Optimal Testing of Reed-Muller Codes

Abstract

We consider the problem of testing if a given function \( f : \mathbb{F}_2^n \rightarrow \mathbb{F}_2 \) is close to any degree \( d \) polynomial in \( n \) variables, also known as the Reed-Muller testing problem. The Gowers norm is based on a natural \( 2^{d+1} \)-query test for this property. Alon et al. [AKK+05] rediscovered this test and showed that it accepts every degree \( d \) polynomial with probability 1, while it rejects functions that are \( \Omega(1) \)-far with probability \( \Omega(1/(d^{2d})) \). We give an asymptotically optimal analysis of this test, and show that it rejects functions that are (even only) \( \Omega(2^{-d}) \)-far with \( \Omega(1) \)-probability (so the rejection probability is a universal constant independent of \( d \) and \( n \)). This implies a tight relationship between the \( (d+1) \)-th Gowers norm of a function and its maximal correlation with degree \( d \) polynomials, when the correlation is close to 1.

Our proof works by induction on \( n \) and yields a new analysis of even the classical Blum-Luby-Rubinfeld [BLR93] linearity test, for the setting of functions mapping \( \mathbb{F}_2^n \) to \( \mathbb{F}_2 \). The optimality follows from a tighter analysis of counterexamples to the “inverse conjecture for the Gowers norm” constructed by [GT09, LMS08].

Our result has several implications. First, it shows that the Gowers norm test is tolerant, in that it also accepts close codewords. Second, it improves the parameters of an XOR lemma for polynomials given by Viola and Wigderson [VW07]. Third, it implies a “query hierarchy” result for property testing of affine-invariant properties. That is, for every function \( q(n) \), it gives an affine-invariant property that is testable with \( O(q(n)) \)-queries, but not with \( o(q(n)) \)-queries, complementing an analogous result of [GKNR09] for graph properties.

1 Introduction

Can the proximity of a function to a low-degree polynomial be estimated by sampling the function in few places? Variants of this question have been studied in two different communities for different purposes.

1.1 Gowers norm

In the additive combinatorics community, this issue arose in Gowers’ notable improvement of Szemerédi’s theorem, that any subset of the integers with positive density has infinitely long arithmetic progressions. To make his advance, Gowers introduced his uniformity norms, now usually called Gowers norms. The motivation for these norms is that if a function $f$ has degree $d$, then its derivative in direction $a$, $f(x + a) - f(x)$, has degree at most $d - 1$. Hence the $(d + 1)$-fold derivative is 0. Thus, a natural test to decide if a function $f$ has degree $d$ is to set $k = d + 1$, evaluate the $k$-fold derivative of $f$ in $k$ random directions, and accept only if the derivative evaluates to 0. This is what we call the $k^{th}$ Gowers norm test, $T_{GN(k)}$, for $k = d + 1$.

Our paper focuses on the field $\mathbb{F}_2$ of two elements, and we now restrict to this case. The $k^{th}$ Gowers norm of $f : \mathbb{F}_2 \to \mathbb{F}_2$, denoted $\|f\|_{U^k}$, is given by the expression

$$\|f\|_{U^k} \overset{\text{def}}{=} \left( \Pr[T_{GN(k)} \text{ accepts}] - \Pr[T_{GN(k)} \text{ rejects}] \right)^{1/2^k}.$$  

Gowers [Gow01] (see also [GT08]) showed that the correlation of $f$ to the closest degree $d$ polynomial is at most $\|f\|_{U^{d+1}}$. The well-known Inverse Conjecture for the Gowers Norm states that some sort of converse holds: if $\|f\|_{U^{d+1}} = \Omega(1)$, then the correlation of $f$ to some degree $d$ polynomial is $\Omega(1)$. Lovett et al. [LMS08] and Green and Tao [GT09] disproved this conjecture as stated, but a modification of the conjecture remains open, and was recently proven in high characteristic [TZ, GTZ09, GTZ10]. These conjectures and the Gowers norms have been extremely influential. For example, Green and Tao [GT09] used the Gowers norms over the integers to prove that the primes contain arbitrarily long arithmetic progressions.

Study of the Gowers norms over $\mathbb{F}_2$ has led to impressive results in theoretical computer science. Samorodnitsky and Trevisan [ST06] used Gowers norms to obtain very strong PCPs for Unique-Games-hard languages. This implied that Maximum Independent Set in graphs of maximum degree $\Delta$ could not be approximated within $\Delta / \text{polylog}(\Delta)$ under the Unique Games Conjecture. Using Gowers norms, Bogdanov and Viola [BV07] gave a pseudorandom generator fooling low-degree polynomials over $\mathbb{F}_2$. They could only prove their result under the inverse conjecture for the Gowers norm, but later Lovett [Lov09] and Viola [Vio09] used related ideas to prove an unconditional result. Finally, Viola and Wigderson [VW07] used Gowers norms to prove “XOR” lemmas for correlation to low-degree polynomials and to low communication protocols.

1.2 Local testing of Reed-Muller codes

Traditionally the Gowers norm is used in what Green and Tao call the 1% setting, where the correlation of a function to its closest low-degree polynomial is non-negligible but small. The 99%
setting, where the correlation is close to 1, was addressed by Alon, Kaufman, Krivelevich, Litsyn, and Ron [AKK+05], and is the focus of our work. More precisely, Alon et al. considered the question of testing if a Boolean function $f : \mathbb{F}_2^n \rightarrow \mathbb{F}_2$, given by an oracle, is close to a degree $d$ multivariate polynomial. They rediscovered a variation of the Gowers norm test, where all the derivative directions are linearly independent, and showed that this test suffices for that setting. Thus, their analysis gave the only known relationship between the Gowers norm and the proximity to low-degree polynomials in the 99% setting.

However, their analysis was not optimal. In this work, we give an improved, asymptotically optimal, analysis of the Gowers norm test. This gives a tight connection with the Gowers norm in the 99% setting. Before we elaborate, let us introduce our framework.

Our question is also called testing of Reed-Muller codes, which are codes based on low-degree polynomials. The Reed-Muller codes are parameterized by two parameters: $n$, the number of variables, and $d$, the degree parameter. The Reed-Muller codes consist of all functions from $\mathbb{F}_2^n \rightarrow \mathbb{F}_2$ that are evaluations of polynomials of degree at most $d$. We use $\text{RM}(d, n)$ to denote this class, i.e., $\text{RM}(d, n) = \{ f : \mathbb{F}_2^n \rightarrow \mathbb{F}_2 \mid \text{deg}(f) \leq d \}$.

The proximity of functions is measured by the (fractional Hamming) distance. Specifically, for functions $f, g : \mathbb{F}_2^n \rightarrow \mathbb{F}_2$, we let the distance between them, denoted by $\delta(f, g)$, be the quantity $\Pr_{x \sim \mathbb{F}_2^n}[f(x) \neq g(x)]$. For a family of functions $\mathcal{F} \subseteq \{ g : \mathbb{F}_2^n \rightarrow \mathbb{F}_2 \}$ let $\delta(f, \mathcal{F}) = \min \{ \delta(f, g) \mid g \in \mathcal{F} \}$. We say $f$ is $\delta$-close to $\mathcal{F}$ if $\delta(f, \mathcal{F}) \leq \delta$ and $\delta$-far otherwise.

Let $\delta_d(f) = \delta(f, \text{RM}(d, n))$ denote the distance of $f$ to the class of degree $d$ polynomials. The goal of Reed-Muller testing is to “test”, with “few queries” of $f$, whether $f \in \text{RM}(d, n)$ or $f$ is far from $\text{RM}(d, n)$. Specifically, for a function $q : \mathbb{Z}^+ \times \mathbb{Z}^+ \times (0, 1] \rightarrow \mathbb{Z}^+$, a $q$-query tester for the class $\text{RM}(d, n)$ is a randomized oracle algorithm $T$ that, given oracle access to some function $f : \mathbb{F}_2^n \rightarrow \mathbb{F}_2$ and a proximity parameter $\delta \in (0, 1]$, queries at most $q = q(d, n, \delta)$ values of $f$ and accepts $f \in \text{RM}(d, n)$ with probability 1, while if $\delta(f, \text{RM}(d, n)) \geq \delta$ it rejects with probability at least, say, 2/3. The function $q$ is the query complexity of the test and the main goal here is to minimize $q$, as a function possibly of $d$, $n$ and $\delta$. We denote the test $T$ run using oracle access to the function $f$ by $T^f$.

As mentioned earlier, Alon et al. [AKK+05] gave a tester with query complexity $O(\frac{d}{\delta} \cdot 4^d)$. Their tester consists of repetitions of a basic test, which we denote $T_{\text{GN}}$. $T_{\text{GN}}$ is a modification of the Gowers norm test $T_{\text{GN}}(d+1)$ so that the $(d+1)$-fold derivatives are evaluated in $d+1$ random linearly independent directions. This modified tester, whose rejection probability differs from that of the original Gowers norm tester by only a constant factor, can be described alternatively as follows. Given oracle access to $f$, $T_{\text{GN}}$ selects a random $(d+1)$-dimensional affine subspace $A$, and accepts if $f$ restricted to $A$ is a degree $d$ polynomial. This requires $2^{d+1}$ queries of $f$ (since that is the number of points contained in $A$). Alon et al. show that if $\delta(f) \geq \delta$ then $T_{\text{GN}}$ rejects $f$ with probability $\Omega(\delta/(d \cdot 2^d))$. Their final tester then simply repeated $T_{\text{GN}} O(\frac{d}{\delta} \cdot 2^d)$ times and accepted if all invocations of $T_{\text{GN}}$ accepted. The important feature of this result is that the number of queries is independent of $n$, the dimension of the ambient space. Alon et al. also show that any tester for $\text{RM}(d, n)$ must make at least $\Omega(2^d + 1/\delta)$ queries. Thus their result was tight to within almost quadratic factors, but left a gap open. We close this gap in this work.
1.3 Main Result

Our main result is an optimal analysis of the Gowers norm test, up to constants. We show that if \( \delta_d(f) \geq 0.1 \), in fact even if it’s at least \( 0.1 \cdot 2^{-d} \), then in fact the Gowers norm test rejects with probability lower bounded by some absolute constant. We now formally state our main theorem.

**Theorem 1** There exists a constant \( \epsilon_1 > 0 \) such that for all \( d, n \), and for all functions \( f : \mathbb{F}_2^n \to \mathbb{F}_2 \), we have:

\[
\Pr[T_{GN}^f \text{ rejects}] \geq \min\{2^d \cdot \delta_d(f), \epsilon_1\}.
\]

Therefore, to reject functions \( \delta \)-far from \( \text{RM}(d, n) \) with constant probability, a tester can repeat the test \( T_{GN} \) at most \( O(1/\min\{2^d \cdot \delta_d(f), \epsilon_1\}) = O(1 + 1/\delta^d) \) times, making the total query complexity \( O(2^d + 1/\delta) \). This query complexity is asymptotically tight in view of the earlier mentioned lower bound in [AKK+05].

Our error-analysis is also asymptotically tight. Note that our theorem effectively states that functions that are accepted by \( T_{GN} \) with constant probability (close to 1) are (very highly) correlated with degree \( d \) polynomials. To get a qualitative improvement one could hope that every function that is accepted by \( T_{GN} \) with probability strictly greater than half is somewhat correlated with a degree \( d \) polynomial. Such stronger statements however are effectively ruled out by the counterexamples to the “inverse conjecture for the Gowers norm” given by [LMS08, GT09]. Since the analysis given in these works does not match our parameters asymptotically, we show (see Theorem 24 in Appendix A) how an early analysis due to the authors of [LMS08] can be used to show the asymptotic tightness of the parameters of Theorem 1.

Our analysis of the Gowers norm test implies a tight relationship between the Gowers norm and distance to degree \( d \) in the 99% setting. In particular, we show the following theorem.

**Theorem 2** There exists \( \epsilon > 0 \) such that if \( \|f\|_{U^{d+1}} \geq 1 - \epsilon/2^d \), then \( \delta_d(f) = \Theta(1 - \|f\|_{U^{d+1}}) \).

For comparison, the best previous lower bound comes from the Alon et al. work, whose result can be interpreted as showing that there exists \( \epsilon > 0 \) such that if \( \|f\|_{U^{d+1}} \geq 1 - \epsilon/4^d \), then \( \delta_d(f) = O(4^d(1 - \|f\|_{U^{d+1}})) \).

Before explaining our technique, we describe some applications of our result.

1.4 Tolerant testing of RM codes

Parnas, Ron, and Rubinfeld [PRR06] introduced the notion of tolerant testing, and Guruswami and Rudra [GR05] studied this in the coding theoretic setting. Standard testers are required to reject strings that are far from codewords, but are not required to accept strings that are close to codewords. A tolerant tester is required to accept close codewords. In particular, for a code with minimum (relative) distance \( \delta_{\text{min}} \), there exists constants \( c_1 \) and \( c_2 \) such that the test must accept strings within distance \( c_1 \delta_{\text{min}} \) with probability at least 2/3 (called the acceptance condition),

\[1\text{For a tester } T \text{ and a function } f, \text{ the notation } T^f \text{ indicates the execution of } T \text{ with oracle access to } f.\]
and reject strings that are at least \((c_2\delta_{\text{min}})\)-far with probability at least 2/3 (called the rejection condition).

Any tester which satisfies the rejection condition must make at least \(\Omega(1/\delta_{\text{min}})\) queries. We observe that a tester that satisfies the rejection condition and makes \(C/\delta_{\text{min}}\) queries for a constant \(C\) is also tolerant. This follows because a string with distance \(\delta_{\text{min}}/(3C)\) will be rejected with probability at most 1/3. It even suffices to have the rejection condition with a constant probability (instead of 2/3), because the test can be repeated a constant number of times to boost the probability to 2/3.

In particular, for Reed-Muller codes \(\delta_{\text{min}} = 2^{-d}\), so the Gowers norm test is also tolerant. No tolerant tester for binary Reed-Muller codes appears to have been known.

**Theorem 3** \(T_{\text{GN}}\) is a tolerant tester for \(\text{RM}(d,n)\).

### 1.5 XOR lemma for low-degree polynomials

As mentioned earlier, Viola and Wigderson [VW07] used the Gowers norm and the Alon et al. analysis to give an elegant “hardness amplification” result for low-degree polynomials. Let \(f : \mathbb{F}_2^n \to \mathbb{F}_2\) be such that \(\delta_d(f)\) is noticeably large, say \(\geq 0.1\). Viola and Wigderson showed how to use this \(f\) to construct a \(g : \mathbb{F}_2^n \to \mathbb{F}_2\) such that \(\delta_d(g)\) is significantly larger, around \(1/2 - 2^{-\Omega(m)}\). In their construction, \(g = f\oplus_t\), the \(t\)-wise XOR of \(f\), where \(f\oplus_t : (\mathbb{F}_2^n)^t \to \mathbb{F}_2\) is given by:

\[
f\oplus_t(x_1, \ldots, x_t) = \sum_{i=1}^t f(x_i).
\]

In particular, they showed that if \(\delta_d(f) \geq 0.1\), then \(\delta_d(f\oplus_t) \geq 1/2 - 2^{-\Omega(t/4)}\). Their proof proceeded by studying the rejection probabilities of \(T_{\text{GN}}\) on the functions \(f\) and \(f\oplus_t\). The analysis of the rejection probability of \(T_{\text{GN}}\) given by [AKK\'05] was a central ingredient in their proof. By using our improved analysis of the rejection probability of \(T_{\text{GN}}\) from Theorem 1 instead, we get the following improvement.

**Theorem 4** Let \(\epsilon_1\) be as in Theorem 1. Let \(f : \mathbb{F}_2^n \to \mathbb{F}_2\). Then

\[
\delta_d(f\oplus_t) \geq \frac{1 - (1 - 2\min\{\epsilon_1/4, 2^{d-2}: \delta_d(f)\})t/2^d}{2}.
\]

In particular, if \(\delta_d(f) \geq 0.1\), then \(\delta_d(f\oplus_t) \geq 1/2 - 2^{-\Omega(t/2^d)}\).

### 1.6 Query hierarchy for affine-invariant properties

Our result falls naturally in the general framework of property testing [BLR93, RS96, GGR98]. Goldreich et al. [GKNR09] asked an interesting question in this broad framework: Given an ensemble of properties \(\mathcal{F} = \{\mathcal{F}_N\}_N\) where \(\mathcal{F}_N\) is a property of functions on domains of size \(N\), which functions correspond to the query complexity of some property? That is, for a given complexity function \(q(N)\), is there a corresponding property \(\mathcal{F}\) such that \(\Theta(q(N))\)-queries are necessary and
sufficient for testing membership in \( \mathcal{F}_{N} \)? This question is interesting even when we restrict the class of properties being considered.

For completely general properties this question is easy to solve. For graph properties \([\text{GKNR09}]\) et al. show that for every efficiently computable function \( q(N) = O(N) \) there is a graph property for which \( \Theta(q(N)) \) queries are necessary and sufficient (on graphs on \( \Omega(\sqrt{N}) \) vertices). Thus this gives a “hierarchy theorem” for query complexity.

Our main theorem settles the analogous question in the setting of “affine-invariant” properties. Given a field \( \mathbb{F} \), a property \( \mathcal{F} \subseteq \{ \mathbb{F}^{n} \rightarrow \mathbb{F} \} \) is said to be affine-invariant if for every \( f \in \mathcal{F} \) and affine map \( A : \mathbb{F}^{n} \rightarrow \mathbb{F}^{n} \), the composition of \( f \) with \( A \), i.e., the function \( f \circ A(x) = f(A(x)) \), is also in \( \mathcal{F} \). Affine-invariant properties seem to be the algebraic analog of graph-theoretic properties and generalize most natural algebraic properties (see Kaufman and Sudan \([\text{KS08}]\)).

Since the Reed-Muller codes form an affine-invariant family, and since we have a tight analysis for their query complexity, we can get the affine-invariant version of the result of \([\text{GKNR09}]\). Specifically, given any (reasonable) query complexity function \( q(N) \) consider \( N \) that is a power of two and consider the class of functions on \( n = \log_{2} N \) variables of degree at most \( d = \lceil \log_{2} q(N) \rceil \). We have that membership in this family requires \( \Omega(2^{d}) = \Omega(q(N)) \)-queries, and on the other hand \( O(2^{d}) = O(q(N)) \)-queries also suffice, giving an ensemble of properties \( \mathcal{P}_{N} \) (one for every \( N = 2^{n} \)) that is testable with \( \Theta(q(N)) \)-queries.

**Theorem 5** For every \( q : \mathbb{N} \rightarrow \mathbb{N} \) that is at most linear, there is an affine-invariant property that is testable with \( O(q(n)) \) queries (with one-sided error) but is not testable in \( o(q(n)) \) queries (even with two-sided error). Namely, this property is membership in \( \text{RM}(\lceil \log_{2} q(n) \rceil, n) \).

### 1.7 Technique

Our main theorem (Theorem 1) is obtained by a novel proof that gives a (yet another!) new analysis even of the classical linearity test of Blum, Luby, Rubinfeld \([\text{BLR93}]\). The heart of our proof is an inductive argument on \( n \), the dimension of the ambient space. While proofs that use induction on \( n \) have been used before in the literature on low-degree testing (see, for instance, \([\text{BFL91, BFLS91, FGL+96}]\)), they tend to have a performance guarantee that degrades significantly with \( n \). Indeed no inductive proof was known even for the case of testing linearity of functions from \( \mathbb{F}_{2}^{d} \rightarrow \mathbb{F}_{2} \) that showed that functions at \( \Omega(1) \) distance from linear functions are rejected with \( \Omega(1) \) probability. (We note that the original analysis of \([\text{BLR93}]\) as well as the later analysis of \([\text{BCH+96}]\) do give such bounds - but they do not use induction on \( n \).) In the process of giving a tight analysis of the \([\text{AKK+05}]\) test for Reed-Muller codes, we thus end up giving a new (even if weaker) analysis of the linearity test over \( \mathbb{F}_{2}^{n} \). Below we give the main idea behind our proof.

Consider a function \( f \) that is \( \delta \)-far from every degree \( d \) polynomial. For a “hyperplane”, i.e., an \((n - 1)\)-dimensional affine subspace \( A \) of \( \mathbb{F}_{2}^{n} \), let \( f\big|_{A} \) denote the restriction of \( f \) to \( A \). We first note that the test can be interpreted as first picking a random hyperplane \( A \) in \( \mathbb{F}_{2}^{n} \) and then picking a random \((d + 1)\)-dimensional affine subspace \( A' \) within \( A \) and testing if \( f\big|_{A'} \) is a degree \( d \) polynomial. Now, if on every hyperplane \( A \), \( f\big|_{A} \) is still \( \delta \)-far from degree \( d \) polynomials then we would be done by the inductive hypothesis. In fact our hypothesis gets weaker as \( n \rightarrow \infty \), so that we can even afford a few hyperplanes where \( f\big|_{A} \) is not \( \delta \)-far. The crux of our analysis is when for several (but
just $O(2^d)$) hyperplanes $f|_A$ is close to some degree $d$ polynomial $P_A$. In this case we manage to “sew” the different polynomials $P_A$ (each defined on some $(n-1)$-dimensional subspace within $F_2^n$) into a degree $d$ polynomial $P$ that agrees with all the $P_A$’s. We then show that this polynomial is close to $f$, completing our argument.

To stress the novelty of our proof, note that this is not a “self-correction” argument as in [AKK+05], where one defines a natural function that is close to $P$, and then works hard to prove it is a polynomial of appropriate degree. In contrast, our function is a polynomial by construction and the harder part (if any) is to show that the polynomial is close to $f$. Moreover, unlike other inductive proofs, our main gain is in the fact that the new polynomial $P$ has degree no greater than that of the polynomials given by the induction.

Organization of this paper: We prove our main theorem, Theorem 1, in Section 2 assuming three lemmas, two of which study the rejection probability of the $k$-dimensional affine subspace test, and another that relates the rejection probability of the basic $(d+1)$-dimensional affine subspace test to that of the $k$-dimensional affine subspace test. These three lemmas are proved in the following section, Section 3.

We give the relationship to the Gowers norm in Section 4, and we prove our improved hardness amplification theorem, Theorem 4, in Section 5. Finally, we show the tightness of our main theorem in the appendix.

2 Proof of Main Theorem

In this section we prove Theorem 1. We start with an overview of our proof. Recall that a $k$-flat is an affine subspace of dimension $k$, and a hyperplane is an $(n-1)$-flat.

The proof of the main theorem proceeds as follows. We begin by studying a variant of the basic tester $T_{GN}$, which we call $T_{d,k}$ or the $k$-flat test. For an integer $k \geq d+1$, $T_{d,k}^f$ picks a uniformly random $k$-flat in $F_2^n$, and accepts if and only if the restriction of $f$ to that flat has degree at most $d$. In this language, the tester $T_{GN}$ of interest to us is $T_{d,d+1}$. To prove Theorem 1 we first show that for $k \approx d + 10$, the tester $T_{d,k}^f$ rejects with constant probability if $\delta_d(f)$ is $\Omega(2^{-d})$ (see Lemma 9).

We then relate the rejection probabilities of $T_{d,k}^f$ and $T_{GN}^f$ (see Lemma 10).

The central ingredient in our analysis is thus Lemma 9 which is proved by induction on $n$, the dimension of the ambient space. Recall that we want to show that the two quantities (1) $\delta_d(f)$ and (2) $\Pr[T_{d,k}^f \text{ rejects}]$, are closely related. We consider what happens to $f$ when restricted to some hyperplane $A$. Denote such a restriction by $f|_A$. For a hyperplane $A$ we consider the corresponding two quantities (1) $\delta_d(f|_A)$ and (2) $\Pr[T_{d,k}^f|_A \text{ rejects}]$. The inductive hypothesis tells us that these two quantities are closely related for each $A$. Because of the local nature of tester $T_{d,k}$, it follows easily that $\Pr[T_{d,k}^f \text{ rejects}]$ is the average of $\Pr[T_{d,k}^f|_A \text{ rejects}]$ over all hyperplanes $A$. The main technical content of Lemma 9 is that there is a similar tight relationship between $\delta_d(f)$ and the numbers $\delta_d(f|_A)$ as $A$ varies over all hyperplanes $A$. This relationship suffices to complete the proof. The heart of our analysis focuses on the case where for many hyperplanes (about $2^k$ of them, independent of $n$), the quantity $\delta_d(f|_A)$ is very small (namely, for many $A$, there is a polynomial $P_A$ of degree $d$
that is very close to \( f|_A \). In this case, we show how to “sew” together the polynomials \( P_A \) to get a polynomial \( P \) on \( \mathbb{F}_2^n \) that is also very close to \( f \). In contrast to prior approaches which yield a polynomial \( P \) with larger degree than that of the \( P_A \)’s, our analysis crucially preserves this degree, leading to the eventual tightness of our analysis.

We now turn to the formal proof.

2.1 Preliminaries

We begin by formally introducing the \( k \)-flat test and some related notation.

**Definition 6 (k-flat test \( T_{d,k} \))** The test \( T_{d,k}^f \) picks a random \( k \)-flat \( A \subseteq \mathbb{F}_2^n \) and accepts if and only if \( f|_A \) \( (f \) restricted to \( A) \) is a polynomial of degree at most \( d \).

The rejection probability of \( T_{d,k}^f \) is denoted \( \text{Rej}_{d,k}(f) \). In words, this is the probability that \( f|_A \) is not a degree \( d \) polynomial when \( A \) is chosen uniformly at random among all \( k \)-flats of \( \mathbb{F}_2^n \).

Although we don’t need it for our argument, we note that \( T_{\text{GN}} = T_{d,d+1} \) accepts if and only if the \( 2^{d+1} \) evaluations \( f|_A \) sum to 0.

The following folklore proposition shows that for \( k \geq d + 1 \), \( T_{d,k} \) has perfect completeness.

**Proposition 7** For every \( k, \ell, d \) such that \( k \geq \ell \geq d + 1 \), \( \delta_d(f) = 0 \) if and only if \( \text{Rej}_{d,k}(f) = 0 \).

2.2 Key Lemmas

We now state our three key lemmas, and then use them to finish the proof of Theorem 1. The first is a simple lemma that says if the function is sufficiently close to a degree \( d \) polynomial, then the rejection probability is linear in its distance from degree \( d \) polynomials.

**Lemma 8** For every \( k, \ell, d \) such that \( k \geq \ell \geq d + 1 \), if \( \delta(f) = \delta \) then \( \text{Rej}_{d,k}(f) \geq 2^\ell \cdot \delta \cdot (1 - (2^\ell - 1) \delta) \).

In particular, if \( \delta \leq 2^{-(d+2)} \) then \( \text{Rej}_{d,k}(f) \geq \min\{\frac{1}{8}, 2^{k-1} \cdot \delta\} \).

The next lemma is the heart of our analysis and allows us to lower bound the rejection probability when the function is bounded away from degree \( d \) polynomials.

**Lemma 9** There exist positive constants \( \beta < 1/4, \epsilon_0, \gamma \) and \( c \) such that the following holds for every \( d, k, n, \) such that \( n \geq k \geq d + c \). Let \( f : \mathbb{F}_2^n \rightarrow \mathbb{F}_2 \) be such that \( \delta(f) \geq \beta \cdot 2^{-d} \). Then \( \text{Rej}_{d,k}(f) \geq \epsilon_0 + \gamma \cdot 2^d/2^n \).

The final lemma relates the rejection probabilities of different dimensional tests.

**Lemma 10** For every \( n, d \) and \( k \geq k' \geq d + 1 \), and every \( f : \mathbb{F}_2^n \rightarrow \mathbb{F}_2 \), we have
\[
\text{Rej}_{d,k'}(f) \geq \text{Rej}_{d,k}(f) \cdot 2^{-(k - k')}. 
\]
Given the three lemmas above, Theorem 1 follows easily as shown below.

**Proof of Theorem 1:** Let $\epsilon_0$ and $c$ be as in Lemma 8. We prove the theorem for $\epsilon_1 = \epsilon_0 \cdot 2^{-(c-1)}$. First note that if $\delta(f) \leq 2^{-(d+2)}$, then we are done by Lemma 8. So assume $\delta(f) \geq 2^{-(d+2)} \geq \beta \cdot 2^{-d}$, where $\beta$ is the constant from Lemma 9. By Lemma 9 we know that $\text{Rej}_{d,d+1}(f) \geq \epsilon_0$. Lemma 10 now implies that $\text{Rej}_{d,d+1}(f) \geq \epsilon_0 \cdot 2^{-(c-1)}$, as desired.

### 3 Analysis of the $k$-flat test

Throughout this section we fix $d$, so we suppress it in the subscripts and simply use $\delta(f) = \delta_d(f)$ and $\text{Rej}_k(f) = \text{Rej}_{d,k}(f)$.

#### 3.1 Lemma 8: When $f$ is close to $\text{RM}(d, n)$

Recall that we wish to prove

**Lemma 8 (recalled):** For every $k, \ell, d$ such that $k \geq \ell \geq d + 1$, if $\delta(f) = \delta$ then $\text{Rej}_k(f) \geq 2^\ell \cdot \delta \cdot (1 - (2^{\ell} - 1)\delta)$. In particular, if $\delta \leq 2^{-(d+2)}$ then $\text{Rej}_k(f) \geq \min\{\frac{1}{8}, 2^{k-1} \cdot \delta\}$.

**Proof of Lemma 8:** The main idea is to show that with good probability, the flat will contain exactly one point where $f$ and the closest degree $d$ polynomial differ, in which case the test will reject. The main claim we prove is that $\text{Rej}_k(f) \geq 2^\ell \cdot \delta \cdot (1 - (2^\ell - 1)\delta)$. The first part then follows from the monotonicity of the rejection probability, i.e., $\text{Rej}_k(f) \geq \text{Rej}_l(f)$ if $k \geq \ell$. The second part follows by setting $\ell = k$ if $\delta \leq 2^{-(k+1)}$ and $\ell$ such that $2^{-(\ell+2)} < \delta \leq 2^{-(\ell+1)}$ otherwise. In the former case, we get $\text{Rej}_k(f) \geq 2^{-(k-1)} \cdot \delta$ while in the latter case we get $\text{Rej}_k(f) \geq \text{Rej}_\ell(f) \geq \frac{1}{8}$. We thus turn to proving $\text{Rej}_{\ell}(f) \geq 2^\ell \cdot \delta \cdot (1 - (2^\ell - 1)\delta)$.

Let $g \in \text{RM}(d, n)$ be a polynomial achieving $\delta(f) = \delta(f, g)$. Consider a random $\ell$-flat $A$ of $\mathbb{F}_2^n$. We think of the points of $A$ as generated by picking a random full-rank matrix $M \in \mathbb{F}_{2^{n}}^{n \times \ell}$ and a random vector $b \in \mathbb{F}_{2}^{n}$, and then letting $A = \{a_x \overset{\text{def}}{=} Mx + b \mid x \in \mathbb{F}_{2}^{\ell}\}$. Thus the points of $A$ are indexed by elements of $\mathbb{F}_2^n$.

For $x \in \mathbb{F}_2^\ell$, let $E_x$ be the event that \( "f(a_x) \neq g(a_x)" \). Further let $F_x$ be the event that \( "f(a_x) \neq g(a_y)\) for every $y \neq x" \). We note that if any of the events $F_x$ occurs (for $x \in \mathbb{F}_2^n$), then the $\ell$-flat test rejects $f$. This is because distinct degree $d$ polynomials differ in at least $2^{-d}$ fraction of points, so they cannot differ in exactly one point if $\ell > d$.

We now lower bound the probability of $\bigcup_x F_x$. Using the fact that $a_x$ is distributed uniformly over $\mathbb{F}_2^n$ and $a_y$ is distributed uniformly over $\mathbb{F}_2^n - \{a_x\}$, we note that $\Pr[E_x] = \delta$ and $\Pr[E_x$ and $E_y] \leq \delta^2$. We also have $\Pr[F_x] \geq \Pr[E_x] - \sum_{y \neq x} \Pr[E_x$ and $E_y] \geq \delta - (2^\ell - 1) \cdot \delta^2$. Finally, noticing that the events $E_x$ are mutually exclusive we have that $\Pr[\bigcup_i F_i] = \sum_i \Pr[F_i] \geq 2^\ell \cdot \delta \cdot (1 - (2^\ell - 1) \cdot \delta)$, as claimed.
3.2 Lemma 9: When f is bounded away from RM(d, n)

The main idea of the proof of Lemma 9 is to consider the restrictions of f on randomly chosen “hyperplanes”, i.e., (n - 1)-flats. If on an overwhelmingly large fraction (which will be quantified in the proof) of hyperplanes, our function is far from degree d polynomials, then the inductive hypothesis suffices to show that f will be rejected with high probability (by the k-flat test). The interesting case is when the restrictions of f to several hyperplanes are close to degree d polynomials. In Lemma 12 we use the close polynomials on such hyperplanes to construct a polynomial that has significant agreement with f on the union of the hyperplanes.

We start by first fixing some terminology. We say A and B are complementary hyperplanes if $A \cup B = \mathbb{F}_2^n$. Recalling that a hyperplane is the set of points $\{x \in \mathbb{F}_2^n | L(x) = b\}$ where $L : \mathbb{F}_2^n \to \mathbb{F}_2$ is a nonzero linear function and $b \in \mathbb{F}_2$, we refer to $L$ as the linear part of the hyperplane. We say that hyperplanes $A_1, \ldots, A_\ell$ are linearly independent if the corresponding linear parts are independent. The following proposition lists some basic facts about hyperplanes that we use. The proof is omitted.

**Proposition 11 (Properties of hyperplanes)**

1. There are exactly $2^{n+1} - 2$ distinct hyperplanes in $\mathbb{F}_2^n$.
2. Among any $2^\ell - 1$ distinct hyperplanes, there are at least $\ell$ independent hyperplanes.
3. There is an affine invertible transform that maps independent hyperplanes $A_1, \ldots, A_\ell$ to the hyperplanes $x_1 = 0, x_2 = 0, \ldots, x_\ell = 0$.

We are now ready to prove Lemma 9. We first recall the statement.

**Lemma 9 (recalled):** There exist positive constants $\beta < 1/4, \epsilon_0, \gamma$ and $c$ such that the following holds for every $d, k, n$, such that $n \geq k \geq d + c$. Let $f : \mathbb{F}_2^n \to \mathbb{F}_2$ be such that $\delta(f) \geq \beta \cdot 2^{-d}$. Then $\text{Rej}_{d,k}(f) \geq \epsilon_0 + \gamma \cdot 2^d/2^n$.

**Proof of Lemma 9:** We prove the lemma for every $\beta < 1/24, \epsilon_0 < 1/8, \gamma \geq 72$, and $c$ such that $2^c \geq \max\{4\gamma/(1 - 8\epsilon_0), \gamma/(1 - \epsilon_0), 2/\beta\}$. (In particular, the choices $\beta = 1/25, \epsilon_0 = 1/16, \gamma = 72$ and $c = 10$ work.)

The proof uses induction on $n - k$. When $n = k$ we have $\text{Rej}_k(f) = 1 \geq \epsilon_0 + \gamma \cdot 2^d$ as required, because $2^c \geq \frac{\gamma}{1 - \epsilon_0}$. So we move to the inductive step.

Let $\mathcal{H}$ denote the set of hyperplanes in $\mathbb{F}_2^n$. Let $N = 2(2^n - 1)$ be the cardinality of $\mathcal{H}$. Let $\mathcal{H}^*$ be the set of all the hyperplanes $A \in \mathcal{H}$ such that $\delta(f|_A, \text{RM}(d, n - 1)) < \beta \cdot 2^{-d}$. Let $K = |\mathcal{H}^*|$.

Now because a random $k$-flat of a random hyperplane is a random $k$-flat, we have

$$\text{Rej}_k(f) = \mathbb{E}_{A \in \mathcal{H}}[\text{Rej}_k(f|_A)].$$

By the induction hypothesis, for any $A \in \mathcal{H} \setminus \mathcal{H}^*$, we have

$$\text{Rej}_k(f|_A) \geq \epsilon_0 + \gamma \cdot \frac{2^d}{2^{n-1}}.$$
Thus, \[
\text{Rej}_k(f) \geq \epsilon_0 + \gamma \cdot \frac{2^d}{2^n - 1} - K/N.
\]

We now take cases on whether \(K\) is large or small:

1. **Case 1:** \(K \leq \gamma \cdot 2^d\).
   In this case, \(\text{Rej}_k(f) \geq \epsilon_0 + \gamma \cdot 2^d/2^{n-1} - K/N \geq \epsilon_0 + \gamma \cdot 2^d/2^n\) as desired.

2. **Case 2:** \(K > \gamma \cdot 2^d\).
   Lemma 12 (below) shows that in this case, \(\delta(f) = \frac{3}{2} \beta \cdot 2^{-d} + 9/(\gamma 2^d) \geq \delta_0\), provided \(\beta \cdot 2^{-d} < 2^{-(d+2)}\) (which holds since \(\beta < 1/24 < 1/4\)).

   Note that since \(\beta < 1/24\) and \(9/\gamma < 1/8\), we get \(\delta_0 < 2^{-(d+2)}\) and so Lemma 8 implies that \(\text{Rej}_k(f) \geq \min\{2^{k-1} \cdot \delta(f), \frac{1}{\gamma}\} \geq \min\{2^{k-1}, \beta \cdot 2^{-d}, \frac{1}{8}\}\). We verify both quantities above are at least \(\epsilon_0 + \gamma/2^{(c+1)} \geq \epsilon_0 + \gamma 2^d/2^n\). The condition \(1/8 > \epsilon_0 + \gamma/2^{c+1}\) follows from the fact that \(2^c \geq 4\gamma/(1-8\epsilon_0)\). To verify the second condition, note that \(2^{k-1} \cdot \beta \cdot 2^{-d} \geq 2^{c-1} \beta \geq 1\) since \(2^c \geq 2/\beta\).

We thus conclude that the rejection probability of \(f\) is at least \(\epsilon_0 + \gamma \cdot 2^d/2^n\) as claimed. 

**Lemma 12** For \(f : \mathbb{F}_2^n \to \mathbb{F}_2\), let \(A_1, \ldots, A_K\) be hyperplanes such that \(f|_{A_i}\) is \(\alpha\)-close to some degree \(d\) polynomial on \(A_i\). If \(K > 2^{d+1}\) and \(\alpha < 2^{-(d+2)}\), then \(\delta(f) \leq \frac{3}{2} \alpha + 9/K\).

**Proof** Let \(P_i\) be the degree \(d\) polynomial such that \(f|_{A_i}\) is \(\alpha\)-close to \(P_i\).

**Claim 13** If \(4\alpha < 2^{-d}\) then for every pair of hyperplanes \(A_i\) and \(A_j\), we have \(P_i|_{A_i \cap A_j} = P_j|_{A_j \cap A_i}\).

**Proof** If \(A_i\) and \(A_j\) are complementary then this is vacuously true. Otherwise, \(|A_i \cap A_j| = |A_i|/2 = |A_j|/2\). So \(\delta(f|_{A_i \cap A_j}, P_i|_{A_i \cap A_j}) \leq 2\delta(f|_{A_i}, P_i) \leq 2\alpha\) and similarly \(\delta(f|_{A_i \cap A_j}, P_j|_{A_j \cap A_i}) \leq 2\alpha\). So \(\delta(P_i|_{A_i \cap A_j}, P_j|_{A_j \cap A_j}) \leq 4\alpha < 2^{-d}\). But these are both degree \(d\) polynomials and so if their proximity is less than \(2^{-d}\) then they must be identical.

Let \(\ell = \lceil \log_2(K+1) \rceil\). Thus \(\ell > d\). By Proposition 11 there are at least \(\ell\) linearly independent hyperplanes among \(A_1, \ldots, A_K\). Without loss of generality let these be \(A_1, \ldots, A_\ell\). Furthermore, by an affine transformation of coordinates, for \(i \in [\ell]\) let \(A_i\) be the hyperplane \(\{x \in \mathbb{F}_2^n \mid x_i = 0\}\). For \(i \in [\ell]\) extend \(P_i\) to a function on all of \(\mathbb{F}_2^n\) by making \(P_i\) independent of \(x_i\). We will sew together \(P_1, \ldots, P_\ell\) to get a polynomial close to \(f\).

Let us write all functions from \(\mathbb{F}_2^n \to \mathbb{F}_2\) as polynomials in \(n\) variables \(x_1, \ldots, x_\ell\) and \(y\) where \(y\) denotes the last \(n - \ell\) variables. For \(i \in [\ell]\) and \(S \subseteq [\ell]\), let \(P_{i,S}(y)\) be the monomials of \(P_i\) which contain \(x_i\) for \(i \in S\), and no \(x_j\) for \(j \notin [\ell]\). That is, \(P_{i,S}(y)\) are polynomials such that \(P_i(x_1, \ldots, x_\ell, y) = \sum_{S \subseteq [\ell]} P_{i,S}(y) \prod_{j \in S} x_j\). Note that the degree of \(P_{i,S}\) is at most \(d - |S|\). (In particular, if \(|S| > d\), then \(P_{i,S} = 0\).) Note further that since \(P_i\) is independent of \(x_i\), we have that \(P_{i,S} = 0\) if \(i \in S\).
Claim 14 For every \( S \subseteq [\ell] \) and every \( i, j \in [\ell] - S \), \( P_{i,S}(y) = P_{j,S}(y) \).

Proof Note that \( P_{i \cap A_j}(x,y) = \sum_{S \subseteq [\ell] - \{i,j\}} P_{i,S}(y) \prod_{m \in S} x_m \). Similarly, \( P_{j \cap A_i}(x,y) = \sum_{S \subseteq [\ell] - \{i,j\}} P_{j,S}(y) \prod_{m \in S} x_m \). Since the two functions are equal (by Claim 13), we have that every pair of coefficients of \( \prod_{m \in S} x_m \) must be the same. We conclude that \( P_{i,S} = P_{j,S} \). □

Claim 14 above now allows us to define, for every \( S \subseteq [\ell] \), the polynomial \( P_S(y) \) as the unique polynomial \( P_{i,S} \) where \( i \notin S \). We define

\[
P(x_1, \ldots, x_\ell, y) = \sum_{S \subseteq [\ell]} P_S(y) \prod_{j \in S} x_j.
\]

By construction, the degree of \( P \) is at most \( d \). This is the polynomial that we will eventually show is close to \( f \).

Claim 15 For every \( i \in [K] \), \( P_{|A_i} = P_{i \cap A_i} \).

Proof First note that for each \( i \in [\ell] \), \( P_{|A_i} = P_{i \cap A_i} \). This is because the coefficients of the two polynomials become identical after substituting \( x_i = 0 \) (recall that \( A_i \) is the hyperplane \( \{x \in \mathbb{F}_2^n \mid x_i = 0\} \)).

Now consider general \( i \in [K] \). For any point \( x \in A_i \cap (\bigcup_{j=1}^\ell A_j) \), letting \( j^* \in [\ell] \) be such that \( x \in A_{j^*} \), we have \( P_i(x) = P_{j^*}(x) \) (by Claim 13) and \( P_{j^*}(x) = P(x) \) (by what we just showed, since \( j^* \in [\ell] \)). Thus \( P \) and \( P_i \) agree on all points in \( A_i \cap (\bigcup_{j=1}^\ell A_j) \). Now since \( \ell > d \), we have that \( |A_i \cap (\bigcup_{j=1}^\ell A_j)|/|A_i| \geq 1 - 2^{-\ell} > 1 - 2^{-d} \), and since \( P_{|A_i} \) and \( P_{i \cap A_i} \) are both degree \( d \) polynomials, we conclude that \( P_{|A_i} \) and \( P_{i \cap A_i} \) are identical. Thus for all \( i \in [K] \), \( P_{|A_i} = P_{i \cap A_i} \). □

We will show below that \( P \) is close to \( f \), by considering all the hyperplanes \( A_1, \ldots, A_K \). If these hyperplanes uniformly covered \( \mathbb{F}_2^n \), then we could conclude \( \delta(f, P) \leq \alpha \), as \( f \) is \( \alpha \)-close to \( P \) on each hyperplane. Since the \( A_i \) don’t uniformly cover \( \mathbb{F}_2^n \), we’ll argue that almost all points are covered approximately the right number of times, which will be good enough. To this end, let

\[
\text{BAD} = \{ z \in \mathbb{F}_2^n \mid z \text{ is contained in less than } K/3 \text{ of the hyperplanes } A_1, \ldots, A_K \}.
\]

Let \( \tau = |\text{BAD}|/2^n \).

Claim 16 \( \delta(f, P) \leq 3/2 \cdot \alpha + \tau \).

Proof Consider the following experiment: Pick \( z \in \mathbb{F}_2^n \) and \( i \in [K] \) uniformly and independently at random and consider the probability that \( \{ z \in A_i \text{ and } f(z) \neq P_i(z) \} \). On the one hand, we have

\[
\Pr_{z,i}[z \in A_i \& f(z) \neq P_i(z)] \leq \max_i \Pr_{z}[z \in A_i] \cdot \Pr_{z}[f(z) \neq P_i(z) | z \in A_i] \leq \frac{1}{2} \alpha.
\]
On the other hand, using the fact that $P|_{A_i} = P$, we have that

\[
\begin{align*}
\Pr[z \in A_i \& f(z) \neq P_i(z)] &= \Pr[z \in A_i \& f(z) \neq P(z)] \\
&\geq \Pr[z \in A_i \& f(z) \neq P(z) \& z \notin \text{BAD}] \\
&= \Pr[f(z) \neq P(z) \& z \notin \text{BAD}] \cdot \Pr[z \in A_i | f(z) \neq P(z) \& z \notin \text{BAD}] \\
&\geq \Pr[f(z) \neq P(z) \& z \notin \text{BAD}] \cdot \min_{z \in \text{BAD} \& f(z) \neq P(z)} \Pr[z \in A_i] \\
&\geq (\delta(f, P) - \tau) \cdot \min_{z \in \text{BAD}} \Pr[z \in A_i] \\
&\geq (\delta(f, P) - \tau) \frac{1}{3}
\end{align*}
\]

We thus conclude that $(\delta(f, P) - \tau)/3 \leq \alpha/2$ yielding the claim. ■

**Claim 17** $\tau \leq 9/K$.

**Proof** The proof is a straightforward “pairwise independence” argument, with a slight technicality to handle complementary hyperplanes.

Consider a random variable $z$ distributed uniformly over $\mathbb{F}_2^n$. For $i \in [K]$, let $Y_i$ denote the random variable that is +1 if $z \in A_i$ and −1 otherwise. Note that $z \in \text{BAD}$ if and only if $\sum_i Y_i \leq -K/3$ and so $\tau = \Pr[\sum_i Y_i \leq -K/3]$. We now bound this probability.

For every $i$, note that $E[Y_i] = 0$ and $\text{Var}[Y_i] = 1$. Notice further that if $A_i$ and $A_j$ are not complementary hyperplanes, then $Y_i$ and $Y_j$ are independent and so $E[Y_i Y_j] = 0$, while if they are complementary, then $E[Y_i Y_j] = -1 \leq 0$. We conclude that $E[\sum_i Y_i] = 0$ and $\text{Var}[\sum_i Y_i] \leq K$. Using Chebychev’s bound, we conclude that $\tau = \Pr[\sum_i Y_i \leq -K/3] \leq \text{Var}(\sum_i Y_i)/(K^2/9) \leq 9/K$. ■

The lemma follows from the last two claims above. ■

### 3.3 Lemma 10 Relating different dimensional tests

**Lemma 18** Let $k \geq d + 1$ and let $f : \mathbb{F}_2^{k+1} \rightarrow \mathbb{F}_2$ have degree greater than $d$. Then $\text{Rej}_{d,k}(f) \geq 1/2$.

**Proof** Assume for contradiction that there is a strict majority of hyperplanes $A$ on which $f|_A$ has degree $d$. Then there exists two complementary hyperplanes $A$ and $\bar{A}$ such that $f|_A$ and $f|_{\bar{A}}$ both have degree $d$. We can interpolate a polynomial $P$ of degree at most $d+1$ that now equals $f$ everywhere. If $P$ is of degree $d$, we are done, so assume $P$ has degree exactly $d+1$ and let $P_h$ be
the homogenous degree \(d+1\) part of \(P\) (i.e., \(P = P_h + Q\) where \(\deg(Q) \leq d\) and \(P_h\) is homogenous). Now consider all hyperplanes \(A\) such that \(f|_A = P|_A\) has degree at most \(d\). Since these form a strict majority, there are at least \(\frac{1}{2}(2^{k+2} - 2) + 1 > 2^{k+1} - 1\) such hyperplanes. It follows that there are at least \(k + 1 \geq d + 2\) linearly independent hyperplanes such that this condition holds. By an affine transformation we can assume these hyperplanes are of the form \(x_1 = 0, \ldots, x_{d+2} = 0\). But then \(\prod_{i=1}^{d+2} x_i\) divides \(P_h\) which contradicts the fact that the degree of \(P_h\) is at most \(d + 1\). ■

Lemma 19 Let \(n \geq k \geq d + 1\) and let \(f : \mathbb{F}_2^n \to \mathbb{F}_2\) have degree greater than \(d\). Then \(\text{Rej}_{d,k}(f) \geq 2^{k-n}\).

Proof The proof is a simple induction on \(n\). The base case of \(n = k\) is trivial. Now assume for \(n - 1\). Pick a random hyperplane \(A\). With probability at least \(1/2\) (by the previous lemma), \(f|_A\) is not a degree \(d\) polynomial. By the inductive hypothesis, a random \(k\)-flat of \(A\) will now detect that \(f|_A\) is not of degree \(d\) with probability \(2^{k-n+1}\). We conclude that a random \(k\)-flat of \(\mathbb{F}_2^n\) yields a function of degree greater than \(d\) with probability at least \(2^{k-n}\). ■

We now have all the pieces needed to prove Lemma 10.

Lemma 10 (recalled): For every \(n, d\) and \(k \geq k' \geq d + 1\), and every \(f : \mathbb{F}_2^n \to \mathbb{F}_2\), we have

\[
\text{Rej}_{d,k'}(f) \geq \text{Rej}_{d,k}(f) \cdot 2^{-(k-k')}
\]

Proof of Lemma 10: We view the \(k'\)-flat test as the following process: first pick a random \(k\)-flat \(A_1\) of \(\mathbb{F}_2^n\), then pick a random \(k'\)-flat \(A\) of \(A_1\), and accept iff \(f|_A\) is a degree \(d\) polynomial. Note that this is completely equivalent to the \(k'\)-flat test.

To analyze our test, we first consider the event that \(f|_{A_1}\) is not a degree \(d\) polynomial. The probability that this happens is \(\text{Rej}_{d,k}(f)\). Now conditioned on the event that \(f|_{A_1}\) is not a degree \(d\) polynomial, we can now use Lemma 19 to conclude that the probability that \((f|_{A_1})|_A\) is not a degree \(d\) polynomial is at least \(2^{-(k-k')}\). We conclude that \(\text{Rej}_{d,k'}(f) \geq \text{Rej}_{d,k}(f) \cdot 2^{-(k-k')}\). The lemma follows. ■

4 Gowers norms

Our main theorem can be interpreted as giving a tight relationship between the Gowers norm of a function \(f\) and its proximity to some low degree polynomial. In this section we describe this relationship.

We start by recalling the definition of the test \(T^{f}_{\text{GN}(k)}\) and the Gowers norm \(\|f\|_{U^k}\). On oracle access to function \(f\), the test \(T^{f}_{\text{GN}(k)}\) picks \(x_0\) and directions \(a_1, \ldots, a_k\) uniformly and independently in \(\mathbb{F}_2^n\) and accepts if and only if \(f|_A\) is a degree \(k - 1\) polynomial, where \(A = \{x_0 + \text{span}(a_1, \ldots, a_k)\}\).

The Gowers norm is given by the expression

\[
\|f\|_{U^k} \overset{\text{def}}{=} \left(\Pr[T^{f}_{\text{GN}(k)} \text{ accepts}] - \Pr[T^{f}_{\text{GN}(k)} \text{ rejects}]\right)^{\frac{1}{k}}.
\]

14
Our main quantity of interest is the correlation of $f$ with degree $d$ polynomials, i.e., the quantity $1 - 2\delta_d(f)$.

Our theorem relating the Gowers norm to the correlation is given below.

**Theorem 20** There exists $\epsilon > 0$ such that if $\|f\|_{U^{d+1}} \geq 1 - \epsilon/2^d$, then $\delta_d(f) = \Theta(1 - \|f\|_{U^{d+1}})$.

To prove the theorem we first relate the rejection probability of the test $T_{GN(d+1)}$ with that of the test $T_{GN}$.

**Proposition 21** For every $n \geq d + 1$ and for every $f$, $\Pr[T_{f_{GN+(d+1)}}^f \text{ rejects}] \geq \frac{1}{4} \cdot \Pr[T_{f_{GN}}^f \text{ rejects}]$.

**Proof** We show that with probability at least $1/4$, the $a_i$ are linearly independent. Consider picking $d$ independent vectors $a_1, \ldots, a_d$ in $\mathbb{F}_2^n$. For fixed $\beta_1, \ldots, \beta_d \in \mathbb{F}_2$ (not all zero), the probability that $\sum_i \beta_i a_i = 0$ is at most $2^{-n}$. Taking the union bound over all sequences $\beta_1, \ldots, \beta_d$ we find that the probability that $a_1, \ldots, a_d$ have a linear dependency is at most $2d^{-n} \geq \frac{1}{2}$ if $n \geq d + 1$. For any fixed $a_1, \ldots, a_d$, the probability that $a_{d+1} \in \text{span}(a_1, \ldots, a_d)$ is also at most $\frac{1}{2}$. Thus we find with probability at least $1/4$, the vectors $a_1, \ldots, a_{d+1}$ are linearly independent provided $n \geq d + 1$. The proposition follows since the rejection probability of $T_{f_{GN+(d+1)}}^f$ equals the rejection probability of $T_{f_{GN}}^f$ times the probability that $a_1, \ldots, a_{d+1}$ are linearly independent.

We are now ready to prove Theorem 20.

**Proof of Theorem 20**: The proof is straightforward given our main theorem and the work of Gowers et al. [Gow01, GT08]. As mentioned earlier, Gowers already showed that $1 - 2\delta_d(f) \leq \|f\|_{U^{d+1}}$ [Gow01, GT08], i.e., $\delta_d(f) \geq (1 - \|f\|_{U^{d+1}})/2$.

For the other direction, suppose $\|f\|_{U^{d+1}} = 1 - \gamma$, where $\gamma \leq \epsilon/2^d$ for small enough $\epsilon$. Let $\rho$ denote the rejection probability of $T_{f_{GN+(d+1)}}^f$. By Proposition 21, we have $\rho \geq \frac{1}{4} \cdot \text{Rej}_{d,d+1}(f)$. By choosing $\epsilon$ small enough, we also have $1 - 2\rho = \|f\|_{U^{d+1}}^2 > 1 - \epsilon_1/2$, i.e., $\rho < \epsilon_1/4$, so $\text{Rej}_{d,d+1}(f) < \epsilon_1$. Thus, by Theorem 1

$$\delta_d(f) \leq \frac{1}{2^d} \text{Rej}_{d,d+1}(f)(f)$$

$$\leq \frac{1}{2^d-\gamma} \rho$$

$$= \frac{1}{2^{d-1}} (1 - \|f\|_{U^{d+1}}^2)$$

$$= \frac{1}{2^{d-1}} (1 - (1 - \gamma)^{2d+1})$$

$$\leq \frac{1}{2^{d-1}} (1 - (1 - O(2^{d+1}\gamma)))$$

$$= O(\gamma),$$

as required. ■
5 XOR lemma for low-degree polynomials

A crucial feature of the test $T_{GN(k)}$ (that is not a feature of the $k$-flat test for $k > d + 1$) is that the rejection probability of $f^\oplus t$ can be exactly expressed as a rapidly growing (in $t$) function of the rejection probability of $f$. Let $\text{Rej}^0_d(f)$ denote the rejection probability of $T_{GN(d+1)}^f$. Then we have:

**Proposition 22**

$$(1 - 2\text{Rej}^0_d(f^\oplus t)) = (1 - 2\text{Rej}^0_d(f))^t.$$  

**Proof** We first note that the proposition is equivalent to showing that $\|f^\oplus t\|_{U^{d+1}} = (\|f\|_{U^{d+1}})^t$. It is a standard fact (e.g., Fact 2.6 in [VW07]) that for functions $f, g$ on disjoint sets of inputs, $\|f(x) + g(y)\|_{U^{d+1}} = \|f(x)\|_{U^{d+1}} \cdot \|g(y)\|_{U^{d+1}}$. This immediately yields the proposition.

We also use the following well-known relationship between the Gowers norm and the correlation of a function to the class of degree $d$ polynomials. (We state it in terms of the rejection probability of the test $T_{GN(d+1)}$.)

**Lemma 23 ([Gow01, GT08])**

$$1 - 2\delta_d(g) \leq (1 - 2\text{Rej}^0_d(g))^\frac{1}{2^d}.$$  

We are now ready to prove Theorem 4 which we recall below.

**Theorem 4 (recalled):** Let $f : \mathbb{F}_2^n \rightarrow \mathbb{F}_2$. Then

$$\delta_d(f^\oplus t) \geq 1 - \left(1 - 2\min\{\epsilon_1/4, 2^{d-2} \cdot \delta_d(f)\}\right)^{t/2^d}.$$  

In particular, if $\delta_d(f) \geq 0.1$, then $\delta_d(f^\oplus t) \geq 1 - 2^{-\Omega(t/2^d)}$.

**Proof of Theorem 4:** By Theorem 1 and Proposition 21

$$\text{Rej}^0_d(f) \geq \min\{\epsilon_1/4, 2^{d-2} \cdot \delta_d(f)\}.$$  

Thus by Proposition 22

$$(1 - 2\text{Rej}^0_d(f^\oplus t))^{\frac{1}{2^d}} = (1 - 2\text{Rej}^0_d(f))^{\frac{1}{2^d}} \leq (1 - 2\min\{\epsilon_1/4, 2^{d-2} \cdot \delta_d(f)\})^{\frac{1}{2^d}}.$$  

Finally, Lemma 23 shows that

$$\delta_d(f^\oplus t) \geq 1 - \left(1 - 2\min\{\epsilon_1/4, 2^{d-2} \cdot \delta_d(f)\}\right)^{\frac{1}{2^d}}.$$  

\[\square\]
Acknowledgments

Thanks to Alex Samorodnitsky and Shachar Lovett for sharing some of the unpublished parts of their work \cite{lms2008} and allowing us to present parts of their proof in Appendix A. Thanks to Alex also for numerous stimulating discussions from the early stages of this work, and to Jakob Nordström for bringing some of the authors together on this work.

In this section we show that our main theorem cannot be improved asymptotically. Specifically, we show that there is a constant \( \alpha > 1/2 \) such that for infinitely many \( d \), for sufficiently large \( n \), there exists a function \( f = f_{d,n} : \mathbb{F}_2^n \rightarrow \mathbb{F}_2 \) that passes the degree \( d \) AKKLR test (i.e., the \((d+1)\)-flat test) with probability \( \alpha \) (i.e., strictly greater than half) while being almost uncorrelated with degree \( d \) polynomials.

Our example comes directly from the works of [LMS08, GT09]. In particular, the function \( f_{d,n} \) is simply the degree \( d + 1 \) symmetric polynomial over \( n \) variables (defined formally below). When \( d + 1 \) is a power of two, then [LMS08, GT09] (who in turn attribute the ideas to [AB01]) already show that this function is far from every degree \( d \) polynomial. To complete our theorem we only need to show that this function passes the \((d+1)\)-flat test with probability noticeably greater than \( 1/2 \). [LMS08, GT09] also analyzed this quantity, but the published versions only show that this function passes the \((d+1)\)-flat test with probability \( 1/2 + \epsilon(d) \) where \( \epsilon(d) \rightarrow 0 \) as \( d \rightarrow \infty \). However, it turns out that an early (unpublished) proof by the authors of [LMS08] can be used to show that the acceptance probability is \( 1/2 + \epsilon \) where \( \epsilon \) is an absolute constant. For completeness we include a complete proof here.

We start with the definition of the counterexample functions. For positive integers \( d, n \) with \( d \leq n \), let \( S_{d,n} : \mathbb{F}_2^n \rightarrow \mathbb{F}_2 \) be given by

\[
S_{d,n}(x_1, \ldots, x_n) = \sum_{I \subseteq [n], |I| = d} \prod_{i \in I} x_i.
\]

**Theorem 24** Let \( d + 1 = 2^t \) for some integer \( t \geq 2 \). Then, for every \( \epsilon > 0 \), there exists \( n_0 \) such that for every \( n \geq n_0 \), the following hold:

1. \( \delta_d(S_{d+1,n}) \geq 1/2 - \epsilon \).
2. \( \text{Rej}_{d,d+1}(S_{d+1,n}) \leq 1/2 - 2^{-7} + \epsilon \).

Theorem 24 follows immediately from the following two lemmas.

**Lemma 25** ([GT09, Theorem 11.3]) Let \( d + 1 = 2^t \) for some integer \( t \geq 0 \). Then, for every \( \epsilon > 0 \), for sufficiently large \( n \), we have \( \delta_d(S_{d+1,n}) \geq 1/2 - \epsilon \).

**Lemma 26** For every \( d \geq 3 \) and \( \epsilon > 0 \), for sufficiently large \( n \), we have \( \text{Rej}_{d,d+1}(S_{d+1,n}) \leq 1/2 - 2^{-7} + \epsilon \).
We prove Lemma 26 in the rest of this section. We stress again that this approach is from an unpublished version of LMS08, and we include it for completeness.

We start with some notation. For $x, a_1, \ldots, a_{d+1} \in \mathbb{F}_2^n$, let $I(x, a_1, \ldots, a_{d+1}) = 1$ if the $(d+1)$-flat test rejects $S_{d+1,n}$ when picking the affine subspace $x + \text{span}(a_1, \ldots, a_{d+1})$. Note that $\text{Rej}_{d+1}(S_{d+1,n}) = \mathbb{E}_{x, a_1, \ldots, a_{d+1}}[I(x, a_1, \ldots, a_{d+1})]$, where the expectation is taken over $x, a_1, \ldots, a_{d+1}$ picked uniformly and independently from $\mathbb{F}_2^n$, conditioned on $a_1, \ldots, a_{d+1}$ being linearly independent.

**Lemma 27** For $x, a_1, \ldots, a_{d+1} \in \mathbb{F}_2^n$, let $M \in \mathbb{F}_2^{(d+1) \times n}$ be the matrix whose $i$th row is $a_i$. Then $I(x, a_1, \ldots, a_{d+1}) = 1$ if and only if $M \cdot M^T$ is of full rank.

Note that the acceptance of the $(d + 1)$-flat is independent of $x$; this is explained in the proof.

**Proof** For each $I \subseteq [n]$, $|I| = d + 1$, we define the polynomial $f_I(x) = \prod_{i \in I} x_i$. Note that

$$S_{d+1,n} = \sum_{I \subseteq [n], |I| = d+1} f_I.$$

Now, the $(d + 1)$-flat test accepts $S_{d+1,n}$ when picking the affine subspace $x + \text{span}(a_1, \ldots, a_{d+1})$ if and only if

$$\sum_{J \subseteq [d+1]} S_{d+1,n}(x + \sum_{j \in J} a_j) = 0 \quad (1)$$

Note that the acceptance of the $(d + 1)$-flat test is independent of $x$. This is because $S_{d+1,n}$ is a degree $d + 1$ polynomial, so it’s $(d + 1)$st derivative (the output of the $(d + 1)$-flat test) is constant. Hence, the test accepts if and only if

$$\sum_{J \subseteq [d+1]} S_{d+1,n}(\sum_{j \in J} a_j) = 0 \quad (2)$$

which can be rewritten as

$$\sum_{I \subseteq [n], |I| = d+1} \sum_{J \subseteq [d+1]} f_I(\sum_{j \in J} a_j) = 0.$$

For a fixed $I$, we focus our attention on the expression $\sum_{J \subseteq [d+1]} f_I(\sum_{j \in J} a_j)$. By definition, this equals $\sum_{J \subseteq [d+1]} \prod_{i \in I}(\sum_{j \in J} a_{j,i})$ which in turn equals $\sum_{J \subseteq [d+1]} (-1)^{|d+1|-|J|} \prod_{i \in I}(\sum_{j \in J} a_{j,i})$ (since $1 = -1$ in $\mathbb{F}_2$). By Ryser’s formula, this equals $\text{perm}(M_I)$, where perm is the permanent function, and $M_I$ is the $(d + 1) \times (d + 1)$ submatrix of $M$ formed by the columns of $I$.

Thus, the left hand side of Equation (2) equals

$$\sum_{I \subseteq [n], |I| = d+1} \text{perm}(M_I).$$

Since we are working over $\mathbb{F}_2$, we have that $\text{perm}(M_I) = \det(M_I) = \det(M_I)^2$. Thus,

$$\sum_{I \subseteq [n], |I| = d+1} \text{perm}(M_I) = \sum_{I \subseteq [n], |I| = d+1} \det(M_I)^2 = \det(MM^T).$$

by the Cauchy-Binet formula.
We thus conclude that $I(x, a_1, \ldots, a_{d+1}) = 1$ if and only if $MM^T$ is nonsingular.

We thus turn our attention to the probability that for a randomly chosen matrix $M$, the matrix $M \cdot M^T$ is of full rank. We first note the following fact on the distribution of $M \cdot M^T$ when $M$ is chosen uniformly from the space of full rank matrices.

**Lemma 28** Let $A, B \in \mathbb{F}_2^{(d+1) \times (d+1)}$ be random variables generated as follows: $A$ is a symmetric matrix chosen uniformly at random, and $B = M \cdot M^T$ where $M$ is a random $(d + 1) \times n$ matrix chosen uniformly from matrices of rank $d + 1$. Then the total variation distance between $A$ and $B$ is $O(2^{d-n})$.

**Proof** Let $E$ be the event that the rows of $M$, along with the vector $1$ (the vector which is 1 in each coordinate) are all linearly independent. Note that the probability of $E$ is at least $1 - 2^{d+1-n}$.

We will now show that the distribution of $B \mid E$ is exp($-n$)-close to the distribution of $A$. This will complete the proof.

Let the rows of $M$ be $a_1, \ldots, a_{d+1}$. We pick them one at a time. Having picked $a_1, \ldots, a_i$, the new entries of $B$ that get determined by $a_{i+1}$ are the entries $B_{i+1,j}$ for all $j \leq i + 1$ (these determine the entries $B_{j,i+1}$). If $a_{i+1}$ is picked uniformly from $\mathbb{F}_2^n$, then by the linear independence of $a_1, \ldots, a_i, 1$, we see that the bits

- $B_{i+1,1} = \langle a_{i+1}, a_1 \rangle$,
- $B_{i+1,2} = \langle a_{i+1}, a_2 \rangle$,
- \ldots ,
- $B_{i+1,i} = \langle a_{i+1}, a_i \rangle$,
- $B_{i+1,i+1} = \langle a_{i+1}, a_{i+1} \rangle = \langle a_{i+1}, 1 \rangle$,

are all uniformly random and independent, as required. However, since we have conditioned on $E$, $a_{i+1}$ is not picked uniformly from $\mathbb{F}_2^n$, but picked uniformly from $\mathbb{F}_2^n \setminus \text{span}\{a_1, \ldots, a_i, 1\}$. Still, this distribution of $a_{i+1}$ is $2^{d+1-n}$-close to the uniform distribution over $\mathbb{F}_2^n$, and as a consequence, the distribution of the bits $B_{i+1,1}, \ldots, B_{i+1,i+1}$ is $O(2^{d-n})$-close to the distribution of uniform and independent random bits.

To summarize, the entries of the matrix $B$ are exposed in $d + 1$ rounds. The bits $B_{i,j}$ for $j < i$ are exposed in round $i$, and their distribution, conditioned on the bits exposed in all the previous rounds, is $O(2^{d-n})$-close to that of uniform and independent random bits. This implies the desired claim on the distribution of $B$. ■

The final lemma shows that the random symmetric matrix $A \in \mathbb{F}_2^{(d+1) \times (d+1)}$ is full rank with probability bounded away from $1/2$ by some constant independent of $d$. This seems to be a well-analyzed problem and [BCJ+06, Theorem 4.14] (see also BMSS for related work) already proves this fact; in particular, they show that if $k \geq 3$, a random symmetric $k$-by-$k$ matrix over $\mathbb{F}_2$ is full rank with probability at most $7/16$. For completeness, we include a simple proof that establishes a weaker bound on the probability of non-singularity.
Lemma 29 For $k \geq 4$, the probability that a random symmetric matrix $A \in \mathbb{F}_2^{k \times k}$ has full rank is at most $1/2 - 2^{-7}$.

Proof Let $A_i$ denote the $i \times i$ submatrix containing the first $i$ rows and columns of $A$. We consider the probability that $A$ has full rank, conditioned upon various choices of $A_{k-1}$. The first claim below shows that the probability of this event is at most half if the rank of $A_{k-1}$ is either $k - 1$ or $k - 2$; and zero if the rank of $A_{k-1}$ is at most $k - 3$. We then argue in the next claim that the probability that $A_{k-1}$ has rank at most $k - 3$ is bounded below by a positive constant independent of $k$. The lemma follows immediately.

Claim 30 Fix $B \in \mathbb{F}_2^{(k-1)\times(k-1)}$. The following hold:

1. If $A_{k-1} = B$ and $\text{rank}(B) \leq k - 3$, then $\text{rank}(A) < k$.
2. If $\text{rank}(B) = k - 1$ then $\Pr[\text{rank}(A) = k | A_{k-1} = B] \leq 1/2$.
3. If $\text{rank}(B) = k - 2$ then $\Pr[\text{rank}(A) = k | A_{k-2} = B] \leq 1/2$.

Proof Note that for every $i$, we have $\text{rank}(A_i) \leq \text{rank}(A_{i-1}) + 2$ since $A_i$ may be obtained from $A_{i-1}$ by first adding a column and then a row, and each step may increase the rank by at most 1. Part (1) follows immediately.

For part (2), fix $a_{k,1}, \ldots, a_{k,k-1}$ and consider a random choice of $a_{k,k}$. Since $A_{k-1}$ has full rank, there is a unique linear combination of the $k - 1$ rows of $A_{k-1}$ that generates the row $(a_{k,1}, \ldots, a_{k,k-1})$. $A$ has full rank only if $a_{k,k}$ does not equal the same linear combination of $a_{1,k}, \ldots, a_{k-1,k}$, and the probability of this event is at most $1/2$.

Finally for part (3), assume for notational simplicity that $A_{k-2}$ has full rank and the $(k-1)$th row of $A$ is linearly dependent on the first $k - 2$ rows. Now consider the addition of a $k$th row to $A_{k-1}$ consisting of $a_{k,1}, \ldots, a_{k,k-1}$. Note that a necessary condition for $A$ to have full rank is that the newly added row is linearly independent of the first $k - 2$ rows of $A_{k-1}$ (otherwise, the rank of the first $k - 1$ columns of $A$ is only $k - 2$). But again (as in Part (2)), there is a unique linear combination of the rows of $A_{k-2}$ that generates the row $(a_{k,1}, \ldots, a_{k,k-2})$. The probability that $a_{k,k-1}$ equals this linear combination applied to the $(k-1)$-th column of $A_{k-1}$ is at least $1/2$. ■

Claim 31 $\Pr[\text{rank}(A_{k-1}) \leq k - 3] \geq 2^{-6}$.

Proof We start with the subclaim that for every $\ell$, we have $\Pr[\text{rank}(A_{\ell+1}) = \text{rank}(A_{\ell}) | A_{\ell}] = 2^{(\text{rank}(A_{\ell}) - \ell - 1)}$. To see this, let $I \subseteq [\ell]$ be such that $A_{\ell}$ restricted to rows in $I$ has full rank (and so $|I| = \text{rank}(A_{\ell})$). Then $A_{\ell}$ restricted to rows and columns of $I$ also has full rank. (All the rows not in $I$ are in the span of the rows that are in $I$, and thus, by symmetry, all columns not in $I$ are in the span of the columns in $I$.) Fix $a_{\ell+1,j}$ for $j \in I$ and note that there is unique linear combination of the rows of $I$ in $A_{\ell}$ such that they yield $a_{\ell+1,j}$ for $j \in I$. This linear combination determines a unique setting for the remaining $\ell + 1 - |I|$ entries of the $(\ell + 1)$th row of $A_{\ell+1}$, if the the rank of
$A_{\ell+1}$ is to equal the rank of $A_{\ell}$. The probability of this unique setting occurring equals $2^{|I| - \ell - 1}$. The subclaim follows.

Now the claim follows easily. Let $m$ be the smallest integer $\leq k - 2$ such that rank($A_m$) $\geq k - 4$. If such an $m$ does not exist, then rank($A_{k-1}$) $\leq k - 3$. Otherwise, $m$ exists, $m \geq k - 4$ and rank($A_m$) $\leq k - 3$. Using the subclaim above, we have for every $\ell \in \{m, \ldots, k - 2\}$, it is the case that Pr[rank($A_{\ell+1}$) = rank($A_{\ell}$) | $A_{\ell}$] $\geq 2^{(k-4) - \ell - 1}$. Combining the claims for $\ell \in [m, k - 2]$ (and recalling that $m \geq k - 4$), we get Pr[rank($A_{k-1}$) $\leq k - 3$] $\geq 2^{-6}$. 

Given the claims above, the lemma follows immediately. ■
