A case study of the difficulty of quantifier elimination in constraint databases: the alibi query in moving object databases.

Walied Othman¹ Bart Kuijpers² Rafael Grimson³

In the constraint database model, spatial and spatio-temporal data are stored by boolean combinations of polynomial equalities and inequalities over the real numbers. The relational calculus augmented with polynomial constraints is the standard first-order query language for constraint databases. Although the expressive power of this query language has been studied extensively, the difficulty of the efficient evaluation of queries, usually involving some form of quantifier elimination, has received considerably less attention. The inefficiency of existing quantifier-elimination software and the intrinsic difficulty of quantifier elimination have proven to be a bottle-neck for real-world implementations of constraint database systems.

In this paper, we focus on a particular query, called the alibi query, that was proposed in the context of moving object databases and that asks whether two moving objects whose positions are known at certain moments in time, could have possibly met, given certain speed constraints. This query can be seen as a constraint database query and its evaluation relies on the elimination of a block of three existential quantifiers. Implementations of general purpose elimination algorithms, such as provided by QEPCAD, Redlog and Mathematica, are in the specific case, for practical purposes, too slow in answering the alibi query and fail completely in the parametric case.

The main contribution of this paper is an analytical solution to the parametric alibi query, which can be used to answer this query in the specific case in constant time. We also give an analytic solution to the alibi query at a fixed moment in time, which asks whether two moving objects that are known at discrete moments in time could have met at a given moment in time, given some speed constraints.

The solutions we propose are based on geometric argumentation and they illustrate the fact that some practical problems require creative solutions, where at least in theory, existing systems could provide a solution.

General Terms: Theory, Mathematical Logic, Query Languages, Spatial databases

Additional Key Words and Phrases: Constraint databases, moving objects, beads, alibi query

1. INTRODUCTION AND SUMMARY

The framework of constraint databases was introduced in 1990 by Kanellakis, Kuper and Revesz [Kanellakis et al. 1995] as an extension of the relational database model that allows the use of infinite, but first-order definable relations rather than just finite relations. It provides an elegant and powerful model for applications that
deal with infinite sets of points in some real affine space $\mathbb{R}^n$, such as spatial and spatio-temporal databases [Paredaens et al. 1994]. In the setting of the constraint model, infinite relations in spatial or spatio-temporal databases are finitely represented as boolean combinations of polynomial equalities and inequalities, which are interpreted over the real numbers.

Various aspects of the constraint database model are well-studied by now. For an overview of research results we refer to [Paredaens et al. 2000] and the textbook [Revesz 2002]. The relational calculus augmented with polynomial constraints, or equivalently, first-order logic over the reals augmented with relation predicates to address the database relations $R_1, \ldots, R_m$, $\text{FO}(+, \times, <, 0, 1, R_1, \ldots, R_m)$ for short, is the standard first-order query language for constraint databases. The expressive power of first-order logic over the reals, as a constraint database query language, has been studied extensively [Paredaens et al. 2000]. It is well-known that first-order constraint queries can be effectively evaluated [Tarski 1951; Paredaens et al. 2000]. However, the difficulty of the efficient evaluation of first-order queries, usually involving some form of quantifier elimination, has been largely neglected [Heintz and Kuijpers 2004]. The existing constraint database systems or prototypes, such as Dedale and Disco [Paredaens et al. 2000, Chapters 17 and 18] are based on general purpose quantifier-elimination algorithms and are, in most cases, restricted to work with linear data, i.e., they use first-order logic over the reals without multiplication [Paredaens et al. 2000, Part IV]. Of the general purpose elimination algorithms [Basu et al. 1996; Collins 1975; Grigor’ev and Vorobjov 1988; Heintz et al. 1990; Renegar 1992], some are now available in software packages such as QEPCAD [Hong 1990], Redlog [Sturm 2000] and Mathematica [Wolfram 2007]. But the intrinsic inefficiency of quantifier elimination and the inefficiency of its current implementations represent a bottle-neck for real-world implementations of constraint database systems [Heintz and Kuijpers 2004].

In this paper, we focus on a case study of quantifier elimination in constraint databases. Our example is the alibi query in moving object databases, which was introduced and studied in the area of geographic information systems (GIS) [Pfoser and Jensen 1999; Egenhofer 2003; Hornsby and Egenhofer 2002; Miller 2005]. This query can be expressed in the constraint database formalism and, at least in theory could be answered, both in the specific and the parametric case, by existing implementations of quantifier elimination over the reals. The evaluation of the alibi query adds up to the elimination of a block of three existential quantifiers. It turns out that packages such as QEPCAD [Hong 1990], Redlog [Sturm 2000] and Mathematica [Wolfram 2007], can only solve the alibi query in specific cases, with a running time that is not acceptable for moving object database users. In the parametric case, these quantifier-elimination implementations fail miserably. The main contribution of this paper is a theoretic and practical solution to the alibi query in the parametric case (and thus the specific cases).

The research on spatial databases, which started in the 1980s from work in geographic information systems, was extended in the second half of the 1990s to deal with spatio-temporal data. In this field, one particular line of research, started by Wolfson, concentrates on moving object databases (MODs) [Güting and Schneider 2005; Wolfson 2002], a field in which several data models and query languages have
been proposed to deal with moving objects whose position is recorded at discrete moments in time. Some of these models are geared towards handling uncertainty that may come from various sources (measurements of locations, interpolation, ...). Several query formalisms have been proposed [Su et al. 2001; Geerts 2004; Kuijpers and Othman 2007]. For an overview of models and techniques for MODs, we refer to the book by Güting and Schneider [Güting and Schneider 2005].

In this paper, we focus on the trajectories that are produced by moving objects and which are stored in a database as a collection of tuples $(t_i, x_i, y_i)$, $i = 0, ..., N$, i.e., as a finite sample of time-stamped locations in the plane. These samples may have been obtained by GPS-measurements or from other location aware devices.

One particular model for the management of the uncertainty of the moving object’s position in between sample points is provided by the bead model. In this model, it is assumed that besides the time-stamped locations of the object also some background knowledge, in particular a (e.g., physically or law imposed) speed limitation $v_i$ at location $(x_i, y_i)$ is known. The bead between two consecutive sample points is defined as the collection of time-space points where the moving objects can have passed, given the speed limitation (see Figure 1 for an illustration). The chain of beads connecting consecutive trajectory sample points is called a lifeline necklace [Egenhofer 2003]. Whereas beads were already conceptually known in the time geography of Hägerstrand in the 1970s [Hägerstrand 1970], they were introduced in the area of GIS by Pfoser [Pfoser and Jensen 1999] and later studied by Egenhofer and Hornsby [Egenhofer 2003; Hornsby and Egenhofer 2002], and Miller [Miller 2005], and in a query language context by the present authors [Kuijpers and Othman 2007].

In this setting, a query of particular interest that has been studied, mainly by Egenhofer and Hornsby [Egenhofer 2003; Hornsby and Egenhofer 2002], is the alibi query. This boolean query asks whether two moving objects, that are given by samples of time-space points and speed limitations, can have physically met. This question adds up to deciding whether the necklaces of beads of these moving objects intersect or not. This problem can be considered solved in practice, when we can efficiently decide whether two beads intersect.

Although approximate solutions to this problem have been proposed [Egenhofer 2003], also an exact solution is possible. We show that the alibi query can be formulated in the constraint database model by means of a first-order query. Experiments with software packages such as QEPCAD [Hong 1990], Redlog [Sturm 2000] and Mathematica [Wolfram 2007] on a variety of beads show that deciding if two concrete beads intersect can be computed on average in 2 minutes (running Windows XP Pro, SP2, with a Intel Pentium M, 1.73GHz, 1GB RAM). This means that evaluating the alibi query on the lifeline necklaces of two moving objects that each consist of 100 beads would take around $100 \times 100 \times 2$ minutes, which is almost two weeks, or, if we work with ordered time intervals and first test on overlapping time intervals, $(100 + 100) \times 2$ minutes, which is almost 7 hours. Clearly, such an amount of time is unacceptable.

Another solution within the range of constraint databases is to find a formula, in which the apexes and limit speeds of two beads appear as parameters, that parametrically expresses that two beads intersect. We call this problem the parametric
alibi query. A quantifier-free formula for this parametric version could, in theory, also be obtained by eliminating one block of three existential quantifiers from a formula with 17 variables using existing quantifier-elimination packages. We have attempted this approach using Mathematica, Redlog and QEPCAD, but after several days of running, with the configuration described above, we have interrupted the computation, without successful outcome. Clearly, the eliminating a block of three existential quantifiers from a formula in 17 variables is beyond the existing quantifier-elimination implementations. In fact, it is well known that these implementations fail on complicated, higher-dimensional problems. The benefit of having a quantifier-free first-order formula that expresses that two beads intersect is that the alibi query on two beads can be answered in constant time. The problem of deciding whether two lifeline necklaces intersect can then be done in time proportional to the product (or the sum, if we first test on overlapping time intervals) of the lengths of the two necklaces of beads.

The main contribution of this paper is the description of an analytic solution to the alibi query. We give a quantifier-free formula, that contains square roots, however, and that expresses the (non-)emptiness of the intersection of two parametrically given beads. Although, in a strict sense, this formula cannot be seen as quantifier-free first-order formula (due to the roots), it still gives the above mentioned complexity benefits. Also, this formula with square roots can easily be turned into a quantifier-free formula of similar length. At the basis of our solution is a geometric theorem that describes three exclusive cases in which beads can intersect. These three cases can then be transformed into an analytic solution that can be used to answer the alibi query on the lifeline necklaces of two moving objects in less than a minute. This provides a practical solution to the alibi query.

To back up our claim that the execution time of our method requires milliseconds or less we implemented this in Mathematica and compared it to using traditional quantifier elimination to decide this query. We have included this implementation in the Appendix and used it to perform numerous experiments which only confirm our claims.

We give another example of a problem where common sense prevails over the existing implementations of general quantifier elimination methods. This problem is the alibi query at a fixed moment in time, which asks whether two moving objects that are known at discrete moments in time could have met at a given moment in time. This problem can be translated in deciding whether four disks in the two-dimensional plane have a non-empty intersection. Again, this problem can be formulated in the context of the constraint model and adds up to the elimination of a block of two existential quantifiers. Also for this problem we provide an exact solution in terms of a quantifier-free formula.

This paper is organized as follows. In Section 2, we describe a model for trajectory (or moving object) databases with uncertainty using beads. In Section 3, we discuss the alibi query. The geometry of beads is discussed in Section 4. An analytic solution to this query is given in Section 5 and experimental results in Section 6 of our implementation that can be found in the Appendix. The alibi query at a fixed moment in time is solved in Section 7.
2. A MODEL FOR MOVING OBJECT DATA WITH UNCERTAINTY

In this paper, we consider moving objects in the two-dimensional \((x, y)\)-space \(\mathbb{R}^2\) and describe their movement in the \((t, x, y)\)-space \(\mathbb{R} \times \mathbb{R}^2\), where \(t\) is time (we denote the set of the real numbers by \(\mathbb{R}\)).

In this section, we define trajectories, trajectory samples, beads and trajectory (sample) databases. Although it is more traditional to speak about moving object databases, we use the term trajectory databases to emphasize that we manage the trajectories produced by moving objects.

2.1 Trajectories and trajectory samples

Moving objects, which we assume to be points, produce a special kind of curves, which are parameterized by time and which we call trajectories.

**Definition 1.** A trajectory \(T\) is the graph of a mapping \(I \subseteq \mathbb{R} \rightarrow \mathbb{R}^2 : t \mapsto \alpha(t) = (\alpha_x(t), \alpha_y(t))\), i.e.,

\[
T = \{(t, \alpha_x(t), \alpha_y(t)) \in \mathbb{R} \times \mathbb{R}^2 \mid t \in I\},
\]

where \(I\) is the time domain of \(T\). \(\square\)

In practice, trajectories are only known at discrete moments in time. This partial knowledge of trajectories is formalized in the following definition. If we want to stress that some \(t, x, y\)-values (or other values) are constants, we will use sans serif characters.

**Definition 2.** A trajectory sample is a finite set of time-space points \(\{(t_0, x_0, y_0), (t_1, x_1, y_1), \ldots, (t_N, x_N, y_N)\}\), on which the order on time, \(t_0 < t_1 < \cdots < t_N\), induces a natural order. \(\square\)

For practical purposes, we may assume that the \((t_i, x_i, y_i)\)-tuples of a trajectory sample contain rational values.

A trajectory \(T\), which contains a trajectory sample \(\{(t_0, x_0, y_0), (t_1, x_1, y_1), \ldots, (t_N, x_N, y_N)\}\), i.e., \((t_i, \alpha_x(t_i), \alpha_y(t_i)) = (t_i, x_i, y_i)\) for \(i = 0, \ldots, N\), is called a geospatial lifeline for this trajectory sample [Egenhofer 2003]. A common example of a lifeline, is the reconstruction of a trajectory from a trajectory samples by linear interpolation [Gütting and Schneider 2005].

2.2 Modeling uncertainty with beads

Often, in practical applications, more is known about trajectories than merely some sample points \((t_i, x_i, y_i)\). For instance, background knowledge like a physically or law imposed speed limitation \(v_i\) at location \((x_i, y_i)\) might be available. Such a speed limit might even depend on \(t_i\). The speed limits that hold between two consecutive sample points can be used to model the uncertainty of a moving object’s location between sample points.

More specifically, we know that at a time \(t\), \(t_i \leq t \leq t_{i+1}\), the object’s distance to \((x_i, y_i)\) is at most \(v_i(t - t_i)\) and its distance to \((x_{i+1}, y_{i+1})\) is at most \(v_i(t_{i+1} - t)\). The spatial location of the object is therefore somewhere in the intersection of the disc with center \((x_i, y_i)\) and radius \(v_i(t - t_i)\) and the disc with center \((x_{i+1}, y_{i+1})\) and radius \(v_i(t_{i+1} - t)\). The geometric location of these points is referred to as...
a bead [Pfoser and Jensen 1999; Egenhofer 2003] and defined, for general points
$p = (t_p, x_p, y_p)$ and $q = (t_q, x_q, y_q)$ and speed limit $v_{\text{max}}$ as follows.

\begin{align*}
\Psi_B(t, x, y, t_p, x_p, y_p, t_q, x_q, y_q, v_{\text{max}}) &:= (x - x_p)^2 + (y - y_p)^2 \leq (t - t_p)^2 v_{\text{max}}^2 \\
&\quad \land (x - x_q)^2 + (y - y_q)^2 \leq (t_q - t)^2 v_{\text{max}}^2 \land t_p \leq t \leq t_q.
\end{align*}

We denote this set by $B(p, q, v_{\text{max}})$ or $B(t_p, x_p, y_p, t_q, x_q, y_q, v_{\text{max}})$. □

In the formula $\Psi_B(t, x, y, t_p, x_p, y_p, t_q, x_q, y_q, v_{\text{max}})$, we consider $t_p, x_p, y_p, t_q, x_q,$
$y_q, v_{\text{max}}$ to be parameters, whereas $t, x, y$ are considered variables defining the subset
of $\mathbb{R} \times \mathbb{R}^2$.

Figure 2 illustrates the notion of bead in time-space. Whereas a continuous curve
connecting the sample points of a trajectory sample was called a geospatial lifeline,
a chain of beads connecting succeeding trajectory sample points is called a lifeline necklace [Egenhofer 2003].

2.3 Trajectory databases

We assume the existence of an infinite set $\text{Labels} = \{a, b, \ldots, a_1, b_1, \ldots, a_2, b_2, \ldots\}$ of
trajectory labels, that serve to identify individual trajectory samples. We now define
the notion of trajectory database.

\footnote{Later on, this type of formula’s will be refered to as $\text{FO}(+, \times, <, 0, 1)$-formulas.}

ACM Journal Name, Vol. V, No. N, 20YY.
Definition 4. A trajectory (sample) database is a finite set of tuples \((a_i, t_{i,j}, x_{i,j}, y_{i,j}, v_{i,j})\), with \(i = 1, ..., r\) and \(j = 0, ..., N_i\), such that \(a_i \in \text{Labels}\) cannot appear twice in combination with the same \(t\)-value, such that \(\{(t_{i,0}, x_{i,0}, y_{i,0}), (t_{i,1}, x_{i,1}, y_{i,1}), \ldots, (t_{i,N_i}, x_{i,N_i}, y_{i,N_i})\}\) is a trajectory sample for each \(i = 1, ..., r\) and such that the \(v_{i,j} \geq 0\) for each \(i = 1, ..., r\) and \(j = 0, ..., N_i\).

3. TRAJECTORY QUERIES AND THE ALIBI QUERY

In this section, we define the notion of trajectory database query, we show how constraint database languages can be used to query trajectories and we define the alibi query and the parametric alibi query.

3.1 Trajectory queries

A trajectory database query has been defined as a partial computable function from trajectory databases to trajectory databases [Kuijpers and Othman 2007]. Often, we are also interested in queries that express a property, i.e., in boolean queries. More formally, we can say that a boolean trajectory database query is a partial computable function from trajectory databases to \{True, False\}.

When we say that a function is computable, this is with respect to some fixed encoding of the trajectory databases (e.g., rational numbers are represented as pairs of natural numbers in bit representation).

3.2 A constraint-based query language

Several languages have been proposed to express queries on moving object data and trajectory databases (see [Güting and Schneider 2005] and references therein). One particular language for querying trajectory data, that was recently studied in detail by the present authors, is provided by the formalism of constraint databases. This query language is a first-order logic which extends first-order logic over the real numbers with a predicate \(S\) to address the input trajectory database. We denote this logic by \(\text{FO}(+, \times, <, 0, 1, S)\) and define it as follows.

Definition 5. The language \(\text{FO}(+, \times, <, 0, 1, S)\) is a two-sorted logic with label variables \(a, b, c, \ldots\) (possibly with subscripts) that refer to trajectory labels and real variables \(x, y, z, \ldots, v, \ldots\) (possibly with subscripts) that refer to real numbers. The atomic formulas of \(\text{FO}(+, \times, <, 0, 1, S)\) are

\[-P(x_1, ..., x_n) > 0,\] where \(P\) is a polynomial with integer coefficients in the real variables \(x_1, ..., x_n\);
\[-a = b;\] and
\[-S(a, t, x, y, v) (S\ is a 5-ary predicate).\]

The formulas of \(\text{FO}(+, \times, <, 0, 1, S)\) are built from the atomic formulas using the logical connectives \(\land, \lor, <, \ldots\) and quantification over the two types of variables: \(\exists x, \forall x\) and \(\exists a, \forall a\).

The label variables are assumed to range over the labels occurring in the input trajectory database and the real variables are assumed to range over \(\mathbb{R}\). The formula \(S(a, t, x, y, v)\) expresses that a tuple \((a, t, x, y, v)\) belongs to the input trajectory database. The interpretation of the other formulas is standard.
For example, the FO\((+, \times, <, 0, 1, S)\)-sentence
\[
\exists a \exists b (\neg (a = b) \land \forall t \forall x \forall y \forall v S(a, t, x, y, v) \leftrightarrow S(b, t, x, y, v))
\]
expresses the boolean trajectory query that says that there are two identical trajectories in the input database with different labels.

When we instantiate the free variables in a FO\((+, \times, <, 0, 1, S)\)-formula \(\varphi(a, b, \ldots, t, x, y, \ldots)\) by concrete values \(a, b, \ldots, t, x, y, \ldots\) we write \(\varphi[a, b, \ldots, t, x, y, \ldots]\) for the formula we obtain.

### 3.3 The alibi query

The *alibi query* is the boolean query which asks whether two moving objects, say with labels \(a\) and \(a'\), that are available as samples in a trajectory database, can have physically met. Since the possible positions of these moving objects are, in between sample points, given by beads, the alibi query asks to decide if the two lifeline necklaces of \(a\) and \(a'\) intersect or not.

More concretely, if the trajectory \(a\) is given in the trajectory database by the tuples \((a, t_0, x_0, y_0, v_0), \ldots, (a, t_N, x_N, y_N, v_N)\) and the trajectory \(a'\) by the tuples \((a', t'_0, x'_0, y'_0, v'_0), \ldots, (a', t'_M, x'_M, y'_M, v'_M)\), then \(a\) has an alibi for not meeting \(a'\) if for all \(i, 0 \leq i \leq N - 1\) and all \(j, 0 \leq j \leq M - 1\),
\[
B(t_i, x_i, y_i, t_{i+1}, x_{i+1}, y_{i+1}, v_{i+1}) \cap B(t'_j, x'_j, y'_j, t'_{j+1}, x'_{j+1}, y'_{j+1}, v'_{j+1}) = \emptyset. \quad (\dagger)
\]

We remark that the alibi query can be expressed by a formula in the logic FO\((+, \times, <, 0, 1, S)\), which we know give. To start, we denote the subformula
\[
S(a, t_1, x_1, y_1, v_1) \land S(a, t_2, x_2, y_2, v_2) \land \\
\forall t_3 \forall x_3 \forall y_3 \forall v_3 (S(a, t_3, x_3, y_3, v_3) \rightarrow \neg (t_1 < t_3 \land t_3 < t_2)),
\]
that expresses that \((t_1, x_1, y_1)\) and \((t_2, x_2, y_2)\) are consecutive sample points on the trajectory \(a\) by \(\sigma(a, t_1, x_1, y_1, v_1, t_2, x_2, y_2, v_2)\).

The alibi query on \(a\) and \(a'\) is then expressed as \(\varphi_{\text{alibi}}[a, a'] = \)
\[
\neg \exists x_1 \exists y_1 \exists x_2 \exists y_2 \exists t_1 \exists t_2 \exists v_1 \exists v_2 ((\sigma(a, t_1, x_1, y_1, v_1, t_2, x_2, y_2, v_2) \land \sigma(a', t'_1, x'_1, y'_1, v'_1, t'_2, x'_2, y'_2, v'_2) \land \exists x \exists y (t_1 \leq t \land t \leq t'_2 \land (x - x_1)^2 + (y - y_1)^2 \leq (t - t_1)^2 v_1^2 \land (x - x_2)^2 + (y - y_2)^2 \leq (t - t_2)^2 v_2^2)
\]

It is well-known that FO\((+, \times, <, 0, 1, S)\)-expressible queries can be evaluated effectively on arbitrary trajectory database inputs [Paredaens et al. 2000; Kuipjers and Othman 2007]. Briefly explained, this evaluation can be performed by (1) replacing the occurrences of \(S(a, t, x, y, v)\) by a disjunction describing all the sample points belonging to the trajectory sample \(a\); the same for \(a'\); and (2) eliminating all the quantifiers in the obtained formula. In concreto, using the notation from above, each occurrence of \(S(a, t, x, y, v)\) would be replaced in \(\varphi_{\text{alibi}}[a, a']\) by \(\bigvee_{i=0}^{N-1} (t = t_i \land x = x_i \land y = y_i \land v = v_i)\), and similar for \(a'\). This results in a (rather complicated) first-order formula over the reals \(\varphi_{\text{alibi}}[a, a']\) in which the predicate \(S\) does not occur any more. Since first-order logic over the reals admits the elimination of quantifiers (i.e., every formula can be equivalently expressed by a quantifier-free formula), we
can decide the truth value of $\dot{\varphi}_{\text{alibi}}[a, a']$ by eliminating all quantifiers from this expression. In this case, we have to eliminate one block of existential quantifiers.

We can however simplify the quantifier-elimination problem. It is easy to see, looking at (1) above, that $\neg \dot{\varphi}_{\text{alibi}}[a, a']$ is equivalent to

\[
\bigvee_{i=0}^{N-1} \bigvee_{j=0}^{M-1} \varphi_{\text{alibi}}[t_i, x_i, y_i, t_{i+1}, x_{i+1}, y_{i+1}, v_i, t_j', x_j', y_j', t_{j+1}', x_{j+1}', y_{j+1}', v_j'],
\]

where the restricted alibi-query formula $\varphi_{\text{alibi}}(t_i, x_i, y_i, t_{i+1}, x_{i+1}, y_{i+1}, v_i, t_j', x_j', y_j', t_{j+1}', x_{j+1}', y_{j+1}', v_j')$ abbreviates the formula

\[
\exists \exists \exists \exists (t_i \leq t \leq t_{i+1} \wedge t_j' \leq t \leq t_{j+1}' \wedge (x - x_i)^2 + (y - y_i)^2 \leq (t - t_i)^2 v_i^2 \wedge \\
(x - x_{i+1})^2 + (y - y_{i+1})^2 \leq (t_{i+1} - t)^2 v_i^2 \wedge \\
(x - x_j')^2 + (y - y_j')^2 \leq (t - t_j')^2 v_j'^2 \wedge (x - x_{j+1}')^2 + (y - y_{j+1}')^2 \leq (t_{j+1}' - t)^2 v_j'^2)
\]

that expresses that two beads intersect.

So, the instantiated formula

\[
\varphi_{\text{alibi}}[t_i, x_i, y_i, t_{i+1}, x_{i+1}, y_{i+1}, v_i, t_j', x_j', y_j', t_{j+1}', x_{j+1}', y_{j+1}', v_j']
\]

expresses (1). To eliminate the existential block of quantifiers ($\exists \exists \exists \exists \exists$) from this expression, existing software-packages for quantifier elimination, such as QEPCAD [Hong 1990], Redlog [Sturm 2000] and Mathematica [Wolfram 2007] can be used. We experimented with QEPCAD, Redlog and Mathematica to decide if several beads intersected. The latter two programs have a similar performance and they outperform QEPCAD. To give an idea of their performance, we give some results with Mathematica: the computation of $\varphi_{\text{alibi}}[0, 0, 1, 2, 2, \sqrt{3}, 0, 3, 3, 1, 2, 2, 2]$ took 6 seconds; that of $\varphi_{\text{alibi}}[0, 0, 0, 1, 2, 2, \sqrt{3}, 0, 3, 3, 4, 1, 2, 2, 2]$ took 209 seconds and the computation of $\varphi_{\text{alibi}}[0, 0, 0, 1, -1, -1, 1, 0, 1, 1, 2, -1, 1, 2]$ took 613 seconds. Roughly speaking, our experiments show that, using Mathematica, this quantifier elimination can be computed on average in about 2 minutes (running Windows XP Pro, SP2, with a Intel Pentium M, 1.73GHz, 1GB RAM). This means that evaluating the alibi query on the lifeline necklaces of two moving objects that each consist of 100 beads would take around $100 \times 100 \times 2$ minutes, which is almost two weeks, when applied naively and at most $(100 + 100) \times 2$ minutes or a quarter day, when first the intersection of time-intervals is tested. Clearly, in both cases, such an amount of time is unacceptable.

There is a better solution, however, which we discuss next, that can decide if two beads intersect or not in a couple of milliseconds.

3.4 The parametric alibi query

The uninstantiated formula

\[
\varphi_{\text{alibi}}(t_i, x_i, y_i, t_{i+1}, x_{i+1}, y_{i+1}, v_i, t_j', x_j', y_j', t_{j+1}', x_{j+1}', y_{j+1}', v_j')
\]

can be viewed as a parametric version of the restricted alibi query, where the free variables are considered parameters. This formula contains three existential quantifiers and the existing software-packages for quantifier elimination could be used to obtain a quantifier-free formula $\dot{\varphi}_{\text{alibi}}(t_i, x_i, y_i, t_{i+1}, x_{i+1}, y_{i+1}, v_i, t_j', x_j', y_j', t_{j+1}')$, which
that is equivalent to \( \psi_{alibi} \). The formula \( \tilde{\psi}_{alibi} \) could then be used to straightforwardly answer the alibi query in time linear in its size, which is independent of the size of the input and therefore constant. We have tried to eliminate the existential block of quantifiers \( \exists t \exists x \exists y \) from \( \psi_{alibi} \) using Mathematica, Redlog and QEPCAD. After some minutes of running, Redlog invokes QEPCAD. After several days of running QEPCAD on the configuration described above, we have interrupted the computation without result. Also Mathematica ran into problems without giving an answer. It is clear that eliminating a block of three existential quantifiers from a formula in 17 variables is beyond the existing quantifier-elimination implementations. Also, the instantiation of several parameters to adequately chosen constant values does not help to produce a solution. For instance, without loss of generality we can locate \( (t_i, x_i, y_i) \) in the origin \((0, 0, 0)\) and locate the other apex of the first bead above the \( y \)-axis, i.e., we can take \( x_{i+1} = 0 \). Furthermore, we can take \( v_i = 1 \) and \( t_{i+1} = 1 \). But Mathematica, Redlog and QEPCAD cannot also not cope with this simplified situation.

The main contribution of this paper is the description of a quantifier-free formula equivalent to \( \psi_{alibi}(t_i, x_i, y_i, t_{i+1}, x_{i+1}, y_{i+1}, v_i, t'_j, x'_j, y'_j, t'_{j+1}, x'_{j+1}, y'_{j+1}, v'_j) \). The solution we give is not a quantifier-free first-order formula in a strict sense, since it contains root expressions, but it can be easily turned into a quantifier-free first-order formula of similar length. It answers the alibi query on the lifeline necklaces of two moving objects that each consist of 100 beads in less than a minute. This description of this quantifier-free formula is the subject of the next section.

4. PRELIMINARIES ON THE GEOMETRY OF BEADS

Before, we can give an analytic solution to the alibi query and prove its correctness, we need to introduce some terminology concerning beads.

4.1 Geometric components of beads

Various geometric properties of beads have already been described [Egenhofer 2003; Kuijpers and Othman 2007; Miller 2005]. Here, we need some more definitions and notations to describe various components of a bead. These components are illustrated in Figure 2. In this section, let \( p = (t_p, x_p, y_p) \) and \( q = (t_q, x_q, y_q) \) be two time-space points, with \( t_p \leq t_q \) and let \( v_{\text{max}} \) be a positive real number.

The bead \( B(p, q, v_{\text{max}}) \) is the intersection of two filled cones, given by the equations \((x - x_p)^2 + (y - y_p)^2 \leq (t - t_p)^2 v_{\text{max}}^2 \land t \leq t_p \) and \((x - x_q)^2 + (y - y_q)^2 \leq (t - t_q)^2 v_{\text{max}}^2 \land t \leq t_q \) respectively. The border of its lower cone is the set of all points \((t, x, y)\) that satisfy

\[
\Psi_{C^-}(t, x, y, t_p, x_p, y_p, v_{\text{max}}) := (x - x_p)^2 + (y - y_p)^2 = (t - t_p)^2 v_{\text{max}}^2 \land t \leq t_p
\]

and is denoted by \( C^-(t_p, x_p, y_p, v_{\text{max}}) \); and the border of its upper cone is the set of all points \((t, x, y)\) that satisfy

\[
\Psi_{C^+}(t, x, y, t_q, x_q, y_q, v_{\text{max}}) := (x - x_q)^2 + (y - y_q)^2 = (t - t_q)^2 v_{\text{max}}^2 \land t \leq t_q
\]

and is denoted by \( C^+(q, v_{\text{max}}) \) or \( C^+(t_q, x_q, y_q, v_{\text{max}}) \).

The set of the two apexes of \( B(p, q, v_{\text{max}}) \) is denotes \( \tau B(p, q, v_{\text{max}}) \), i.e., \( \tau B(p, q, v_{\text{max}}) = \{p, q\} \).
We call the topological border of the bead $B(p,q,\max)$ its mantel and denote it by $\partial B(p,q,\max)$. It can be easily verified that the mantel consists of the set of points $(t,x,y)$ that satisfy

$$\Psi_{\partial}(t,x,y,\tp,\xp,\yp,\tp,\xp,\yp,\max) := \tp \leq t \leq \tp \land$$

$$\begin{cases} 
2x(\xp-x) + x^2 - x^2 + 2y(\yp-y) + y^2 - y^2 \leq \max^2 (2t(\tp-\tp) + \tp^2 - \tp^2) \\
(x-\xp)^2 + (y-\yp)^2 = (t-\tp)^2 \max^2 \land \end{cases} \land 2x(\xp-x) + x^2 - x^2 + 2y(\yp-y) + y^2 - y^2 \geq \max^2 (2t(\tp-\tp) + \tp^2 - \tp^2) .$$

The first conjunction describes the lower half of the mantel and the second conjunction describes the upper half of the mantel. The upper and lower half of the mantel are separated by a plane. The intersection of this plane with the bead is an ellipse, and the border of this ellipse is what we will refer to as the rim of the bead. We denote the rim of the bead $B(p,q,\max)$ by $\rho B(p,q,\max)$ and remark that it is described by the formula

$$\Psi_{\rho}(t,x,y,\tp,\xp,\yp,\tp,\xp,\yp,\max) :=$$

$$\begin{cases} 
(x-\xp)^2 + (y-\yp)^2 = (t-\tp)^2 \max^2 \land \tp \leq t \leq \tp \\
2x(\xp-x) + x^2 - x^2 + 2y(\yp-y) + y^2 - y^2 = \max^2 (2t(\tp-\tp) + \tp^2 - \tp^2) . \end{cases}$$

The plane in which the rim lies splits the bead into an upper-half bead and a bottom-half bead. The bottom-half bead is the set of all points $(t,x,y)$ that satisfy

$$\Psi_{B^-}(t,x,y,\tp,\xp,\yp,\tp,\xp,\yp,\max) :=$$

$$\begin{cases} 
(x-\xp)^2 + (y-\yp)^2 \leq (t-\tp)^2 \max^2 \land \tp \leq t \leq \tp \\
2x(\xp-x) + x^2 - x^2 + 2y(\yp-y) + y^2 - y^2 \leq \max^2 (2t(\tp-\tp) + \tp^2 - \tp^2) \end{cases}$$

and is denoted by $B^- (\tp,\xp,\yp,\tp,\xp,\yp,\max)$.

The upper bead is the set of all points $(t,x,y)$ that satisfy

$$\Psi_{B^+}(t,x,y,\tp,\xp,\yp,\tp,\xp,\yp,\max) :=$$

$$\begin{cases} 
(x-\xp)^2 + (y-\yp)^2 \leq (t-\tp)^2 \max^2 \land \tp \leq t \leq \tp \\
2x(\xp-x) + x^2 - x^2 + 2y(\yp-y) + y^2 - y^2 \geq \max^2 (2t(\tp-\tp) + \tp^2 - \tp^2) \end{cases}$$

and is denoted by $B^+ (\tp,\xp,\yp,\tp,\xp,\yp,\max)$.

### 4.2 The intersection of two cones

Let $C^-(t_1, x_1, y_1, v_1)$ and $C^-(t_2, x_2, y_2, v_2)$ be two bottom cones. A bottom cone, e.g., $C^-(t_1, x_1, y_1, v_1)$, can be seen as a circle in 2-dimensional space $(x,y)$-space with center $(x_1, y_1)$ and linearly growing radius $(t-t_1)v_1$ as $t_1 \leq t$.

Let us assume that the apex of neither of these cones is inside the other cone, i.e., $(x_1-x_2)^2 + (y_1-y_2)^2 > (t_1-t_2)^2 v_1^2 \lor t_1 < t_2$ and $(x_1-x_2)^2 + (y_1-y_2)^2 > (t_1-t_2)^2 v_2^2 \lor t_2 < t_1$. This assumption implies that at $t_1$ and $t_2$ neither radius is larger than or equal to the distance between the two cone centers. So, at first the two circles are disjoint and after growing for some time they intersect in one point.

We call the first (in time) time-space point where the two circles touch in a single point, and thus for which the sum of the two radii is equal to the distance between the two centers the initial contact of the two cones $C^-(t_1, x_1, y_1, v_1)$ and $C^-(t_2, x_2$, \textit{ACM Journal Name, Vol. V, No. N, 20YY.}
Fig. 2. A dissection of the bead $B(t_p, x_p, y_p, t_q, x_q, y_q, v_{\text{max}})$.  

$y_2, v_2$). It is the unique point $(t, x, y)$ that satisfies the formula

$$\Psi_{IC}^- (t, x, y, t_1, x_1, y_1, v_1, t_2, x_2, y_2, v_2) := t_1 \leq t \land t_2 \leq t \land (x - x_1)^2 + (y - y_1)^2 = (t - t_1)^2 v_1^2 \land (x - x_2)^2 + (y - y_2)^2 = (t - t_2)^2 v_2^2 \land ((t - t_1)v_1 + (t - t_2)v_2)^2 = (x_1 - x_2)^2 + (y_1 - y_2)^2.$$  

The initial contact of two cones $C^+(t_1, x_1, y_1, v_1)$ and $C^+(t_2, x_2, y_2, v_2)$ is given by the formula $\Psi_{IC}^+(t, x, y, t_1, x_1, y_1, v_1, t_2, x_2, y_2, v_2)$ that we obtain from $\Psi_{IC}^-$ by replacing in $t_1 \leq t \land t_2 \leq t$ by $t \leq t_1 \land t \leq t_2$. We denote the singleton sets containing the initial contacts by $IC(C^-(t_1, x_1, y_1, v_1), C^-(t_2, x_2, y_2, v_2))$ and $IC(C^+(t_1, x_1, y_1, v_1), C^+(t_2, x_2, y_2, v_2))$.

Fig. 3. Intersecting cones and their initial contact (3-dimensional view on the left and 2-dimensional view on the right).

ACM Journal Name, Vol. V, No. N, 20YY.
From the last equation in of the system in $\Psi_{IC}^-$ and $\Psi_{IC}^+$, we easily obtain $t = \frac{\sqrt{(x_1 - x_2)^2 + (y_1 - y_2)^2 + t_1 v_1 + t_2 v_2}}{v_1 + v_2}$. To compute the other two coordinates $(x, y)$ of the initial contact, we observe that for in the plane of this time value $t$, it is on the line segment bounded by $(x_1, y_1)$ and $(x_2, y_2)$ and that its distance from $(x_1, y_1)$ is $v_1(t - t_1)$ and its distance from $(x_1, y_1)$ is $v_2(t - t_2)$. We can conclude that the initial contact has $(t, x, y)$-coordinates given by the following system of equations

$$
\begin{cases}
  t &= \frac{\sqrt{(x_1 - x_2)^2 + (y_1 - y_2)^2 + t_1 v_1 + t_2 v_2}}{v_1 + v_2} \\
  x &= x_1 + v_1 (t - t_1) \frac{x_2 - x_1}{\sqrt{(x_2 - x_1)^2 + (y_2 - y_1)^2}} \\
  y &= y_1 + v_1 (t - t_1) \frac{y_2 - y_1}{\sqrt{(x_2 - x_1)^2 + (y_2 - y_1)^2}}
\end{cases}
$$

This means that we can give more explicit descriptions to replace $\Psi_{IC}^-$ and $\Psi_{IC}^+$.

5. AN ANALYTIC SOLUTION TO THE ALIBI QUERY

In this section, we first describe our solution to the alibi query on a geometric level. Next, we prove its correctness and transform it into an analytic solution and finally we show how to construct a quantifier-free first-order formula out of the analytic solution.

5.1 Preliminary geometric considerations

The solution we present is based on the observation that the two main cases of intersection (that do not exclude each other) are: (1) an apex of one bead is in the other; and (2) the mantels of the beads intersect.

The inclusion of one bead in the other, illustrated in Figure 4, is an example of the first case. It is clear that if no apex is contained in another bead and we still assume that the beads intersect, than their mantels must intersect. We show this more formally in Lemma 1. In this second case, the idea is to find a special point (a witness point) that is easily computable and necessarily in the intersection.

Fig. 4. One bead is contained in the other.
Let us consider two beads with bottom cones $C^- (t_1, x_1, y_1, v_1)$ and $C^- (t_2, x_2, y_2, v_2)$ and let us assume that none of the apexes is inside the other cone. One special point is the point of initial contact $IC(C^- (t_1, x_1, y_1, v_1), C^- (t_2, x_2, y_2, v_2))$. However, this point can not be guaranteed to be in the intersection if the mantels of the two beads intersect, as we will show in the following example. Consider two beads with bottom cones $C^- (0, 0, 0, 1)$ and $C^- (0, 2, 0, 1)$. The intersection is a hyperbola in the plane $x = 1$ with equation $t^2 - y^2 = 1$. The initial contact of the two bottom cones is the point $(1, 0, 1)$. To show that this point of initial contact does not need to be in the intersection of the two beads, the idea is to cut this point out of the intersection as follows. Suppose one bead has apexes, $(0, 0, 0)$ and $(a, b, c)$ and speed 1. The plane in which its rim lies is given by $-2ax + a^2 - 2by + b^2 + 2ct - c^2 = 0$. This plane cuts the plane $\alpha$ given by the equality $x = 1$ in a line given by the equation $-2by + 2ct - 2a + a^2 - c^2 = 0$. Clearly, we can choose $(a, b, c)$ such that the line contains the points $\left(\frac{\sqrt{5}}{2}, 1, \frac{1}{2}\right)$ and $\left(\sqrt{2}, 1, 1\right)$. Everything below this line will be part of the first bead and the second cone, but the initial contact is situated above the line, effectively cutting it out of the intersection. All this is illustrated in Figure 6.

We notice how the plane in which the rim lies and the rim itself is the evil doer. If neither rim intersects the mantel of the other bead, then the intersection of mantels is the same as an intersection of cones. In which case the initial contact will not be cut out and can be used to determine if there is intersection in this manner.

Using contraposition on the statement in the previous paragraph we get: if there is an intersection and no initial contact is in the intersection then a rim must intersect the other bead’s mantel.

To verify intersection with the apexes and initial contacts is straightforward. Verifying if a rim intersects a mantel results in solving a quartic polynomial equation in one variable and verifying the solution in a single inequality in which no variable

ACM Journal Name, Vol. V, No. N, 20YY.
appears with a degree higher than one.

5.2 Outline of the solution

Suppose, for the remainder of this section, we wish to verify if the beads $B_1 = B(t_1, x_1, y_1, t_2, x_2, y_2, v_1)$ and $B_2 = B(t_3, x_3, y_3, t_4, x_4, y_4, v_2)$ intersect. Moreover, we assume the beads are non-empty, i.e., $(x_2 - x_1)^2 + (y_2 - y_1)^2 \leq (t_2 - t_1)^2 v_1^2$ and $(x_4 - x_3)^2 + (y_4 - y_3)^2 \leq (t_4 - t_3)^2 v_2^2$.

We first observe that an intersection between beads can be classified into three, mutually exclusive, cases. The three cases then are:

(I) an apex of one bead is contained in the other, i.e.,
$$\tau B_1 \cap B_2 \neq \emptyset \text{ or } B_1 \cap \tau B_2 \neq \emptyset;$$

(II) not (I), but the rim of one bead intersects the mantel of the other, i.e.,
$$\rho B_1 \cap \partial B_2 \neq \emptyset \text{ or } \rho B_2 \cap \partial B_1 \neq \emptyset;$$
(III) not (I) and not (II) and the initial contact of the upper or lower cones is in the intersection of the beads, i.e.,

$$IC(C_1^{-}, C_2^{-}) \subset B_1 \cap B_2$$

$$IC(C_1^{+}, C_2^{+}) \subset B_1 \cap B_2.$$ 

If none of these three cases occur then the beads do not intersect, as we show in the correctness proof below. First, we give the following geometric lemma.

**Lemma 1.** If $B_1 \cap B_2 \neq \emptyset$, $\tau B_1 \cap B_2 = \emptyset$ and $\tau B_2 \cap B_1 = \emptyset$, then $\partial B_1 \cap \partial B_2 \neq \emptyset$.

**Proof.** From the assumptions, we know there is a point $p_1$ in $B_2$, e.g., an apex of $B_2$, that is not in $B_1$. Also, there is a point $p_2$ that is in $B_2$ and in $B_1$. The line segment bounded by $p_1$ and $p_2$ lies in $B_2$, since $B_2$ is convex. The line segment cuts the mantel of $B_3$ since $p_2$ is inside $B_3$ and $p_1$ is not. Let $p$ be this point where the segment bounded by $p_1$ and $p_2$ intersects $\partial B_3$. This point lies either on the upper-half bead $B_2^1$ or on the bottom-half bead $B_2^{-}$. Let $r$ be the apex of this half bead. Since $p$ is inside $B_2$ and $r$ is not, the line segment bounded by $p$ and $r$ must cut $\partial B_2$ in a point $q$. This point lies of course on $\partial B_2$ and on $\partial B_1$ since the line segment bounded by $p$ and $r$ is a part of $\partial B_1$. Hence their mantels must have a non-empty intersection if the beads have a non-empty intersection and neither bead contains the apexes of the other.

Now, we show that if $B_1$ and $B_2$ intersect and neither (I), nor (II) occur, then (III) occurs.

**Theorem 1.** If $B_1 \cap B_2 \neq \emptyset$, $\tau B_1 \cap B_2 = \emptyset$, $\tau B_2 \cap B_1 = \emptyset$, $\rho B_1 \cap \partial B_2 = \emptyset$ and $\rho B_2 \cap \partial B_1 = \emptyset$, then $IC(C_1^{-}, C_2^{-}) \subset B_1 \cap B_2$ or $IC(C_1^{+}, C_2^{+}) \subset B_1 \cap B_2$.

**Proof.** Let us assume that the hypotheses of the statement of the theorem is true. It is sufficient to prove that either $C_1^{-} \cap C_2^{-} \subset B_1^+ \cap B_2^-$ or $C_1^{+} \cap C_2^{+} \subset B_1^+ \cap B_2^+$. We will split the proof in two cases. From the fourth and fifth hypotheses it follows that either (1) $\rho B_1 \subset B_2$ or $\rho B_2 \subset B_1$; or (2) $\rho B_1 \cap B_2 = \emptyset$ and $\rho B_2 \cap B_1 = \emptyset$.

Case (1): We assume $\rho B_2 \subset B_1$ (the case $\rho B_1 \subset B_2$ is completely analogous). We prove $C_1^{-} \cap C_2^{-} \subset B_1^+ \cap B_2^-$ (the case for upper cones is completely analogous). The following argument is illustrated in Figure 7.

Since $\rho B_2 \subset B_1$, we know that $\rho B_2$ is inside $C_1^{-}$, and $(t_3, x_3, y_3)$ is outside. We can show that $v_2 < v_1$. Consider the plane spanned by the two axis of symmetry of both $C_1^{-}$ and $C_2^{-}$. Both $C_1^{-}$ and $C_2^{-}$ intersect this plane in two half lines each. Moreover, we know that $C_1^{-}$ intersects the axis of symmetry of $C_2^{-}$. Let $t_0$ be the moment at which this happens. Obviously $t_0 > t_1$, but we know also know $t_0 > t_3$ since $(t_3, x_3, y_3)$ is outside $C_1^{-}$. We have that $v_1(t_0 - t_1) = \sqrt{(x_1 - x_3)^2 + (y_1 - y_3)^2}$. Since $\rho B_2$ is inside $C_1^{-}$ and $(t_3, x_3, y_3)$ is outside, this means both half lines from $C_1^{-}$ intersect the half lines from $C_2^{-}$. Let $t_0'$ and $t_0''$ be the moments in time at which this happens and let $t_0' > t_0''$. We have again that $t_0' > t_1$ and $t_0'' > t_3$. Then $v_1(t_0' - t_1) = \sqrt{(x_1 - x_3)^2 + (y_1 - y_3)^2 + v_2(t_0' - t_3)}$ if and only if $v_1(t_0' - t_0) = v_2(t_0' - t_3)$. Since $t_0 > t_3$, we get $v_2 < v_1$. This is depicted in Figure 7.

It follows that every straight half line starting in $(t_3, x_3, y_3)$ on $C_2^{-}$ intersects $C_1^{-}$ between $(t_3, x_3, y_3)$ and $\rho B_2$, since $\rho B_2$ is inside $C_1^{-}$, and $(t_3, x_3, y_3)$ is outside. We also know that this line does not intersect $C_1^{-}$ beyond $\rho B_2$ since the cone $C_2^{-}$ is entirely inside $C_1^{-}$ beyond the rim $\rho B_2$. Therefore, $C_1^{-} \cap C_2^{-} \subset B_2^-$. 

ACM Journal Name, Vol. V, No. N, 20YY.
Clearly, $B_2^-$ intersects $B_1^+$ since it can not intersect $B_1^+$. We know $C_1^- \cap \partial B_2^-$ is a closed continuous curve that lies entirely in $C_1^-$. This curve is also contained in $B_1^-$. Indeed, if we assume this is not the case, then it intersects the plane in which $\rho B_1$ lies, and hence it intersects $\rho B_1$ itself, contradicting the assumption $\rho B_1 \cap \partial B_2 = \emptyset$.

**Case (2):** Now assume $\rho B_1 \cap B_2 = \emptyset$ and $\rho B_2 \cap B_1 = \emptyset$. Clearly, $v_1$ can not be equal to $v_2$, otherwise the depicted intersection can not occur. So suppose without loss of generality that $v_2 < v_1$. Now either $B_2^-$ intersects both $B_1^-$ and $B_1^+$ or $B_2^+$ intersects both $B_1^-$ and $B_1^+$. These cases are mutually exclusive because of the following. If $B_2^+$ intersects $B_1^+$ then $\rho B_2$ is inside $C_1^+$, likewise if $B_2^-$ intersects $B_1^-$ then $\rho B_2$ is inside $C_1^-$. Hence $\rho B_2 \subset B_1$ which contradicts our hypothesis. If $B_2^+$ intersects $B_1^-$ then $\rho B_2$ must be outside $C_1^+$ and thus $B_2$ must be as well, hence $B_2^-$ intersects neither $B_1^-$ nor $B_1^+$. Likewise, if $B_2^-$ intersects $B_1^+$ then $B_2^+$ can not intersect $B_1^-$.

To prove that if $B_2^-$ intersects $B_1^-$ then it also intersects $B_1^+$ and if $B_2^+$ intersects $B_1^+$ then it also intersects $B_1^-$ we proceed as follows (the case for $B_2^-$ is analogous). Suppose $B_2^-$ intersects $B_1^-$, then $B_2^+ \cap B_1^- \subset B_1$, but $\rho B_2$ is outside $B_1$, that means $B_2^-$ must intersect $B_1^-$ since it can not intersect $B_1^-$ anymore. This is the “what goes in must come out”-principle. Likewise, suppose $B_2^+$ intersects $B_1^+$, then $B_2^- \cap B_1^+ \subset B_1$, but $(t_3, x_3, y_3)$ is outside $B_1$, that means $B_2^+$ must intersect $B_1^-$ since it can not intersect $B_1^-$ anymore.

So suppose now that $B_2^-$ intersects both $B_1^-$ and $B_1^+$ (the case for $B_2^+$ is completely analogous). If $B_2^-$ intersects $B_1^-$ that means $\rho B_2$ is completely inside $C_1^-$ and therefore that $C_1^- \cap B_2^- \subset B_2^-$. We proceed like in the first case, we know that $C_1^- \cap B_2^-$ is a closed continuous curve. This curve lies entirely in $C_1^-$. If this curve is not entirely in $B_1^-$ that means it intersects the plane in which $\rho B_1$ lies, and hence intersects $\rho B_1$ itself. But this is contradictory to the assumption that $\rho B_1 \cap \partial B_2 = \emptyset$. □

In Theorem 1, we proved that if there is an intersection and neither rim cuts the
other bead’s mantel and neither apex of a bead is contained in the other then there must be an initial contact in the intersection. Visualizing how beads intersect might tempt one to think there is always an initial contact in the intersection. There exist counterexamples in which there is an intersection and no initial contact is in that intersection. That means case (II) is not redundant. This situation is depicted in Figure 8. The beads are $B(0,0,0,2,0,2,1.9)$ and $B(0,3,0,2,3,2,1.9)$.

It is clear that the initial contact of the bottom cones lies in the plane spanned by the axis of symmetry of those bottom cones, in this case this is the plane $y = 0$. The intersection of Figure 8 can be seen in Figure 9, where the two beads clearly have no intersection and thus no initial contact in the intersection.

In the case of the upper cones the initial contact must lie in the plane $y = 3$. The intersection of Figure 8 can be seen in Figure 10, where the two beads clearly have no intersection and there is again no initial contact in the intersection.
5.3 A formula for Case (I)

In Case (I), we verify whether \( \tau B_1 \cap B_2 \neq \emptyset \) or \( B_1 \cap \tau B_2 \neq \emptyset \). To check if that is the case we merely need to verify if one of the apexes satisfies the set of equations of the other bead. In this way we obtain

\[
\Phi_I(t_1, x_1, y_1, t_2, x_2, y_2, v_1, t_3, x_3, y_3, t_4, x_4, y_4, v_2) :=
(\Psi_B(t_3, x_3, y_3, t_1, x_1, t_2, x_2, y_2, v_1) \lor \Psi_B(t_4, x_4, y_4, t_1, x_1, t_2, x_2, y_2, v_1)) \lor
\Psi_B(t_1, x_1, y_1, t_3, x_3, y_3, t_4, x_4, y_4, v_2) \lor \Psi_B(t_2, x_2, y_2, t_3, x_3, t_4, x_4, y_4, v_2)).
\]

For the following sections we assume that the apex sets of the beads are not singletons, i.e., \( t_1 < t_2 \) and \( t_3 < t_4 \).

5.4 A formula for Case (II)

Now, let us assume that \( \Phi_I \) failed in the previous section. Note that we can always apply a speed-preserving [Kuijpers and Othman 2007] transformation to \( \mathbb{R} \times \mathbb{R}^2 \) to obtain easier coordinates. We can always find a transformation such that \( (t'_1, x'_1, y'_1) = (0, 0, 0) \) and that the line-segment connecting \( (t'_1, x'_1, y'_1) \) and \( (t'_2, x'_2, y'_2) \) is perpendicular to the \( y \)-axis, i.e., \( y'_2 = 0 \). This transformation is a composition of a translation in \( \mathbb{R} \times \mathbb{R}^2 \), a spatial rotation in \( \mathbb{R}^2 \) and a scaling in \( \mathbb{R} \times \mathbb{R}^2 \) [Kuijpers and Othman 2007]. Let the coordinates without a prime be the original set, and let coordinates with a prime be the image of the same coordinates.
The constraints for \( \varphi_A \) are

\[
\varphi_A(t_1, x_1, y_1, t_2, x_2, y_2, t, x, y, t', x', y') := (y_2 \neq y_1 \land \\
(t - t_1) \sqrt{(x_2 - x_1)^2 + (y_2 - y_1)^2} \land \\
(x - x_1)(x_2 - x_1) + (y - y_1)(y_2 - y_1) \land \\
(y_2 = y_1 \land t' = (t - t_1) \land x' = (x - x_1) \land y' = (y - y_1)).
\]

The translation is over the vector \((-t_1, -x_1, -y_1)\), the rotation over minus the angle that \((t_2 - t_1, x_2 - x_1, y_2 - y_1)\) makes with the \(x\)-axis, and a scaling by a factor \( \sqrt{(x_2 - x_1)^2 + (y_2 - y_1)^2} \). Notice that the rotation and scaling only need to occur if \(y_2\) is not already in place, i.e., if \(y_2 \neq y_1\).

The formula \( \psi_{crd}(t_1', x_1', y_1', t_1, x_1, y_1, t_2', x_2', y_2', t_2, x_2, y_2, t_3', x_3', y_3', t_3, x_3, y_3, t_4', x_4', y_4', t_4, x_4, y_4) \) is short for \( \varphi_A(t_1, x_1, y_1, t_2, x_2, y_2, t_3, x_3, y_3, t_4, x_4, y_4) \) and gives \( \varphi_A(t_1, x_1, y_1, t_2, x_2, y_2, t_3, x_3, y_3, t_4, x_4, y_4) \) and \( \varphi_A(t_1, x_1, y_1, t_2, x_2, y_2, t_3, x_3, y_3, t_4, x_4, y_4) \).

This transformation yields some simple equations for the rim \( \rho B_1 \):

\[
\rho B_1 \leftrightarrow \begin{cases} 
  x^2 + y^2 = t_1^2 v_1^2 \\
  2x(x_2') + x_2'^2 = v_1^2 (2t - t_2') + t_2'^2 \\
  0 \leq t \leq t_2'.
\end{cases}
\]

Not only that, but with these equations we can deduce a simple parametrization in the \(x\)-coordinate for the rim,

\[
\rho B_1 \leftrightarrow \begin{cases} 
  t = \frac{2x(x_2' - x_2^2 + v_1^2 t_2'^2)}{2v_1^2 t_2'} \\
  y = \pm \sqrt{v_1^2 \left( \frac{2x(x_2' - x_2^2 + v_1^2 t_2'^2)}{2v_1^2 t_2'} \right)^2 - x^2} \\
  0 \leq t \leq t_2'.
\end{cases}
\]

We remark that this implies \( t_2' \neq 0 \) and \( v_1 \neq 0 \). If \( t_2' = 0 \), then \( B_1 \) is a point, hence degenerate. If \( v_1 = 0 \), then \( B_1 \) is a line segment, and again degenerate. Next we will inject these parameterizations in the constraints for \( \partial B_2^+ \) and \( \partial B_2^- \) separately. The constraints for \( \partial B_2^- \) are

\[
\begin{cases} 
  (x - x_3')^2 + (y - y_3')^2 = (t - t_3')^2 v_3^2 \\
  2x(x_3' - x_3') + x_3'^2 - x_3^2 + 2y(y_3' - y_3') + y_3'^2 - y_3^2 \leq v_3^2 (2t(t_3' - t_4') + t_4'^2 - t_3'^2) \\
  t_3' \leq t \leq t_4'.
\end{cases}
\]

We will explain how to proceed to compute the intersection with \( \partial B_2^- \) and simply reuse formulas for intersection with \( \partial B_2^+ \). First, we insert our expressions for \( x \) and \( y \) in the first equation. This is equivalent to computing intersections of \( \rho B_1 \) with \( C_2^- \) and gives

\[
(x - x_3')^2 + \left( \pm \sqrt{v_1^2 \left( \frac{2x(x_2' - x_2^2 + v_1^2 t_2'^2)}{2v_1^2 t_2'} \right)^2 - x^2} - y_3' \right)^2.
\]
or equivalently

\[ \pm 2y_1 \sqrt{x^2(2xx'_2 - x_2^2) + x_4x_2^2 (v_1^2 t_2^2 - x_2^2) + (v_1^2 t_2^2 - x_2^2)^2} = x^2 4x_2^2 (v_2^2 - v_1^2) + \]

\[ x^4 (-x_2^2 v_2^2 (-x_2^2 + v_1^2 t_2^2 - 4v_1^4 t_2^2 t_3^4) + 2v_1^4 t_2^2 x_3 + v_2^2 x_2^2 (v_1^2 t_2^2 - x_2^2)) + (v_2^2 (-x_2^2 + v_1^2 t_2^2 - 4v_1^4 t_2^2 t_3^4) - v_1^4 (-x_2^2 + v_1^2 t_2^2)) \].

By squaring left and right hand in this last expression, we rid ourselves of the square root and obtain the following polynomial equation of degree four. Squaring may create new solutions, so to ensure we only get useful solutions, we have to add the condition that the square root exists. This is the case if and only if

\[ \phi_4(x, t'_2, x'_2, v_1) := x^2 4 \left( x_2^2 - v_1^2 t_2^2 + x_4 x_2^2 (v_1^2 t_2^2 - x_2^2) + (v_1^2 t_2^2 - x_2^2)^2 \right) \geq 0 \]

is satisfied.

We notice that if \( B_1 \) is degenerate, i.e., \( x_2^2 = v_1^2 t_2^2 \), then the square root vanishes and the polynomial in \( \phi_4 \) is the square of a polynomial of degree two, yielding to at most two roots and intersection points as we expect. The case were \( v_1 = 0 \) is captured by the formula in the next section, that is why we leave that case out here and demand that \( v_1 \neq 0 \). So the following still works if one or both beeds is degenerate:

\[ \phi_4(x, t'_2, x'_2, v_1, t'_3, x_3, v_3, v_2) := \exists a \exists b \exists c \exists d \exists e (ax^4 + bx^3 + cx^2 + dx + e = 0 \]

\[ \wedge a = (4x_2^2 (v_2^2 - v_1^2))^2 \wedge b = -32x_2^4 x_2^2 (v_2^2 - v_1^2) (-x_2^2 + v_1^2 t_2^2 - 4v_1^4 t_2^2 t_3^4) \]

\[ + 2v_1^4 t_2^2 x_3 + v_2^2 x_2^2 (v_1^2 t_2^2 - x_2^2)) \wedge c = 8 (x_2^2 - v_1^2 t_2^2) (-4v_1^4 t_2^2 (x_3^2 + y_3^2) + \]

\[ + v_2^2 (-x_2^2 + v_1^2 t_2^2 - 4v_1^4 t_2^2 t_3^4) - v_1^4 (-x_2^2 + v_1^2 t_2^2)) + (2v_1 y_3)^2 (x_2^2 - v_1^2 t_2^2) \]

\[ + (4 (-x_2^2 v_2^2 (-x_2^2 + v_1^2 t_2^2 - 4v_1^4 t_2^2 t_3^4) + 2v_1^4 t_2^2 x_3 + v_2^2 x_2^2 (v_1^2 t_2^2 - x_2^2)))^2 \]

\[ \wedge d = 8 (x_2^2 - v_1^2 t_2^2) (-x_2^2 + v_1^2 t_2^2 - 4v_1^4 t_2^2 t_3^4) + 2v_1^4 t_2^2 x_3 + v_2^2 x_2^2 (v_1^2 t_2^2 - x_2^2)) \]

\[ (v_2^2 (-x_2^2 + v_1^2 t_2^2 - 4v_1^4 t_2^2 t_3^4) - v_1^4 (x_3^2 + y_3^2) - v_1^4 (-x_2^2 + v_1^2 t_2^2)) \]

\[ + (2v_1 y_3)^2 (x_2^2 - v_1^2 t_2^2) \wedge e = (2v_1 y_3)^2 (x_2^2 - v_1^2 t_2^2) \]

\[ (x_2^2 - v_1^2 t_2^2 - 4v_1^4 t_2^2 t_3^4) - v_1^4 (-x_2^2 + v_1^2 t_2^2) )^2 \).

ACM Journal Name, Vol. V, No. N, 20YY.
The quantifiers we introduced here are only in place for esthetical considerations and can be eliminated by direct substitution.

We note that if \( v_1 = v_2 \), we get polynomials of degree merely two. This can be solved in an exact manner using nested square roots (or Maple if you will). This gives us at most four values for \( x \). Let

\[
\phi_{\text{roots}}(x_a, x_b, x_c, x_d, t_2', x_2', v_1, t_3', x_3', y_3', v_2)
\]

be a formula that returns all four real roots, if they exist, that satisfy both \( \phi_4(x, t_2', x_2, v_1, t_3', x_3', y_3', v_2) \) and \( \phi_3(x, t_2', x_2', v_1) \). We substitute these values in the parameter equations of \( \rho B_1 \). By substituting these in the last equation above, we can determine the sign of the square root we need to take for \( y \). A point \((t, x, y)\) satisfies the following formula is a point on \( \rho B_1 \), but instead of using the square root for \( y \), we use an expression from above to get the correct sign for the square root if \( y_3' \neq 0 \).

If \( y_3' = 0 \) we have to use the square root expression and then it does not matter which sign the square root has; we need both:

\[
\psi_p(t, x, y, t_2', x_2', v_1, t_3', x_3', y_3', v_2) := (y_3' \neq 0 \land t (2v_1^2 t_2') = 2x x_2' - x_2^2 + v_1^2 t_2'^2 \land 2y_3' (2v_1^2 t_2') y = (2x x_2' - x_2^2 + v_1^2 t_2'^2 - (2v_1^2 t_2') t_3')^2 v_2 - (2v_1^2 t_2')^2 (x - x_3')^2 - (2v_1^2 t_2')^2 y_3'^2 - (v_1^2 (2x x_2' - x_2^2 + v_1^2 t_2'^2)^2 - (2v_1^2 t_2')^2 x^2) \land 0 \leq t \leq t_2' ) \lor (y_3' = 0 \land t (2v_1^2 t_2') = 2x x_2' - x_2^2 + v_1^2 t_2'^2 \land 0 \leq t \leq t_2' \land (2v_1^2 t_2')^2 y^2 = (2x x_2' - x_2^2 + v_1^2 t_2'^2)^2 - (2v_1^2 t_2')^2 x^2).
\]

The four roots give us four spatio-temporal points on \( \rho B_1 \cap C^- \). In order for these points \((t, x, y)\) to be in \( \rho B_1 \cap \partial B_2^- \), they need to satisfy

\[
\psi_-(t, x, y, t_3', x_3', y_3', t_4', x_4', y_4', v_2) := 2x(x_3' - x_4') + x_3'^2 - x_3^2 + 2y(y_3' - y_4') + y_3'^2 - y_3^2 \leq v_2^2 (2t(t_3' - t_4') + t_3'^2 - t_4^2 ) .
\]

This formula returns \text{TRUE} if \((t, x, y)\) lies in the same half space as the bottom-half bead.

![Fig. 11. The rim intersects the cone and solutions are verified in a half-space.](image)

The formula \(\psi_+\) returns \text{TRUE} if \((t, x, y)\) lies in the same half space as the upper-half bead, i.e., \(\psi_+(t, x, y, t_3', x_3', y_3', t_4', x_4', y_4', v) := \psi_-(t, x, y, t_3', x_3', y_3', t_4', x_4', y_4', v)\). By combining \(\psi_p(t, x, y, t_2', x_2', v_1, t_3', x_3', y_3', v_2)\) and \(\psi_-(t, x, y, t, \tilde{x}, \tilde{y}, \tilde{t}, \tilde{\tilde{x}}, \tilde{\tilde{y}}, v)\) we get a formula that decides the emptiness of the intersection \(\rho B_1 \cap \partial B_2^-\) in terms of a parameter \(x\):

\[
\psi_{p\cap}\partial(t, t_2', x_2', v_1, t_3', x_3', y_3', v_2, \tilde{x}, \tilde{y}, \tilde{t}, \tilde{\tilde{x}}, \tilde{\tilde{y}}, v) :=
\]

ACM Journal Name, Vol. V, No. N, 20YY.
\[ \exists y \left( y_3 = 0 \land y^2 \left( 2v_1^2t_2^2 \right)^2 = (2x'x'_2 - x'_2^2 + v_1^2t_2^2) v_3^2 - (2v_1^2t_2^2)^2 x^2 \right) \lor \\
( y_3 \neq 0 \land 2y_3 (2v_1^2t_2^2) y = (2x'x'_2 - x'_2^2 + v_1^2t_2^2 - (2v_1^2t_2^2) t_3) v_2^2 - (2v_1^2t_2^2)^2 x^2 \\
(x - x'_3)^2 - (2v_1^2t_2^2)^2 y^2 - \left( v_1^2 (2x'x'_2 - x'_2^2 + v_1^2t_2^2)^2 - (2v_1^2t_2^2)^2 x^2 \right) \land \\
(2x(\hat{x} - \hat{x}) + \hat{x}^2 - \hat{x}^2 + 2y(\hat{y} - \hat{y}) + \hat{y}^2 - \hat{y}^2) (2v_1^2t_2^2) \leq \\
v^2 \left( (2v_1^2t_2^2) (2x'x'_2 - x'_2^2 + v_1^2t_2^2) (\hat{t} - \hat{t}) + (2v_1^2t_2^2) (\hat{k}^2 - \hat{k}^2) \right) \land 0 \leq \hat{t}_2^\prime \\
(2x'x'_2 - x'_2^2 + v_1^2t_2^2) \leq 2v_1^2t_2^2 \land (\hat{t}_2 (2x'x'_2 - x'_2^2 + v_1^2t_2^2) \leq \hat{t} (2v_1^2t_2^2) \\
\lor \hat{t} (2v_1^2t_2^2) \leq \hat{t}_2^\prime (2x'x'_2 - x'_2^2 + v_1^2t_2^2) \leq \hat{t} (2v_1^2t_2^2) ) .
\]

We are ready now to construct the formula that decides if \( \rho B_1 \) and \( B_2^- \) have a non-empty intersection:

\[
\varphi_{\rho_1 \cap \partial_2} (t'_2, x'_2, x_1, x'_3, y'_3, t'_4, x'_4, y'_4, v_2) := \exists x \exists x_a \exists x_b \exists x_c \exists x_d \\
\phi_{\text{roots}}(x_a, x_b, x_c, x_d, t'_2, x'_2, v_1, t'_4, x'_3, y'_3, v_2) \land (x = x_a \lor x = x_b \lor x = x_c \lor x = x_d) \\
\lor \psi_{\rho \cap \partial} (x, t'_2, x'_2, v_1, t'_4, x'_3, y'_3, v_2) .
\]

The formula that decides if \( \rho B_1 \) intersects \( \partial B_2^- \) looks strikingly similar:

\[
\varphi_{\rho_1 \cap \partial_2} (t'_2, x'_2, x_1, x'_3, y'_3, t'_4, x'_4, y'_4, v_2) := \exists x \exists x_a \exists x_b \exists x_c \exists x_d \\
\phi_{\text{roots}}(x_a, x_b, x_c, x_d, t'_2, x'_2, v_1, t'_4, x'_3, y'_3, v_2) \land (x = x_a \lor x = x_b \lor x = x_c \lor x = x_d) \\
\lor \psi_{\rho \cap \partial} (x, t'_2, x'_2, v_1, t'_4, x'_3, y'_3, v_2) .
\]

The quantifiers introduced here can also be eliminated in a straightforward manner. Notice that \( \phi_{\text{roots}} \) acts as a function rather than a formula that inputs \((t'_2, x'_2, v_1, t'_4, x'_4, y'_4, v_2)\) to construct a polynomial of degree four and returns the four roots \((x_a, x_b, x_c, x_d)\), if they exist, of that polynomial. The existential quantifier for the variable \( x \) is used to cycle through those roots to see if any of them does the trick. Finally we are ready to present the formula for Case (II):

\[
\Phi_{\text{II}} (t_1, x_1, y_1, t_2, x_2, y_2, v_1, t_3, x_3, y_3, t_4, x_4, y_4, v_2) := (v_1 \neq 0 \land v_2 \neq 0) \land \\
\neg \Phi_{\text{I}} (t_1, x_1, y_1, t_2, x_2, y_2, v_1, t_3, x_3, y_3, t_4, x_4, y_4, v_2) \land \\
\exists x' \exists x'_1 \exists x'_3 \exists y'_2 \exists y'_2 \exists y'_3 \exists y'_4 \exists y'_4 \exists y'_4 \exists y'_4 ( \\
\psi_{\text{cd}}(t'_1, x'_1, y'_1, t_1, x_1, y_1, t'_2, x'_2, y'_2, t_2, x_2, y_2, t'_3, x'_3, y'_3, t_3, x_3, y_3, t'_4, x'_4, y'_4, t_4, x_4, y_4) \\
\land \left( \varphi_{\rho_1 \cap \partial_2} (t'_2, x'_2, v_1, t'_3, x'_3, y'_3, t'_4, x'_4, y'_4, v'_2) \lor \\
\varphi_{\rho_1 \cap \partial_2} (t'_2, x'_2, v_1, t'_3, x'_3, y'_3, t'_4, x'_4, y'_4, v'_2) \right) \lor \\
\psi_{\text{cd}}(t'_3, x'_3, y'_3, t_3, x_3, y_3, t'_4, x'_4, y'_4, t_4, x_4, y_4, v_2) \land \\
\varphi_{\rho_1 \cap \partial_2} (t'_3, x'_3, y'_3, t_1, x_1, y_1, t'_2, x'_2, y'_2, v_1, t'_4, x'_4, y'_4, v'_2) \lor \\
\varphi_{\rho_1 \cap \partial_2} (t'_3, x'_3, y'_3, t_1, x_1, y_1, t'_2, x'_2, y'_2, v_1, t'_4, x'_4, y'_4, v'_2)) .
\]

The reader may notice that a lot of quantifiers have been introduced in the formula above. These quantifiers are merely there to introduce easier coordinates and can be straightforwardly computed (and eliminated) by the formula \( \psi_{\text{cd}} \) and hence
the formula $\varphi_A(t_1, x_1, y_1, t_2, x_2, y_2, t, x, y, t', x', y')$. The latter actually acts like a function, parameterized by $(t_1, x_1, y_1, t_2, x_2, y_2)$, that inputs $(t, x, y)$ and outputs $(t', x', y')$.

5.5 A formula for Case (III)

Here, we assume that both $\varphi_1$ and $\varphi_2$ fail. So, there is no apex contained in the other bead and neither rim cuts the mantel of the other bead.

As we proved in Theorem 1, the intersection between two half beads will reduce to the intersection between two cones and that means there is an initial contact that is part of the intersection. To verify if this is the case we compute the two initial contacts and verify if they are effectively part of the intersection.

Using the expression for the initial contact $IC(C_1^-, C_2^-)$, we computed in Section 4.2 we can construct a formula that decides if it is part of $B_1^- \cap B_2^-$. We will recycle the formulas $\psi_-$ from the previous section to construct an expression without the need for extra variables. The following formula that returns TRUE if $IC(C_1^-, C_2^-)$ satisfies $\psi_-(t_0, x_0, y_0)$.

$$\phi_-(t_1, x_1, y_1, t_3, x_3, y_3, t', x', y', \hat{t}, \hat{x}, \hat{y}, v):$$

$$
2(x' - \hat{x}) \left( x_1 v_2 + x_3 v_1 \sqrt{(x_1 - x_3)^2 + (y_1 - y_3)^2} + v_1 ((t_3 - t_1) v_2 (x_3 - x_1))
\right)
+ 2(y' - \hat{y}) \left( y_1 v_2 + y_3 v_1 \sqrt{(x_1 - x_3)^2 + (y_1 - y_3)^2} + v_1 ((t_3 - t_1) v_2 (y_3 - y_1))
\right)
+ \sqrt{(x_1 - x_3)^2 + (y_1 - y_3)^2} (v_1 + v_2) \left( x^2 - x'^2 + y^2 - y'^2 \right)
\leq v^2 \left( (t^2 - t'^2) (v_1 + v_2) + 2 \right) \sqrt{(x_1 - x_3)^2 + (y_1 - y_3)^2}.
$$

The following formula expresses that the time coordinate $t_0$ of $IC(C_1^-, C_2^-)$ satisfies the constraints $t' \leq t \leq t''$ and $\hat{t} \leq t \leq \hat{t}$:

$$\psi_+(t_1, x_1, y_1, t_3, x_3, y_3, t', x', y', \hat{t}, \hat{x}, \hat{y}, v):$$

$$t'(v_1 + v_2) \leq \sqrt{(x_1 - x_3)^2 + (y_1 - y_3)^2} + t_1 v_1 + t_3 v_2 \leq t''(v_1 + v_2)$$

$$\land \hat{t}(v_1 + v_2) \leq \sqrt{(x_1 - x_3)^2 + (y_1 - y_3)^2} + t_1 v_1 + t_3 v_2 \leq \hat{t}(v_1 + v_2).$$

Now, $IC(C_1^-, C_2^-) \subset B_1^- \cap B_2^+$ if and only if $\psi_-(t_1, x_1, y_1, t_2, x_2, y_2, v_1, t_3, x_3, y_3, t_4, x_4, y_4, v_2)$ where $\psi_-(t_1, x_1, y_1, t_2, x_2, y_2, v_1, t_3, x_3, y_3, t_4, x_4, y_4, v_2) := \psi_+(t_1, x_1, y_1, t_2, x_2, y_2, v_1, t_3, x_3, y_3, t_4, x_4, y_4, v_2) \land \varphi_-(t_1, x_1, y_1, t_2, x_2, y_2, v_1, t_3, x_3, y_3, t_4, x_4, y_4, v_2)$ and $IC(C_1^-, C_2^-) \subset B_1^+ \cap B_2^-$ if and only if $\psi_+(t_1, x_1, y_1, t_2, x_2, y_2, v_1, t_3, x_3, y_3, t_4, x_4, y_4, v_2) := \psi_+(t_1, x_1, y_1, t_2, x_2, y_2, v_1, t_3, x_3, y_3, t_4, x_4, y_4, v_2) \land \varphi_+(t_1, x_1, y_1, t_2, x_2, y_2, v_1, t_3, x_3, y_3, t_4, x_4, y_4, v_2)$.

The formula that expresses the criterion for Case (III) then looks as follows:

$$\Phi_{III}(t_1, x_1, y_1, t_2, x_2, y_2, v_1, t_3, x_3, y_3, t_4, x_4, y_4, v_2) := (v_1 + v_2 \neq 0) \land$$

$$\neg \Phi_1(t_1, x_1, y_1, t_2, x_2, y_2, v_1, t_3, x_3, y_3, t_4, x_4, y_4, v_2) \land$$

$$\psi_{IC}-(t_1, x_1, y_1, t_2, x_2, y_2, v_1, t_3, x_3, y_3, t_4, x_4, y_4, v_2) \vee$$

$$\psi_{IC}+(t_1, x_1, y_1, t_2, x_2, y_2, v_1, t_3, x_3, y_3, t_4, x_4, y_4, v_2).$$

ACM Journal Name, Vol. V, No. N, 20YY.
5.6 The formula for the parametric alibi query

The final formula that decides if two beads, $B_1 = B(t_1, x_1, y_1, t_2, x_2, y_2, v_1)$ and $B_2 = B(t_3, x_3, t_4, x_4, y_4, v_2)$, do not intersect looks as follows

$$\psi_{alibi}(t_1, x_1, y_1, t_2, x_2, y_2, t_3, x_3, y_3, t_4, x_4, y_4, v_2) := \neg((t_1 < t_2 \land t_3 < t_4) \land (\Phi_{II}(t_1, x_1, y_1, t_2, x_2, y_2, t_3, x_3, y_3, t_4, x_4, y_4, v_2) \lor \Phi_{III}(t_1, x_1, y_1, t_2, x_2, y_2, t_3, x_3, y_3, t_4, x_4, y_4, v_2)) \lor \Phi_{I}(t_1, x_1, y_1, t_2, x_2, y_2, v_1, t_3, x_3, y_3, t_4, x_4, y_4, v_2))$$.

6. EXPERIMENTS

In this section, we compare our solution to the alibi query (using the formula given in Section 5.6) with the method of eliminating quantifiers of Mathematica.

In the following table it is clear that traditional quantifier elimination performs badly on the example beads. Its running times highly deviates from their average and range in the minutes. Whereas the method described in this paper performs in running times that consistently only needs milliseconds or less. This shows our method is efficient and our claim, that it runs in milliseconds or less, holds.

For this first set of beads we chose to verify intersection of two oblique beads (1-2) and the intersection of one oblique and one straight bead (3-4). The beads that actually intersected had a remarkable low running time with the QE-method.

|   | The beads         | The running times |
|---|------------------|-------------------|
|   | $B_1$            | $B_2$             | QE                | Our Method  |
| 1 | (0, 0, 0, 2, 0, 2, 1.9) | (0, 3, 0, 2, 3, 2, 2) | 0.656 Seconds     | 0.016 Seconds |
| 2 | (0, 0, 0, 2, 0, 2, 1.9) | (0, 4, 0, 2, 4, 4, 2) | 324.453 Seconds   | 0.063 Seconds |
| 3 | (0, 0, 0, 2, 0, 2, 1.9) | (0, 3, 0, 2, 3, 0, 2) | 0.438 Seconds     | 0.015 Seconds |
| 4 | (0, 0, 0, 2, 0, 2, 1.9) | (0, 4, 0, 2, 4, 0, 2) | 475.719 Seconds   | 0.031 Seconds |

The type of beads in this second set are as in the first. However, these beads all have overlapping time intervals unlike the first set, where the time intervals coincided.

|   | The beads         | The running times |
|---|------------------|-------------------|
|   | $B_1$            | $B_2$             | QE                | Our Method  |
| 1 | (0, 0, 0, 2, 0, 2, 1.9) | (1, 3, 0, 3, 2, 2) | 63.375 Seconds    | 0.078 Seconds |
| 2 | (0, 0, 0, 2, 0, 2, 1.9) | (1, 4, 0, 3, 4, 2) | 59.485 Seconds    | 0.078 Seconds |
| 3 | (0, 0, 0, 2, 0, 2, 1.9) | (1, 3, 0, 3, 3, 2) | 29.734 Seconds    | 0.031 Seconds |
| 4 | (0, 0, 0, 2, 0, 2, 1.9) | (1, 4, 0, 3, 4, 0) | 27.281 Seconds    | 0.032 Seconds |

The type of beads in this third set are as in the first. But this time the time intervals are completely disjoint. Note that the running times for the QE-method are more consistent in this set and the previous one.

|   | The beads         | The running times |
|---|------------------|-------------------|
|   | $B_1$            | $B_2$             | QE                | Our Method  |
| 1 | (0, 0, 0, 2, 0, 2, 1.9) | (3, 3, 0, 4, 3, 2) | 63.641 Seconds    | 0.046 Seconds |
| 2 | (0, 0, 0, 2, 0, 2, 1.9) | (3, 4, 0, 4, 4, 2) | 61.781 Seconds    | 0.016 Seconds |
| 3 | (0, 0, 0, 2, 0, 2, 1.9) | (3, 3, 0, 4, 3, 0) | 52.735 Seconds    | 0.031 Seconds |
| 4 | (0, 0, 0, 2, 0, 2, 1.9) | (3, 4, 0, 4, 4, 0) | 56.875 Seconds    | 0.046 Seconds |
7. THE ALIBI QUERY AT A FIXED MOMENT IN TIME

7.1 Introduction

In this section, we present another example where common sense prevails over the general quantifier-elimination methods. The problem is the following. As in the previous setting, we have lists of time-stamped locations of two moving objects and upper bounds on the object’s speed between time stamps. We wish to know if two objects could have met at a given moment in time.

For the remainder of this section, we reuse the assumptions from the previous section. We wish to verify if the beads $B_1 = B(t_1, x_1, y_1, t_2, x_2, y_2, v_1)$ and $B_2 = B(t_3, x_3, y_3, t_4, x_4, y_4, v_2)$ intersect at a moment in time $t_0$. Moreover, we assume the beads are non-empty, i.e., $(x_2 - x_1)^2 + (y_2 - y_1)^2 \leq (t_2 - t_1)^2 v_1^2$ and $(x_4 - x_3)^2 + (y_4 - y_3)^2 \leq (t_4 - t_3)^2 v_2^2$ and that $t_1 \leq t_0 \leq t_2$ and $t_3 \leq t_0 \leq t_4$ are satisfied. This means we need to eliminate the quantifiers in

$$
\exists x \exists y \left( (x - x_1)^2 + (y - y_1)^2 \leq v_1^2 (t_0 - t_1)^2 \land (x - x_2)^2 + (y - y_2)^2 \leq v_1^2 (t_0 - t_2)^2 \right.
\land \left. (x - x_3)^2 + (y - y_3)^2 \leq v_2^2 (t_0 - t_3)^2 \land (x - x_4)^2 + (y - y_4)^2 \leq v_2^2 (t_0 - t_4)^2 \right)
$$

Eliminating quantifiers gives us a formula that decide whether or not four discs have a non-empty intersection. For ease of notation we will use the following abbreviations: $(x, y) \in D_i$ if and only if $(x - x_i)^2 + (y - y_i)^2 \leq r_i^2$ and $(x, y) \in C_i$ if and only if $(x - x_i)^2 + (y - y_i) = r_i^2$.

7.2 Main theorem

Using Helly’s theorem we can simplify the problem even more. Helly’s theorem states that if you have a set $S$ of $m$ convex sets in $n$ dimensional space and if any subset of $S$ of $n+1$ convex sets has a non-empty intersection, then all $m$ convex sets have a non-empty intersection. For the plane, this means we only need to find a quantifier free-formula that decides if three discs have a non-empty intersection. For the remainder of this section assume that we want to verify whether $D_1 \cap D_2 \cap D_3$ is non-empty.

**Theorem 2.** Three discs, $D_1$, $D_2$ and $D_3$, have a non-empty intersection if and only if one of the following cases occur:

1. there is a disc whose center is in the other two discs; or
2. the previous case does not occur and there exists a pair of discs for which one of both intersection points of their bordering circles lies in the remaining disc.

**Proof.** The if-direction is trivial. The only if-direction is less trivial. We will use the following abbreviations, $D = D_1 \cap D_2 \cap D_3$ and $C = \partial D$.

Assume $D$ is non-empty and that neither (1) nor (2) holds. The intersection $D$ is convex as it is the intersection of convex sets. We distinguish between the case where $D$ is a point or and the case where $D$ is not a point.

--- Suppose $D$ is a single point $p$. This point $p$ can not lie in the interior of the three discs, because $D$ would not be a point then.

Nor can $p$ lie in the interior of two discs. If that would be the case then there exists a neighborhood of $p$ that is part of the intersection of those two discs,
say \( D_1 \) and \( D_2 \). Moreover \( p \) would be part of \( C_3 \) and this neighborhood would intersect the interior of \( D_3 \). This means \( D \) is not a point.

So \( p \) must lie on the border of two discs, say \( D_1 \) and \( D_2 \), and \( p \) must also be part of \( D_3 \) because \( D = \{ p \} \). This contradicts our assumption that (2) does not hold.

---

Assume \( D \) is not a point. All points on \( C \) belong to at least one \( C_i \). If there is a point that does not belong to any \( C_i \), then it is in the interior of all \( D_i \) and there exists a neighborhood of that point that is in the interior of all \( D_i \) and hence in \( D \). That contradicts the fact that this point is in \( C \).

Furthermore, not all points of \( C \) belong to a single \( C_i \). If that was the case then \( D_i \) would be part of (and equal to) \( D \) and its center would be inside the other two discs which contradicts the assumption that (1) does not hold.

So, \( C \) is made up of parts of the \( C_i \), of which some may coincide but not all of them. When traveling along \( C \) you will encounter a point \( p \) that connects part of a \( C_i \) and part of a \( C_j \), where \( i \neq j \), that do not coincide, otherwise (1) must occur again which is a contradiction. However, this \( p \) also yields to a contradiction since it belongs to two different \( C_i \), say \( C_1 \) and \( C_2 \), and is part of \( C \) hence \( D \) and \( D_3 \).

This contradicts the assumption that (2) does not occur. □

### 7.3 Translating the theorem in a formula

We can simplify the equations even further using coordinate transformations. By applying a translation, rotation and scaling we may assume that \((x_1, y_1) = (0, 0)\), \( x_2 \geq 0 \), \( r_1 = 1 \) and \( y_2 = 0 \). Using these simplifications and translating Theorem 2, we get the following formula.

\[
\Psi_1(x_2, r_2, x_3, y_3, r_3) := ((-x_2)^2 \leq r_2^2 \land (-x_3)^2 + (-y_3)^2 \leq r_3^2) \lor \\
\exists x \exists y \left( x^2 + y^2 = 1 \land (x - x_2)^2 + y^2 = r_2^2 \land (x - x_3)^2 + (y - y_3)^2 \leq r_3^2 \right).
\]

This is a formula that decides if either the center of the first disc is part of the two other discs, see the first line, or if either there exists a point in the intersection of the first two circles that is part of the third disc. All that remains now is making the expression

\[
\exists x \exists y \left( x^2 + y^2 = 1 \land (x - x_2)^2 + y^2 = r_2^2 \land (x - x_3)^2 + (y - y_3)^2 \leq r_3^2 \right)
\]

quantifier free.

To do this we assume that \( C_1 \) and \( C_2 \) do not coincide but have a non-empty intersection. This is equivalent to \( x_2 \neq 0 \land x_2 \leq r_2 + 1 \). Next, we need to compute the point(s) where \( C_1 \) and \( C_2 \) intersect.

\[
\begin{cases}
  x^2 + y^2 = 1 \\
  (x - x_2)^2 + y^2 = r_2^2
\end{cases}
\]

or

\[
\begin{cases}
  x = \frac{x_2^2 + 1 - r_2^2}{2x_2} \\
  y = \pm \sqrt{1 - \left(\frac{x_2^2 + 1 - r_2^2}{2x_2}\right)^2}
\end{cases}
\]

or

\[
\begin{cases}
  x = \frac{x_2^2 + 1 - r_2^2}{2x_2} \\
  y = \pm \sqrt{\left(1 - \frac{x_2^2 + 1 - r_2^2}{2x_2}\right) \left(1 + \frac{x_2^2 + 1 - r_2^2}{2x_2}\right)}
\end{cases}
\]

ACM Journal Name, Vol. V, No. N, 20YY.
or \(\begin{align*} x &= \frac{x^2 + 1 - r_2^2}{2x_2} \\
y &= \pm\frac{1}{2x_2}\sqrt{r_2^2 - (x_2 - 1)^2} \left((1 + x_2)^2 - r_2^2\right)\end{align*}\).

If \(y = 0\), then verifying if that single point of intersection is part of \(D_3\) is easy, one only needs to verify if
\[
\left(\frac{x^2 + 1 - r_2^2}{2x_2} - x_3\right)^2 + y_3^2 \leq r_3^2
\]
or equivalently \((1 - r_2^2 - x_2^2)^2 + 4x_2^2y_3^2 \leq 4x_2^2r_3^2\).

If \(y \neq 0\), then verifying if one both points of intersection is part of \(D_3\) is less trivial, since this involves square roots
\[
\left(\frac{x^2 + 1 - r_2^2}{2x_2} - x_3\right)^2 + \left(\pm\frac{1}{2x_2}\sqrt{r_2^2 - (x_2 - 1)^2} \left((1 + x_2)^2 - r_2^2\right) - y_3\right)^2 \leq r_3^2
\]
\[
(x_2^2 + 1 - r_2^2 - 2x_2x_3)^2 + \left(\pm\sqrt{r_2^2 - (x_2 - 1)^2} \left((1 + x_2)^2 - r_2^2\right) - 2x_2y_3\right)^2 \leq 4x_2^2r_3^2
\]
or \((x_2^2 + 1 - r_2^2 - 2x_2x_3)^2 + \left(r_2^2 - (x_2 - 1)^2\right) \left((1 + x_2)^2 - r_2^2\right) + (2x_2y_3)^2 \leq 4x_2^2r_3^2\).

This is almost a \(\mathsf{FO(+, \times, <, 0, 1)}\)-formula except for the square root. However, the square root can be eliminated as we will show next. The previous expression is of the form \(L \leq \pm a\sqrt{W}\). The presence of the \(\pm\) simplifies this a lot, this means either sign of the square root will do, and also that we may assume the right hand side is positive. Of course the square root must exist as well, this means \(W \geq 0\).

This expression can then be simplified to
\[
W \geq 0 \land (L \leq 0 \lor L^2 \leq a^2W)
\]
and gives us the expression
\[
\Phi_2(x_2, r_2, x_3, y_3, r_3) := \left(r_2^2 - (x_2 - 1)^2\right) \left((1 + x_2)^2 - r_2^2\right) \geq 0
\]
\[
\land \left(\left(x_2^2 + 1 - r_2^2 - 2x_2x_3\right)^2 + \left(r_2^2 - (x_2 - 1)^2\right) \left((1 + x_2)^2 - r_2^2\right) + (2x_2y_3)^2 - 4x_2^2r_3^2 \leq 0 \lor \left(x_2^2 + 1 - r_2^2 - 2x_2x_3\right)^2 + \left(r_2^2 - (x_2 - 1)^2\right) \left((1 + x_2)^2 - r_2^2\right) + (2x_2y_3)^2 - 4x_2^2r_3^2 \leq (4x_2y_3)^2 \left(r_2^2 - (x_2 - 1)^2\right) \left((1 + x_2)^2 - r_2^2\right)\right).
\]
7.4 The safety formula

Now, all that remains to be constructed is a formula that returns the convenient coordinates and a formula that guarantees that $C_1$ and $C_2$ actually intersect for safety, i.e., to exclude the case of empty intersection. The latter is constructed as follows. The formula $\varphi(x_1, y_1, r_1, x_2, y_2, r_2)$ returns True if and only if the two circles, with centers $(x_1, y_1)$ and $(x_2, y_2)$ and radii $r_1$ and $r_2$ respectively, have a distance between their centers that is not larger that the sum of their radii and not equal to zero to ensure they do not coincide. We have

$$\varphi(x_1, y_1, r_1, x_2, y_2, r_2) := 0 < (x_2 - x_1)^2 + (y_2 - y_1)^2 \leq (r_1 + r_2)^2.$$  

The formula $\phi(x_1, y_1, r_1, x_2, y_2, r_2)$ returns True if and only if the second circle is not fully enclosed by the first, i.e., the sum of the distance between the centers plus the second radius is bigger than the first radius and vice versa. We can write

$$\phi(x_1, y_1, r_1, x_2, y_2, r_2) := (x_2 - x_1)^2 + (y_2 - y_1)^2 \geq (r_1 - r_2)^2.$$  

These two safety conditions give us our safety formula

$$\Phi_{\text{safety}}(x_1, y_1, r_1, x_2, y_2, r_2) := \varphi(x_1, y_1, r_1, x_2, y_2, r_2) \land \phi(x_1, y_1, r_1, x_2, y_2, r_2).$$

7.5 The change of coordinates

The transformation consists of a translation, rotation and scaling. The translation to move the first circle’s center to the origin. The rotation to align the second center with the x-axis. Finally the scaling to ensure that the first circle’s radius is equal to one. First, the translation $T(x, y) := (x - x_1, y - y_1)$. The rotation is

$$R(x, y) := \frac{1}{\sqrt{(x_2 - x_1)^2 + (y_2 - y_1)^2}} \begin{pmatrix} x_2 - x_1 & y_2 - y_1 \\ y_1 - y_2 & x_2 - x_1 \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix}$$  

and finally, the scaling is $S(x, y) := \frac{1}{r_1}(x, y)$. The transformation is then a composition of those three transformations $A(x, y) = (S \circ R \circ T)(x, y) :=$

$$A(x, y) := \left(\frac{(x_2 - x_1)(x - x_1) + (y_2 - y_1)(y - y_1)}{r_1\sqrt{(x_2 - x_1)^2 + (y_2 - y_1)^2}}, \frac{(y_1 - y_2)(x - x_1) + (x_2 - x_1)(y - y_1)}{r_1\sqrt{(x_2 - x_1)^2 + (y_2 - y_1)^2}}\right).$$

The following formula takes three circles with centers $(x_i, y_i)$ and radii $r_i$ respectively, and transforms them in three new circles where the first circle has center $(0, 0)$ and radius 1, the second circle has center $(x'_2, 0)$ and radius $r'_2$ and the third circle has center $(x'_3, y'_3)$ and radius $r'_3$.

$$\Phi_{\text{transformation}}(x_1, y_1, r_1, x_2, y_2, r_2, x_3, y_3, r_3, x'_2, y'_3, r'_2, x'_3, y'_3, r'_3) :=$$

$$x'_2 = \frac{\sqrt{(x_2 - x_1)^2 + (y_2 - y_1)^2}}{r_1} \land r'_2 = \frac{r_2}{r_1} \land r'_3 = \frac{r_3}{r_1} \land$$

$$x'_3 = \frac{(x_2 - x_1)(x_3 - x_1) + (y_2 - y_1)(y_3 - y_1)}{r_1\sqrt{(x_2 - x_1)^2 + (y_2 - y_1)^2}} \land$$

$$y'_3 = \frac{(y_1 - y_2)(x_3 - x_1) + (x_2 - x_1)(y_3 - y_1)}{r_1\sqrt{(x_2 - x_1)^2 + (y_2 - y_1)^2}}.$$
Note that this is not a \(\text{FO}(+, \times, <, 0, 1)\)-formula anymore due to the square roots and fractions. This "formula" is meant to act like a function, which substitutes coordinates. The substituted coordinates have fractions and square roots but these can easily be disposed of when having the entire inequality on a common denominator, isolating the square root and squaring the inequality, as we showed in Section 7.3.

7.6 The formula for the alibi query at a fixed moment in time

First, we construct a formula that checks for any of two circles out of three if any of the conditions in Theorem 2 are satisfied.

\[
\Phi_{\text{transformation}}(x_1, y_1, r_1, x_2, y_2, r_2, x_3, y_3, r_3, x'_2, x'_3, y'_3, r'_3) \land \\
\Phi_{\text{safety}}(x_1, y_1, r_1, x_2, y_2, r_2) \land \\
\Phi_{\text{transformation}}(x_2, y_2, r_2, x_3, y_3, r_3, x_1, y_1, r_1, x'_2, x'_3, y'_3, r'_3) \land \\
\Phi_{\text{safety}}(x_2, y_2, r_2, x_3, y_3, r_3) \land \\
\Phi_{\text{transformation}}(x_1, y_1, r_1, x_2, y_2, r_2, x_3, y_3, r_3) \land \\
\Phi_{\text{safety}}(x_1, y_1, r_1, x_2, y_2, r_2, x'_3, y'_3, r'_3) \\
\lor \\
\Phi_{\text{transformation}}(x_1, y_1, r_1, x_2, y_2, r_2, x_3, y_3, r_3, x'_2, x'_3, y'_3, r'_3) \land \\
\Phi_{\text{safety}}(x_1, y_1, r_1, x'_2, x'_3, y'_3, r'_3) \\
\lor \\
\Phi_{\text{transformation}}(x_1, y_1, r_1, x_2, y_2, r_2, x_3, y_3, r_3, x'_2, x'_3, y'_3, r'_3) \land \\
\Phi_{\text{safety}}(x_1, y_1, r_1, x'_2, x'_3, y'_3, r'_3)
\]

This formula is all we need to incorporate Helly’s theorem in our final formula. Four discs have a non-empty intersection if and only if the following formula is satisfied

\[
\Psi(x_1, y_1, r_1, x_2, y_2, r_2, x_3, y_3, r_3, x_4, y_4) := \\
\Psi_{2/3}(x_1, y_1, r_1, x_2, y_2, r_2, x_3, y_3, r_3) \land \\
\Psi_{2/3}(x_1, y_1, r_1, x_2, y_2, r_2, x_3, y_4, r_4) \land \\
\Psi_{2/3}(x_1, y_1, r_1, x_2, y_2, r_2, x_4, y_4, r_4) \land \\
\Psi_{2/3}(x_1, y_1, r_1, x_3, y_3, r_3, x_4, y_4, r_4) \land \\
\Psi_{2/3}(x_2, y_2, r_2, x_3, y_3, r_3, x_4, y_4, r_4) \land \\
\Psi_{2/3}(x_2, y_2, r_2, x_3, r_3, x_4, y_4, r_4). \]
in theory, existing systems could provide a solution.

Appendix: The Mathematica implementation

The function alibi, using the method described in this paper, returns True if the bead with apexes \((t_1, x_1, y_1)\) and \((t_2, x_2, y_2)\) and speed \(v_1\) intersects the bead with apexes \((t_3, x_3, y_3)\) and \((t_4, x_4, y_4)\) and speed \(v_2\) and False otherwise. The function alibiQE does the same except it uses the built-in quantifier elimination method of Mathematica.

Note that Case (II) in our implementation corresponds to Case (III) in the description and vice versa. The reason for doing so is that Case (III), in the description, is computationally a lot easier than Case (II). Moreover, once any of the three cases returns True, our implementation exits and returns that result and thus omitting further computation.
