicated by arrows in Fig. 1D]. These results suggest that the decreased angiogenesis in netδ/δ mice could be due to decreased expression of VEGF.

If Net positively regulates angiogenesis through effects on VEGF expression, then VEGF-expressing cells should also contain activated Net, phosphorylated on critical residues of the C-terminal activation domain. We previously described phospho-Net-specific antibodies targeted around critical amino acids, phospho-Ser 365 [2F3] or phospho-Thr 329 [1F12]. These antibodies have been characterized by ELISA with phosphorylated and nonphosphorylated peptides, Western blotting and IHC, and shown not to interact with nonphosphorylated Net, or phosphorylated Elk that is detected by phospho-Elk-specific antibodies [Ducret et al. 2000; data not shown]. Cryosections of 6-day-old wounds were dual-stained with P-Net and VEGF antibodies [Fig. 1E]. VEGF and P-Net were found to be up-regulated in the same cells, in the newly formed keratinocytes and granular mononuclear cells. Groups of cells closer to the wound stain more strongly for both P-Net and VEGF than those further away. VEGF was detected in the cytoplasm and P-Net in the nucleus of the same cells, and cells stained strongly or weakly for both. The two P-Net antibodies gave similar results [data not shown]. The secondary antibodies alone did not give any staining [data not shown]. These results show that P-Net is expressed in the cells that produce VEGF, 6 d after wounding.

Earlier during wound healing [after 48 h], VEGF is expressed by the activated keratinocytes close to the wound, and expression decreases with distance from the wound [Fig. 1F, cf. arrows and arrowhead; Kishimoto et al. 2000]. In adjacent sections, P-Net was found to be expressed in the activated keratinocytes close to the wound [Fig. 1G, arrows], and the levels of expression decrease to low levels in the epidermis far from the wound [Fig. 1G, arrowhead]. These results show that P-Net is expressed in the same types of cells and in the same pattern as VEGF. Overall, these results show that during wound healing Net is phosphorylated on amino acids that are critical for activation of its transcription function. P-Net is detected in mononuclear cells in the granulation tissue and in activated keratinocytes. Wound healing, angiogenesis, and VEGF expression are
impaired in net mutant mice, suggesting that Net is a positive regulator of angiogenesis and VEGF expression during wound healing in adult mice.

Net is required for angiogenesis induced by transformed cells in mice

To study the role of Net in angiogenesis in solid tumors, we established stable clones of NIH3T3 cells expressing KSHV–GPCR, a viral oncogene and a potent angiogenesis activator [Bais et al. 1998]. Clones with reduced levels of Net were prepared by cotransfecting a vector that expresses antisense-net (net sequences in the reverse orientation in the expression vector). This method was shown to specifically down-regulate net expression [Giovane et al. 1994]. We further confirmed that the antisense is specific by Western blotting. In the transformed clones, antisense-net decreased the levels of endogenous Net without affecting the highly related Elk-1 [75% at the protein level; Fig. 2A; data not shown]. Furthermore, in short-term transfections, antisense-net decreased endogenous Net without affecting Elk-1, Ras, or KSHV–GPCR expression [data not shown], demonstrating that antisense-net specifically down-regulates Net. The antisense-net clones grew normally according to cell-cycle analysis by FACS [data not shown].

The KSHV–GPCR clones were injected subcutaneously in nude mice. The clones with normal levels of Net formed rapidly growing tumors, reaching a volume of 200–300 mm^3 in 16 d [Fig. 2B]. The tumors were red...
and hemorrhagic, and induced newly formed supplying blood vessels (Fig. 2C, arrows). In contrast, the clones with decreased levels of Net grew more slowly, and the tumors were white and poorly vascularized. Vessels in the tumors were examined by IHC for the CD31 marker (Fig. 2D, dark-gray stain). There was a significant rarefaction of vessels in the KSHV–GPCR-antisense-net tumors compared to the KSHV–GPCR controls. The proportion of the area occupied by vessels [vessel-occupied area, Fig. 2E] was reduced by about 75%. Moreover, the vessels in the GPCR-anti-net tumors were relatively smaller. There was a marked decrease in vessels larger than 2000 µm² in the GPCR-anti-net tumors [number of vessels larger than 2000 µm², GPCR-anti-net tumors/GPCR-control tumors, 32 ± 3%, n = 5, P < 0.01], but not in vessels smaller than 2000 µm², GPCR-anti-net tumors/GPCR-control tumors, 113 ± 26%, n = 5, P < 0.01]. Similar data were obtained with six KSHV–GPCR-control clones [24 tumors] and four KSHV–GPCR-antisense-net clones [16 tumors]. The difference in vascularity between the two types of tumors was maintained, even when equivalent-sized tumors were evaluated [data not shown]. The reduced vessel density would be expected to reduce the oxygen tension. In the tumors, the oxygen tension was measured by EF5 immunodetection [Fig. 2F]. KSHV–GPCR tumors that lack Net had a lower oxygen tension (see overall stronger red staining, in particular the regions indicated by arrows), as expected from the reduced blood vessel density. These results show that Net is required for angiogenesis induced by transformed cells in vivo.

Net is required for angiogenesis in ex vivo and in vitro model systems

Three different assays were used to study the role of Net in angiogenesis: corneal micropockets [Kenyon et al. 1996], aortic rings [Nicosia and Ottinetti 1990; Nicosia et al. 1997], and microtubule formation by HUVEC cells in Matrigel [Bais et al. 1998]. For the corneal micropocket assay, FGF-2 pellets were implanted in the cornea of wild-type and net<sup>H9</sup> littermates. FGF-2 clearly induced vessel formation in the wild-type cornea [Fig. 3A,
Net regulates the angiogenic switch

Figure 3. Net is required for angiogenesis in model systems. (A) Corneal pocket assay. FGF-2 induces angiogenesis in the cornea of wild-type but not net<sup>h/h</sup> mice. Circles are FGF-2 heads. (B) Microvessel sprouting from aortic rings. Pairs of aortic rings from net<sup>h/h</sup> [MUTANT] and wild-type mice are shown. The Matrigel-embedded rings were covered by EBM medium with FGF-2 (40 ng/mL) and VEGF [60 ng/mL] where indicated. (C) P-Net expression in aortic rings. Aortic rings were cultured in Matrigel with or without FGF-2 (40 ng/mL). Four days later the rings with the sprouts were collected for frozen sections and processed for IHC. P-Net is expressed in smooth muscle cells of aortic rings only after FGF-2 treatment (arrowheads). Magnification, 100×. (D–I) HUVEC microtube formation induced by conditioned medium from transfected NIH3T3 cells. The transfections contained the GPCR vector and the empty vector for antisense net [p601D, D], the GPCR and antisense net vectors [E], and the GPCR and TD-

Note that on the mixed BL/6×129 background used for these experiments, fewer vessels are induced than on some other backgrounds; see Rohan et al. 2000). The FGF-2-induced vascular response was strongly impaired in the cornea of net<sup>h/h</sup> mutant mice [Fig. 3A]. Similar results were obtained in eight pairs of cornea from four pairs of net<sup>h/h</sup> and wild-type littermates.

In the aortic ring assay, FGF-2-induced sprouting from net<sup>h/h</sup> aortic rings was severely impaired compared to wild type after 4 d in culture [Fig. 3B; six rings from each animal from four net<sup>h/h</sup> and four wild-type littermates were analyzed, with similar results]. VEGF addition restored sprouting from the net<sup>h/h</sup> aortic rings to levels similar to the wild type, suggesting that impaired production of VEGF is responsible for the decreased sprouting. IHC analysis of sections of the aortas with P-Net-specific antibodies showed that FGF-2 induced phosphorylation of Net in smooth muscle cells in the aortic wall but not in the sprouting cells [Fig. 3C]. The ERK cascade-specific inhibitor U0126 [10 µM] inhibited sprouting in the presence of FGF-2, and washing out the inhibitor restored sprouting [data not shown]. These results indicate that FGF-2-induced phosphorylation of Net through the MAP kinase pathway converts Net to an activator of angiogenic processes.

Conditioned medium from KSHV–GPCR-expressing NIH3T3 cells has been reported to contain pro-angiogenic factors that induce microtubule formation by HUVEC cells in Matrigel [Fig. 3D; Bais et al. 1998]. We tested whether down-regulation of Net affected KSHV–GPCR-induced secretion of “microtube-forming” activity. Conditioned medium from fibroblasts transfected with KSHV–GPCR and antisense net vectors had reduced microtubule-forming activity [Fig. 3, cf. D and E]. Similar reduced microtubule-forming activity was observed by the expression of a transdominant Net mutant [Fig. 3F, TD-Net, Net 219–409] that has been shown to inhibit transactivation by Net [Maira et al. 1996; data not shown]. These results show that down-regulation of Net inhibits the secretion of HUVEC “microtubule-forming” activity. VEGF has been shown to be a critical component of this activity, as microtube formation is inhibited by antibodies against VEGF [Fig. 3G; Bais et al. 1998]. VEGF is also apparently the critical component affected by down-regulating Net, because adding VEGF to the conditioned media restored microtubule formation [Fig. 3, cf. E and H, F and I]. These results suggest that down-regulation of Net inhibits VEGF expression (see below). In conclusion, Net is required for angiogenesis in three different models of angiogenesis.

Regulation of VEGF expression by Net

Oncogenic H-Ras [Ras-V12] and KSHV–GPCR induce angiogenesis by increasing VEGF secretion [Arbiser et al. 1997; Bais et al. 1998, Bosshoff and Weiss 1998]. We investigated the mechanisms by which Net may be involved in these pathways. We showed previously that Ras-V12 induces Net phosphorylation by an ERK1/2-dependent pathway [Fig. 4A; Ducret et al. 2000]. We found that KSHV–GPCR expression in NIH3T3 fibroblasts also stimulates endogenous Net phosphorylation through ERK- and p38 pathway-dependent mechanisms, as shown using the pathway-specific inhibitors U0126 and...
SB203580, respectively (Fig. 4A). This agrees with previous studies showing that KSHV–GPCR stimulates both pathways (Bais et al. 1998). In addition, we showed that KSHV–GPCR stimulated Net transcriptional activity in transfection assays (data not shown). Because down-regulation of Net inhibits FGF-2-induced angiogenesis in several assays (see above), we also investigated FGF-2. We found that FGF-2 induces Net phosphorylation through an ERK-1/2-dependent pathway (Fig. 4A). We studied whether down-regulation of Net inhibits VEGF expression, by measuring VEGF peptide levels in conditioned media with an ELISA assay. As expected, VEGF levels were increased by the expression of KSHV–GPCR or oncogenic Ras-V12 (Fig. 4B). VEGF induction was inhibited by down-regulation of Net with antisense. We found that FGF-2 induces Net phosphorylation through an ERK-1/2-dependent pathway (Fig. 4A).

We studied whether down-regulation of Net inhibits VEGF expression, by measuring VEGF peptide levels in condition media with an ELISA assay. As expected, VEGF levels were increased by the expression of KSHV–GPCR or oncogenic Ras-V12 (Fig. 4B). VEGF induction was inhibited by down-regulation of Net with antisense. These results show that Net is required for VEGF expression. To investigate whether Net regulates VEGF promoter activity, we used transfection assays with a mouse VEGF promoter-luciferase reporter, and we either down-regulated Net with antisense or increased Net levels with expression vectors. A control reporter (pCMV–LacZ) was systematically cotransfected as an internal control. We found that the VEGF promoter is activated by the expression of KSHV–GPCR, and that decreasing the level of endogenous Net with antisense inhibits this activation, without affecting control promoters [mdm2-luc and p21WAF1-luc, data not shown]. Increasing activated P-Net levels, by the expression of exogenous Net together with Ras-V12, stimulated VEGF promoter activity (−1217/+370 Luc) to a fourfold higher level than Ras-V12 alone (Fig. 4C). Expression of Net without Ras-V12 did not stimulate the VEGF promoter. Western blots were used to show that P-Net levels increased in the presence of Ras-V12. Furthermore, endogenous VEGF expression, at the protein and RNA levels, was increased by Net + Ras-V12 expression compared to Ras-V12 or Net alone, or in the absence of exogenous proteins (Fig. 4C; data not shown).

To show that endogenous VEGF expression is increased in the same cells that have elevated levels of P-Net, we used immunocytochemistry (ICC) with antibodies against VEGF and P-Net, corresponding fluorescent secondary antibodies, and DAPI (nuclei), and examined by confocal microscopy. Transfected cells fluoresced brightly [white arrowheads], with VEGF [red] in the cytoplasm and P-Net [green] in the nucleus. Nontransfected cells gave clearly lower fluorescence signals [yellow arrows].

**Figure 4.** Net regulation of VEGF expression in cell culture. (A) Endogenous Net is phosphorylated by GPCR, Ras, and FGF-2 through MAP kinase cascades. NIH3T3 cells were transfected with expression vectors for KSHV–GPCR or Ras-V12, or induced with FGF-2. Cell extracts were analyzed by Western blotting for P-Net, activated P-ERK, and TBP [control for loading]. (B) Down-regulation of Net inhibits VEGF expression induced by GPCR and Ras-V12. NIH3T3 cells were transfected with GPCR, Ras-V12, antisense net, and corresponding control vectors, as indicated. Transfected cells were kept in 0.5% FCS medium for 48 h after the wash. VEGF in this conditioned media was measured by ELISA. Results are averaged from four independent transfection experiments [corrected for cell numbers]. (C) P-Net regulates VEGF promoter activity and stimulates endogenous VEGF expression. NIH3T3 cells were transfected with the mouse VEGF promoter luciferase reporter (−1217/+370), the pCMV LacZ internal control, and expression vectors for Net and Ras-V12. VEGF promoter activity relative to the transfections with empty vectors was determined [graph]. Cell extracts were analyzed by Western blotting for the expression of P-Net, endogenous VEGF, and TBP [loading control, lower panels]. (D) Coexpression of P-Net and VEGF in transfected cells. NIH3T3 cells were transfected with expression vectors for P-Net and Ras-V12. The cells were stained with antibodies against VEGF and P-Net, corresponding fluorescent secondary antibodies, and DAPI (nuclei), and examined by confocal microscopy. Transfected cells fluoresced brightly [white arrowheads], with VEGF [red] in the cytoplasm and P-Net [green] in the nucleus. Nontransfected cells gave clearly lower fluorescence signals [yellow arrows].
the signals also contained the other [Fig. 4D, white arrowheads, about 400 cells in different fields were counted in four independent experiments]. Transfections with empty vectors or the Net vector alone gave only background staining [similar to the nontransfected cells when both vectors were included, data not shown]. Transfections with the Ras-V12 vector gave a small increase in VEGF- and P-Net-positive cells, but the number of positive cells was over fivefold lower than that obtained with both vectors [data not shown]. This could be due to Ras-V12 phosphorylation of endogenous Net and increased expression of VEGF. Taken together, these results show that P-Net positively regulates VEGF expression and VEGF promoter activity.

The region of the mouse VEGF promoter that contains two Sp1 motifs mediates Net + Ras-V12 activation

The mouse VEGF promoter contains different motifs [Shima et al. 1996], including a hypoxia responsive element [HRF; Oosthuyse et al. 2001] and two proximal Sp1 motifs [Maeno et al. 2002]. There are a number of other putative motifs, some of those in the −449/+1 region are shown in Figure 5A. We localized the elements that mediate VEGF promoter activation by Net + Ras-V12 with a series of upstream and downstream deletion mutants. Deletion mutants lacking sequences up to −449, −204, −125, and −80 were efficiently activated by cotransfection of the Net and Ras-V12 expression vectors, compared to cotransfections with either of the vectors alone, or the empty vectors [whose value is set to 1]. The levels of activation were similar to the −1217/+370 reporter [Fig. 4C], indicating that sequences upstream from −80 are not required for Net + Ras-V12 activation. Further mutation of the upstream Sp1 motif [GGGGCGGG to CTCGAGGG] decreased Net + Ras-V12 activation, and deletion of both motifs [−53 to −40] reduced activation to an even greater extent. Point mutation of the two ets sites at −37 to −18 in various contexts (−40, −80, −125, or −204 to +370) had no effect on Net + Ras-V12 activation.
We used electrophoretic mobility shift assays (EMSAs) to identify the factors that bind to the Sp1 motifs. Nuclear extracts of NIH3T3 cells transected with the Net and Ras-V12 expression vectors were analyzed with a probe spanning the Sp1 motifs (−79 to −51). Two complexes were detected that were putatively identified as Sp1 and Sp3 from comparisons with previous reports [Fig. 5B, lane 4; Maeno et al. 2002]. The same two bands were also present in nuclear extracts from cells transected with just the Net vector, just the Ras-V12 vector, or the empty vectors [Fig. 5B, lanes 1–3; the Sp3 band was clearly detected in all conditions in other experiments; data not shown]. Overall, these results suggest that Sp1 may mediate Net + Ras-V12 activation of the VEGF promoter.

We have shown that endogenous Net is phosphorylated on critical amino acids in response to FGF-2, KSHV–GPCR, and Ras-V12. Phosphorylation of the C-domain converts Net from a repressor to an activator of transcription (Criqui-Filipe et al. 1999; Ducret et al. 2000). FGF-2, KSHV–GPCR, and Ras-V12 have been shown to suppress Net in EMSA experiments (Maira et al. 1996), suggesting that the complexes do not contain Net. These results show that Sp1 and Sp3 are the principle factors that bind to the Sp1 motifs in the presence of Net + Ras-V12, and they suggest that activated P-Net stimulates VEGF promoter activity through effects on Sp1 and Sp3.

**Discussion**

This study provides strong in vivo and in vitro evidence that Net is a regulator of the angiogenesis switch in the adult. Net is required for VEGF expression in response to growth factors and oncogenes that activate angiogenesis and MAP kinase signaling cascades. Net is phosphorylated and activated by these inducers of angiogenesis. Activated P-Net stimulates VEGF expression through a mechanism that probably involves Sp1, a major regulator of VEGF expression.

We have shown that endogenous Net is phosphorylated on critical amino acids in response to FGF-2, KSHV–GPCR, and Ras-V12. Phosphorylation of the C-domain converts Net from a repressor to an activator of transcription (Criqui-Filipe et al. 1999; Ducret et al. 2000). FGF-2, KSHV–GPCR, and Ras-V12 have been shown to have important roles in angiogenesis (Gerwins et al. 2000; Kerbel and Folkman 2002), showing that molecules involved in angiogenesis can regulate Net. P-Net is detected in keratinocytes and mononuclear cells dur-
ing wound healing, and in different transformed cells in human tumors, reflecting activation of Net by poorly defined signaling pathways involved in these processes. In Kaposi's sarcoma and HNSSC, P-Net is detected in similar cells in adjacent sections, which implicates the ERK cascade in Net phosphorylation in these tumors. 

Net is required for efficient wound angiogenesis, which could account for the decreased rate of wound closure in net mutant mice. During wound healing, keratinocytes are activated and migrate to cover the wound bed. Inflammatory cells, fibroblasts, and new blood vessels infiltrate the blood clots to form mature stroma and replace the blood clots with granulation tissue [Jacinto et al. 2001; Yamaguchi and Yoshikawa 2001]. VEGF is expressed at high levels from 2 to 7 d after wounding [Fukumura et al. 1998; Kishimoto et al. 2000]. VEGF functions as an endothelial cell mitogen and increases vascular permeability, thereby promoting the deposition of the extravascular fibrin matrix. At early stages of healing, VEGF is mainly generated by keratinocytes at wound edges, whereas at later stages it is also produced by the granulation tissue [Brown et al. 1992; Fukumura et al. 1998; Kishimoto et al. 2000]. VEGF is up-regulated by FGF-2 produced by injured cells [Martin 1997]. We found that P-Net is expressed in cells that express VEGF. Early after wounding, P-Net is detected at wound edges in keratinocytes that express VEGF, but not in adjacent normal skin that does not express VEGF. Interestingly, in normal skin, net RNA can be detected in the epidermis and hair follicles, and low levels of P-Net are detectable in hair follicles and epidermis [data not shown]. VEGF is also expressed in growing hair follicles and at low levels in the epidermis [Kishimoto et al. 2000]. Later during healing, mononuclear cells that contribute to the formation of granulation tissue express high levels of P-Net and VEGF, and become the principal cells that express these two molecules. VEGF expression is impaired in keratinocytes and mononuclear cells of the wound in net/H9254/H9254 mice, indicating that Net is required for VEGF up-regulation. The same cells express P-Net and VEGF, suggesting that P-Net regulates VEGF expression in response to inducing signals. Defects in VEGF production have previously been associated with impaired wound healing [Frank et al. 1995].

VEGF-dependent angiogenesis and capillary hyperpermeability are important in the adult animal, in the uterus and corpus luteum during the female reproductive cycle [Chakraborty et al. 1995; Halder et al. 2000; Ma et al. 2001], in the kidney [Kaipainen et al. 1993; Peters et al. 1993; Simon et al. 1995], and in the liver [LeCouter et al. 2003]. P-Net is up-regulated at sites of VEGF expression, including the stroma of the uterus during the estrous cycle and during pregnancy, the lutein cells of the corpus luteum during pregnancy, the distal
These cells produce angiogenic lesions resembling KS in taner et al. 2003). Stable ectopic expression of KSHV–KSVH genes have transforming potential, KSHV–GPCR novel herpesvirus KSHV or HHV8. Although many angiogenesis and VEGF expression are dependent on Net. However, we do not know to what extent Net may be a general regulator of angiogenesis and VEGF expression.

We have not observed any overt defects in vascularization during development or in adult net+/− mice. Furthermore, stromal but not epithelial cells of the uterus have decreased VEGF levels in net mutant mice (data not shown). There are different explanations for these observations. Net may regulate angiogenesis and VEGF expression in response to specific signals in some defined situations. A complex balance of positive and negative factors regulates angiogenesis, and a variety of factors have been shown to regulate adult angiogenesis but to have no effect during development [Carmeliet and Jain 2000; Rossant and Howard 2002]. Established vasculature in the adult is more stable and is regulated by different mechanisms compared to embryonic development. VEGF is regulated by many factors, including cytokines, growth factors, hypoxia, differentiation, and transformation, and there are multiple routes to VEGF induction [Ferrara and Davis-Smyth 1997; Kerbel and Folkman 2002; Mazure et al. 2003]. We have shown that Net in the presence of Ras-V12 activates VEGF expression through a mechanism involving Sp1 in cell culture, raising the possibility that Net has a specific role in this particular pathway in different processes in the animal. There could also be compensation for Net functions by related factors [Elk-1 and Sap-1] in net mutant animals, and experiments in double, triple, and conditional knockout mice could be used to study this possibility. Net mutant mice develop chylothorax, a phenotype associated with the lymphatic system [Ayadi et al. 2001b]. VEGF as well as VEGF-C are required for lymphangiogenesis [Lymphoussaki et al. 1999; Nagy et al. 2002], raising the possibility that altered expression of VEGF may lead to the defect observed in Net mutant mice. Furthermore, the VEGF-C promoter contains an Sp1 element [Chiov et al. 1997], suggesting that Net may also regulate VEGF-C expression, and this may be a link with the phenotype.

Kaposi’s sarcomas (KS) are cancerous angiogenic red skin lesions that are observed mainly in AIDS patients. All forms of KS are associated with infections with the novel herpesvirus KSHV or HHV8. Although many KSHV genes have transforming potential, KSHV–GPCR induced focus formation in NIH-3T3 cells, and these cells produce angiogenic lesions resembling KS in nude mice. KSHV–GPCR expression activates ERK and p38 MAP kinase signaling pathways and VEGF expression [Bais et al. 1998]. To study the role of Net in tumor angiogenesis, we used KSHV–GPCR-transformed NIH3T3 cells with down-regulated endogenous Net. The tumors lacking Net grew more slowly in nude mice, and were visibly less angiogenic with fewer vessels. Decreased angiogenesis was confirmed by IHC and quantitation of the number of vessels and the total area occupied by vessels. Furthermore, as expected from reduced angiogenesis, the tumors had diminished oxygen tension. These results show that Net is required for angiogenesis induced by KSHV–GPCR-transformed cells. We also showed that KSHV–GPCR expression induces Net phosphorylation through ERK and p38 MAP kinase signaling pathways and increases its transcriptional activity. Down-regulation of Net decreases VEGF expression, showing that Net is required for KSHV–GPCR-induced VEGF expression. Conditioned medium from KSHV–GPCR-expressing cells contains factors that induce microtube formation by HUVECs, principally VEGF [Bais et al. 1998]. Down-regulation of Net inhibited the ability of KSHV–GPCR-conditioned medium to induce microtube formation, and adding VEGF restored this activity. These results show that KSHV–GPCR increases the levels of P-Net, leading to augmented VEGF levels. Interestingly, we observed increased P-Net levels in human KS samples, in transformed cells that express VEGF and contain activated P-ERK. Taken together, these results show that Net is required for angiogenesis and VEGF expression by KSHV–GPCR.

A variety of assays have been used to study angiogenesis, which are more or less complex. The complex assays represent angiogenesis more faithfully, but the mechanisms involved are poorly understood. The simpler assays are more controlled, but only partially reproduce the process [Jain et al. 1997; Auerbach et al. 2003]. We used four classical assays, endothelial cell microtube formation (see above), endothelial cell proliferation induced with KSHV–GPCR-conditioned medium (data not shown), FGF-2–induced corneal angiogenesis, and aortal sprouting. FGF-2–induced angiogenesis is reduced in the latter two assays using net+/− mutant mice, showing that net is required for FGF-2–induced angiogenesis. FGF-2 induces Net phosphorylation, in smooth muscle cells in the aorta and in fibroblasts in culture. Inhibition of the ERK signaling cascade inhibits FGF-2–induced Net phosphorylation and aortal sprouting. FGF-2 has been shown to up-regulate VEGF in vascular smooth muscle cells [Stavri et al. 1995]. VEGF addition restores sprouting in the net mutant mice to the same levels as those in the wild type. These results show that Net is required for FGF-2–induced angiogenesis in several assays, and are consistent with Net having a role in ERK-dependent VEGF expression.

Several of the assays used involve net+/− mutant mice. The net+/− mutation was shown to decrease Net activity [Ayadi et al. 2001b]. It is highly unlikely that the mutant protein (that lacks the DNA-binding domain) acts in a trans-dominant manner, because heterozygous
mice have no detectable phenotype. In the present study in other assays, have down-regulated Net with antisense. Furthermore, down-regulation and up-regulation of Net have converse effects on VEGF expression. It is unlikely that the consistent conclusions are due to undetected artifacts in the different experiments.

We investigated the mechanisms by which Net regulates VEGF expression, using transfection assays and EMSA in fibroblasts. Net expression markedly increases Ras-V12 activation of VEGF promoter activity and endogenous VEGF expression. Conversely, when we down-regulated endogenous Net with net-antisense, VEGF promoter activity in the presence of Ras-V12 was impaired (data not shown). Elevated VEGF levels were detected only in the transfected cells, indicating that the mechanism does not involve secretion of inducers of VEGF expression, which would be expected to increase VEGF expression in neighboring nontransfected cells. A small region of the mouse promoter (−80 to −53) is sufficient to mediate Net + Ras-V12 activation. These sequences specifically bind Sp1 and to a lesser extent Sp3 in EMSA experiments with extracts from Net + Ras-V12-transfected cells. Mithramycin A, which is considered to be a specific inhibitor of Sp1 (Gambari et al. 2000; Marinovic et al. 2002), impairs Net + Ras-V12 activation of the promoter. Net is activated by Ras-V12 expression through phosphorylation by an ERK-dependent pathway. These results indicate that activated P-Net augments VEGF expression through a mechanism that probably involves Sp1 and Sp3. However, we detected additional minor complexes with EMSA, indicating that other factors may also be involved. AP2 and Egr1 have been shown to bind to the related region of the human promoter (Gille et al. 1997).

Sp1 and HIF1 were shown to be two major regulators of VEGF expression, in response to MAPK signaling pathways and hypoxia (Ferrara and Davis-Smyth 1997; Mazure et al. 2003). The Sp1 element is regulated independently of HIF1 by a large number of factors, including fluid shear stress (Urbich et al. 2003), oxidative stress (Sen et al. 2002; Schafer et al. 2003), interferon α (von Marschall et al. 2003), retinoic acid (Maeno et al. 2002), HPV16 E6 (Lopez-Ocejo et al. 2000), p73 (Salimath et al. 2000), p53 (Zhang et al. 2000), Pal et al. 2001), endotoxin (Sakuta et al. 2001), VHL (Mukhopadhyay et al. 1997), and PDGF (Finkenzeller et al. 1997). The mechanisms of regulation are far from being resolved, but they include protein–protein interactions and stability (Mukhopadhyay et al. 1997), increased binding due to phosphorylation (Milanini-Mongiat et al. 2002; Reisinger et al. 2003), and increased synthesis (Maeno et al. 2002). Sp1 is also regulated by glycosylation and acetylation (Bouwman and Philipson 2002). The precise mechanisms of P-Net regulation through the Sp1 elements will require further investigation. We did not detect Net by supershift in EMSA, suggesting that Net is not in the complexes that form on the responsive element, at least in the conditions tested. In some experiments we observed a small increase in the Sp1 complex in EMSA with extracts from Net + Ras-V12-transfected cells, raising the possibility that there could be effects on the binding affinity, degradation, or synthesis of Sp1. Clearly an important future goal is to establish the mechanisms by which many different factors regulate VEGF expression through the Sp1-binding element of the VEGF promoter.

Many cancer cells acquire the ability to synthesize growth factors that induce the switch and maintain abnormally activated angiogenesis (Hanahan and Folkman 1996). In several types of human tumor, we detected high levels of phospho-ERK, phospho-Net, and VEGF in the same group of transfected cells, but not in adjacent normal epithelial and stromal cells. We conclude from this study that the Net transcription factor regulates angiogenesis and VEGF expression in response to growth factors and oncogenes. Our findings provide a new and important link in understanding the crucial upstream events in the angiogenic process.

Materials and methods

Recombinants

We used pCEFL–KSHV–GPCR and control pCEFL [Bais et al. 1998], p601D-antisense-net, pTL2-Net, pCMV LacZ (Giovane et al. 1994), pHa-Ras-V12 and control pΔRas (Wasylyk et al. 1987); pSG5-puromycin [IGBMRC core facility], pEGFP-N1-anti-net, Net cDNA in the 3′–5′ orientation between the Xhol and BamHII sites of pEGFP-N1 (Clontech); TD-Net, pTL2-Net [219–409] as described in Maira et al. (1996); and mouse VEGF-Luc reporters (−1217/+370 and −449/+370; Shima et al. 1996). The VEGF promoter reporters with 5′ (−204, −125, −80, −80 mut, −53, −40/+370) and 3′ (−80/+69, −80/+10) deletions were generated by subcloning MluI/BglII PCR fragment in the corresponding sites of pGL2 basic and sequenced. The −80 mut is derived from the −80 construct, and has a −73 GGGGCGGG −66 to CTCGAGGG mutation in the upstream Sp1 motif. TK-pGL2 and its derivatives with the −80/−10, −80/−38, and −80/−53 VEGF sequences upstream were prepared in two steps. Oligonucleotides with 5′ Sp1h and 3′ XbaI sites were kinased and ligated into pBLCAT4 (Criqui-Filipe et al. 1999), and the PvrII–BglII fragments containing the VEGF promoter elements and the TK promoter were transferred into the Smal–BglII sites of pGL2 Basic and sequenced.

Cell culture

Transfections in NIH3T3 for phosphorylation, promoter activities, VEGF peptide measurements, and conditioned medium: NIH3T3 cells were transfected by the calcium phosphate technique with 0.5 µg pCEFL–KHSV–GPCR [pCEFL as control] or 0.5 µg pRASCTRb2 [Ras-V12] [pΔRas as control], 1 µg p601D-antisense-net [p601D as control]. Following the washes to remove the transfection reagent, the cells were cultured in 7% FCS for 24 h (phosphorylation by Ras-V12 and GPCR, Fig. 4A), 0.05% FCS for 36 h [VEGF expression, Fig. 4C], or 0.5% FCS for 48 h [microtubule-forming assay; Fig. 3D–I]. From 2 mL medium, 1 mL was used for the microtubule-forming assays and 50 µL for the VEGF ELISA assays [mouse-VEGF Quantikine kit, R&D Systems]. VEGF values were corrected for cell number.

GPCR transformed clones: NIH3T3 cells were transfected by the calcium phosphate technique with 0.5 µg pCEFL–KHSV–GPCR and selected with 750 µg/mL G418. Stable clones were expanded and analyzed by reverse transcriptase PCR [RT–PCR].

Net regulates the angiogenic switch
for the expression of GPCR. Transformed clones that expressed GPCR were retransfected with pSG5-puromycin and pEGFP-N1-anti-net or pEGFP-N1 and selected with 750 µg/mL G418 and 2 µg/mL puromycin [Sigma]. Individual clones and pools were expanded and analyzed by Western blotting [Fig. 2A].

Promoter activity measurements, Western blots, ICC, and EMSA of transfected cells: NIH3T3 cells were transfected with the calcium phosphate technique [2 µg pTL2Net, 0.5 µg pRasCTBx2 [Ras-V12], 1 µg mouse-VEGF-promoter-Luc constructs, 15 µg pCMV LacZ or the corresponding empty vectors in 6-well plates]. After removal of the precipitate, the cells were incubated in medium containing 0.05% FCS for 36 h, and extracts were prepared for the Western blots and luciferase assays. Luciferase activities, from three experiments with two plasmid preparations, were corrected for β-galactosidase activity expressed from the internal control and used to calculate fold activation relative to control vectors.

Western blots
Transfections: NIH3T3 cells were transfected with expression vectors for GPCR or Ras-V12, or their controls [pCEFL and pRas, respectively]. Three hours after the wash, the cells were treated with 10 µM SB203580 [Alexis] or 10 µM U0126 [Promega] for 30 min, and, after a further 6–8 h in Dulbecco + 7% FCS, the cells were harvested for SDS-PAGE and Western blotting with antibodies against phospho-Ser365-Net (2F3, Ducret et al. 2000), phosphorylated ERK [V8031, Promega], and TBP.

FGF-2 treatment: NIH3T3 cells were pretreated with SB203580 and U0126 as described above, washed, treated with 40 ng/mL FGF-2 [R&D Systems] for 15 min, harvested, and analyzed by SDS-PAGE and Western-blotting as above.

Stable clones: Cell extracts were analyzed by SDS-PAGE and Western blotting with antibodies against endogenous Net [Ab #375] and Elk-1 [Ab #512, Giovane et al. 1994].

Endogenous VEGF expression measurements: NIH3T3 cells were transfected with 2 µg pTL2-Net and 0.5 µg pRasCTBx2 [Ras-V12] per well and, 36 h after the wash, cell extracts were analyzed by SDS-PAGE and Western blotting [anti-phospho-Net (2F3), goat anti-VEGF [R&D], and mouse anti-TBP [IGBMC]].

Immunohistochemistry
Published methods for histology and immunostaining were used [Bergers et al. 1999; Holash et al. 1999]. Eight-micrometer adjacent paraffin sections were dehydrated, rehydrated in 0.1 M citrate for 60 min at 94°C, cooled for 60 min, incubated with primary antibodies [phospho-ERK #9101, Cell Signalling, 1/50 in TBST; human VEGF [AF-283-NA, R&D Systems], 1/200 in PBST; phospho-Net, (2F3 and 1F12, IGBMC), 1/500 in PBST, CD31 [01951A, Pharmingen], 1/50 in PBST] for 3 h at 25°C followed by overnight at 4°C, and stained with the VECTASTAIN Elite ABC kit [Vector Laboratories]. For VEGF detection, the same conditions were used for the sections from the net−/− as for the wild-type mice. For P-Net and VEGF co-localization, 10-µm cryostat sections were fixed with 2% PFA at 4°C for 10 min. They were incubated with antibodies against P-Net [2F3 and 1F12, 1:50] for 2 h at room temperature and at 4°C overnight, followed by FITC-conjugated anti-mouse [Jackson, 1:500] at room temperature for 1 h. The slides were then incubated with antibodies against VEGF [Santa Cruz, sc-507, 1:50] for 2 h at room temperature and at 4°C overnight, followed by Texas-Red conjugated anti-rabbit [Jackson, 1:500] at room temperature for 1 h. For hypoxic tension detection, 10 µM EF5 [Lord et al. 1993] was injected into mice bearing tumors (1 mg per mouse) 4 h before sacrifice. Ten-micrometer cryostat sections were stained with anti-EF5 antibody coupled to Cy5, and analyzed with a computer-controlled fluorescence microscope and digital camera, with identical exposure. EF5, the anti-EF5 antibody coupled to Cy5, the controls, and the protocols were obtained from The Radiation Oncology Imaging Service Center, University of Pennsylvania.

Immunocytochemistry
NIH3T3 cells [1 × 10⁶ cells in 6-well plates] grown on coverslips were transfected in the same conditions as for the VEGF-promoter luciferase assays. Forty-eight hours after the precipitate was washed off, the cells were fixed for 10 min with 2% PFA in PBS on ice and then permeabilized with 0.1% Triton X-100 in 0.1% sodium citrate for 15 min at room temperature. The coverslips were washed with PBS, blocked with PBS containing 3% bovine serum albumin [BSA] for 30 min, incubated with the first antibody [anti-P-Net (2F3) mouse monoclonal diluted 1:600; antibodies were diluted in PBS containing 0.3% BSA] for 2 h at 37°C, washed five times, and then incubated with the second antibody [rabbit polyclonal anti-VEGF [Santa Cruz] 1:200] for 2 h at 37°C. They were washed five times with 0.2% Tween-20 in PBS and incubated for 60 min at 37°C with FITC-conjugated anti-mouse IgG (diluted 1:100) and Texas-Red-conjugated anti-rabbit [diluted 1:250]. The cells were stained with 0.5 mg/mL DAPI for 2 min and washed five times with PBS-Tween. The coverslips were mounted on microscope slides using VECTASHIELD mounting medium for fluorescence and examined by confocal microscopy.

Wound healing and tumor angiogenesis
Wound healing: The protocols were adapted from Ortega et al. [1998]. After applying an 8-mm-diam full-thickness skin wound in 4-week-old male mice, wound surfaces were measured and photographed every 2 d, with and without removing the clot. After the wounds had healed totally, the same mice were used to generate independent wounds [more than 1 cm from the first wounds] that were used for histological analysis 2 or 6 d after wounding.

Tumor angiogenesis: Stably KSHV–GPCR-transformed cells [3 × 10⁵/200 µL PBS/animal] were detached with 3 mM EDTA in PBS, resuspended in PBS, and injected subcutaneously in the left flank of 8-week-old female BALB/c nu/nu mice. The smaller and larger tumor diameters were measured every 2 d, with four calipers, and tumor volumes were calculated [V = 4/3 × π × (1/2 × smaller diameter)² × (1/2 × larger diameter)]. Sixteen days after injection the mice were sacrificed, and 10-µm paraffin tumor sections were prepared for immunohistochemical analysis. To measure the proportion of the area occupied by vessels, and the number of vessels, we analyzed five representative sections per tumor, and three tumors for each clone. Four randomly selected x100 fields for each section were analyzed with a computer-controlled microscope and digital camera. Morphometric analysis [number and size of vessels in tumor mass] was performed with NsurfX software [Baldock et al. 1997]. The vessels were recognized by their dark-gray stained walls. The number of vessels is the total number of individual vessels that were observed. The size of each vessel is the total area of its lumen and walls. The total vessel-occupied area is the sum of the areas occupied by all of the vessels.

Angiogenesis models in vitro
For the mouse aortic ring angiogenesis assay [Nicussia and Ottini 1990; Rohan et al. 2000], thoracic aortas were excised from...
four pairs of 2- to 4-week-old net+/− mice and their wild-type littermates, washed, cut into 1-mm-long sections, and placed upright in 400 µL of Matrigel [Becton Dickinson Labware] that was allowed to solidify for 30 min. The sections were incubated for 24 h in EG2-1 [Clonetic] followed by 3 d in EBM [Clonetic] with 40 ng/mL FGF-2 [R&D Systems] alone or combined with 60 ng/mL VEGF [R&D Systems] for rings from mutant mice. The microvessel sprouts were examined on day 4. After photography, frozen sections were prepared from the gels containing the rings and sprouts. For the corneal micropocket assay [Kenyon et al. 1996], Hydron (Sigma) pellets containing 90 ng FGF-2 and 45 ng sucrose were implanted in corneal pockets on both eyes of four pairs of 4-week-old net+/− mice and their wild-type littermates. The eyes were examined by biomicroscopy after 3–6 d. For the microtubule formation assay (Bais et al. 1998), 24-well plates were coated with 120 µL per well of Matrigel [Becton Dickinson Labware] for 30 min 37°C. HUVEC cells [107 in 0.5% FCS] were added to allow, the medium was removed, conditioned medium was added (1 mL/well, see Cell Culture), and after 24 h the plates were photographed. For anti-VEGF antibody inhibition and VEGF stimulation, conditioned medium was preincubated with 0.2 µg/mL of anti-mouse-VEGF polyclonal antibody (R&D Systems) or 10 ng/mL of recombinant human VEGF [R&D Systems] for 1 h at room temperature before putting it on the cells.

Electrophoretic mobility shift assays

Nuclear extracts were prepared from NIH3T3 cells that had been transfected under the same conditions as for the VEGF promoter luciferase assays. The transfection efficiencies were up to 30%, as measured by the fluorescence of pGFP-C1 [Promega] transfected in control plates. Nuclei were isolated using the rapid micropreparation technique [Andrews and Faller 1991]. The nuclear pellets were resuspended in cold Buffer C, and protein was quantified by the Bradford assay. The probes, corresponding to the −79 to −51 sequence of the mouse VEGF promoter [wild type: 5′-GTCCCCGGGGCTTGCTGGGCCTGGG GTGTAAAGGGGTGT-3′; Sp1 motif mutant: 5′-GTCCCCGGTGTGGGC TGGTAAAAAGGGGTGT-3′], were end-labeled with γ-[32P] ATP [Amersham Bio] and purified on 10% acrylamide gels. The DNA binding reactions were performed with 5 µg nuclear protein and 100,000 cpm [32P]-labeled oligonucleotides for 30 min in 20 µL of binding buffer [10 mM Tris-HCl at pH 7.5, 1 mM MgCl2, 50 mM NaCl, 0.5 mM dithiothreitol, 0.5 mM EDTA, 4% glycerol, 1 µg of poly[dI-dC], and 0.2% NP40]. The specificity controls were the mutant Sp1 probe and competition reactions in which 50-, 200-, and 1000-fold molar excesses of unlabeled Sp1 oligonucleotides were added to the binding reaction 10 min prior to the addition of the radiolabeled probe. For supershift assays, antibodies [1 µg per reaction of mouse anti-Sp1 and anti-Sp3 protein [Santa Cruz Biotechnology] and mouse anti-Nef α1] were added to the reaction mixture for 10 min at 4°C before the addition of the probe. Electrophoresis was performed on 5% polyacrylamide gels in 0.25x TBE for 4 h at 280–800 V/10–15 mA at 4°C.
