ABSTRACT
We present Rossiter–McLaughlin observations of the transiting super-Earth 55 Cnc e collected during six transit events between 2012 January and 2013 November with HARPS and HARPS-N. We detect no radial velocity signal above 35 cm s⁻¹ (3σ) and confine the stellar \( v \sin i \) to 0.2 ± 0.5 km s⁻¹. The star appears to be a very slow rotator, producing a very low amplitude Rossiter–McLaughlin effect. Given such a low amplitude, the Rossiter–McLaughlin effect of 55 Cnc e is undetected in our data, and any spin–orbit angle of the system remains possible. We also performed Doppler tomography and reach a similar conclusion. Our results offer a glimpse of the capacity of future instrumentation to study low amplitude Rossiter–McLaughlin effects produced by super-Earths.

Key words: planets and satellites: formation – planets and satellites: individual (55 Cancri e) – stars: individual (55 Cancri) – techniques: radial velocities – techniques: spectroscopic

Online-only material: color figures, machine-readable table

1. INTRODUCTION

55 Cnc is a 0.9 \( M_\odot \) star (von Braun et al. 2011) harboring five known planets with masses between 0.025 \( M_\oplus \) and 3.8 \( M_\oplus \), and orbital periods between ~0.74 days and ~4872 days (Nelson et al. 2014). The star also has a ~0.27 \( M_\odot \) binary companion at a projected orbital separation of 1065 AU (Mugrauer et al. 2006).

The innermost planet in the system, 55 Cnc e (\( M_p = 8.3 \pm 0.4 M_{\text{Earth}}, R_p = 1.94 \pm 0.08 R_{\text{Earth}} \)), was found to transit by Winn et al. (2011) and Demory et al. (2011), after Dawson & Fabrycky (2010) provided a revised period of 0.74 days, shorter than the originally reported 2.8 days period by McArthur et al. (2004). The presence of transits makes 55 Cnc e an invaluable potential target for future studies of atmospheric properties of super-Earths and spin–orbit angle studies via the Rossiter–McLaughlin effect (Rossiter 1924; McLaughlin 1924; Queloz et al. 2000; Gaudi & Winn 2007). In the case of spin–orbit angle studies, a result for 55 Cnc e would add to the very few measurements reported so far for Neptune and super-Earth mass planets, e.g., the detection of oblique orbits for HAT-P-11b (Winn et al. 2010; Hirano et al. 2011), and for the

2. OBSERVATIONS

Shortly after the detection of 55 Cnc e’s transit was announced, we requested four spectroscopic time series on HARPS (Prog. ID 288.C-5010; PI: Triaud) as Director Discretionary Time. HARPS is installed on the 3.6 m telescope at the European Southern Observatory on La Silla, Chile (Mayor et al. 2003). The position of 55 Cnc in the sky—R.A.(J2000) = 08:52:35.81, decl.(J2000) = +28:10:50.95—is low as seen from La Silla. The target remains at a zenith distance of $z < 20°$ from the observer for the majority of the night, making it the best suited for observations from the northern hemisphere.

The target is better suited for observations from the north, and, therefore, in 2013 we acquired additional RV time series on HARPS-N (Prog. ID 34-TNG4; PI: Triaud) as Director Discretionary Time. HARPS-N is an updated version of HARPS and is able to reach the same overall RV precision, if not better (see, e.g., Mayor et al. 2009; Molaro et al. 2013; Pepe et al. 2013; Dumusque et al. 2011). After an in-depth study of the behavior of these lines, we identify three sources of velocity errors: the stitching of the CCD, some faint telluric lines, and fringing on the detector that can introduce significant velocity shifts of certain stellar lines that happen to fall near the stationary features, changing the barycentric velocity for different observations scans the stellar lines across the artifacts.

The spectral lines affected by these variations were identified by calculating the periodogram of the RV of each spectral line used in the stellar template. All of the spectral lines that were exhibiting a signal more significant than 10% in false alarm probability were flagged as bad lines and removed from the stellar template. The result is a modified mask, which is used instead of the standard K5 mask to derive the RV of each observed spectrum by cross-correlation.

After performing a new cross-correlation of the data using this cleaned spectrum, the rms of the combined RV curve was reduced from 1.17 m s$^{-1}$ to 1.04 m s$^{-1}$. In the rest of our analysis, we used the set of RV values from this revised reduction (a publication with this analysis is in preparation). Those RVs are presented in Table 1 and in Figure 1.

3. RADIAL VELOCITY EXTRACTION

The spectra were originally reduced with version 3.7 of the HARPS and HARPS-N Data Reduction Software, which includes color systematic corrections (Cosentino et al. 2014). RVs were computed using a numerical weighted mask following the methodology outlined by Baranne et al. (1996). Such a procedure has been shown to yield remarkable precision and accuracy (e.g., Mayor et al. 2009; Molaro et al. 2013; Pepe et al. 2013; Dumusque et al. 2014).

However, there is still room for improvement. A detailed analysis of the RV of individual spectral lines in HARPS spectra has revealed that some lines can show variations $>100$ m s$^{-1}$ as a function of time. These variations cannot be explained by stellar noise in a star like 55 Cnc. Indeed, stellar oscillations, granulation phenomena, and stellar activity are expected to be of the order of a few m s$^{-1}$ on an inactive G dwarf, as reported by Dumusque et al. (2011). After an in-depth study of the behavior of these lines, we identify three sources of velocity errors: the stitching of the CCD, some faint telluric lines, and fringing on the detector that can introduce significant velocity shifts of certain stellar lines that happen to fall near the stationary features, changing the barycentric velocity for different observations scans the stellar lines across the artifacts.

4. ESTIMATES OF LINE BROADENING DUE TO STELLAR ROTATION

The large number of high signal-to-noise ratio (S/N), high-resolution spectra gathered by HARPS-N allowed us to re-determine the stellar parameters of 55 Cnc using the Stellar Parameter Classification pipeline (Buchhave et al. 2014). We analyzed the 55 spectra observed on the night starting on 2013 November 14 with exposure times of 240 s and a resolution of $R = 115,000$, resulting in an average S/N per resolution element of 362 in the MgB region. We also analyzed three spectra, with S/N per resolution element of 143 and resolution $R = 48,000$, obtained between 2013 April 22 and 2014 March 8 with the fiber-fed Tillinghast Reflector Echelle Spectrograph (TRES; Szentgyorgyi & Furész 2007) on the 1.5 m Tillinghast Reflector at the Fred Lawrence Whipple Observatory on Mt. Hopkins, Arizona. The weighted average of each spectroscopic analysis yielded two sets of values from the two instruments, which are in very close agreement. The final parameters are the average of these two sets, yielding $T_{\text{eff}} = 5358 \pm 50$ K, $\log(g) = 4.44 \pm 0.10$, and $[\text{m/H}] = 0.34 \pm 0.08$. Those values agree with the values published in the literature. The HARPS-N spectra yielded a projected rotational velocity of...
1.2 Gyr, the HARPS spectra yields similar results, i.e., age = 1.1 Gyr, a rotational period of $\pm 43 \text{ km s}^{-1}$ (jek & Hillenbrand 2008). We arrive at an age for the star of 9.3 $v \sin i_\star = 2.4 \text{ km s}^{-1}$ and $\beta = 0^\circ$.

Figure 1. Left: radial velocity data, in phase. HARPS data points are represented by inverted red triangles and HARPS-N by upright orange triangles. Right: the same data, binned in 14 equidistant points, and a model of the Rossiter–McLaughlin effect, for $v \sin i_\star = 4.3 \text{ km s}^{-1}$ with an upper limit of 1.43 km s$^{-1}$, and the TRES spectra gave $v \sin i_\star = 0.85 \text{ km s}^{-1}$ with a upper limit of 1.85 km s$^{-1}$. Both values agree with each other, but are lower than the value of $2.4 \pm 0.5 \text{ km s}^{-1}$ reported by Valenti & Fischer (2005).

We also computed the $R'_\text{HK}$ activity index from our spectra and derived the age and rotation period of the star following Mamajek & Hillenbrand (2008). We arrive at an age for the star of 9.3 $b$ (R$_c$) = 0.00 ± 0.24, 0.16 ± 0.13, and a log of $R'_\text{HK} = -5.07 \pm 0.02$ using the HARPS-N spectra. The analysis of the HARPS spectra yields similar results, i.e., age = 10.0 ± 1.2 Gyr, $P_{\text{rot}} = 54 \pm 5$ days, and a log of $R'_\text{HK} = -5.11 \pm 0.02$. Both results agree with previously published values (von Braun et al. 2011; Dragomir et al. 2014) and imply a rotational velocity slower than 1 km s$^{-1}$, in agreement with our line broadening estimates.

### 5. ANALYSIS OF THE RADIAL VELOCITY DATA

The first step of our RV analysis consisted of removing the Keplerian orbital motion signals of the five planets discovered around 55 Cnc from each of our six data sets. We used the most recent orbital solution of the system obtained by Nelson et al. (2014). As recommended by these authors, we used the planetary masses and orbital parameters from their Case 2, in which they considered the errors of RV observations taken within 10 minutes of each other to be perfectly correlated. The corrected RVs for each data set are given in Table 1. Later tests using the Nelson et al. (2014) system parameters for their Case 1, and also the planetary masses and orbital parameters of the system derived by Dawson & Fabrycky (2010) in their Tables 7, 8, and 10, yield similar results.

After removing the five planet signal, we modeled the Rossiter–McLaughlin effect for the six data sets combined using the formalism of Giménez (2006), based on Kopal (1942), and adjusted with a Monte Carlo Markov-Chain described in Triaud et al. (2013). All parameters determined by the photometry were controlled by priors issued from two independent data sets (see Table 2). Additional priors included the planet’s period ($P_{\text{rot}}$) from mid−transit (hr) 0.0000014 0.7365478 $\pm 0.0000014$ and the $v \sin i_\star$ values estimated in Section 4. We allowed the relative mean of each time series to float in order to absorb any offset produced by slightly different epochs of stellar activity (e.g., Triaud et al. 2009). Thirteen parameters were thus used on a total of 293 data points. A noise term of 70 cm s$^{-1}$ was quadratically added to all measurement errors to reach a final reduced $\chi^2$ of 0.97 ± 0.08. All priors and important results are summarized in Table 2.

We conducted a number of different chains which all converge to the same conclusion: the Rossiter–McLaughlin effect is not detected (see Figure 1). The impossibility of constraining the spin–orbit angle of the system is illustrated in Figure 2, which shows the typical crescent shape expected when there is degeneracy between fast rotation and polar orbits and slow rotation and alignment (Triaud et al. 2011; Albrecht et al. 2011). This shape approximately maps contours of Rossiter–McLaughlin effects of equal semi-amplitudes. From the 3σ contour, we rule-out Rossiter–McLaughlin effects with semi-amplitudes larger

### Table 2

| Analysis Priors and Results |
|-----------------------------|
| Quantities (Units) | Winn et al. (2011) | Demory et al. (2011) | Nelson et al. (2014) | This Letter |
| Transit depth, $\Delta F$ (ppm) | 380 ± 52 | 410 ± 63 | ... | 384 ± 41 |
| Impact parameter, $b$ (R$_c$) | 0.00 ± 0.24 | 0.16 ± 0.13 | ... | 0.18 ± 0.08 |
| Transit duration, $W$ (days) | 0.658 ± 0.0019 | 0.0665 ± 0.0019 | ... | 0.0667 ± 0.0008 |
| Mid-transit time, $T_0$ (BJD-2 450 000) | 6184.50910 ± 0.00087 | 6184.5170 ± 0.0015 | ... | 6184.5120 ± 0.0011 |
| Period, $P$ (days) | ... | ... | 0.7365478 ± 0.0000014 | -0.06 ± 0.42 |
| $\sqrt{V \sin i_\star \cos \beta}$ | ... | ... | ... | 0.06 ± 0.69 |
| $\sqrt{V \sin i_\star \sin \beta}$ | ... | ... | ... | 0.18 ± 0.48 |

**Notes.** The quantities determined by photometry are inserted as Gaussian priors taken from three papers. The values our analysis yields are included to illustrate that our fits did not force solutions to unrealistic values.
The Astrophysical Journal Letters, 792:L31 (6pp), 2014 September 10

López-Morales et al.

Figure 2. Posterior distribution for the projection of the stellar rotational speed, \( v \sin i_* \), and the projection on the sky of the spin–orbit angle, \( \beta \). 1, 2, and 3\( \sigma \) confidence contours are overplotted. Side histograms display the marginalized posteriors for each quantity. In the case of \( v \sin i_* \), the two priors we applied are drawn as gray lines.

(A color version of this figure is available in the online journal.)

than 35 cm s\(^{-1}\). The fact that anti-aligned orbits are as likely as aligned orbits implies that the Rossiter–McLaughlin effect is not detected.

The marginalized distribution in \( v \sin i_* \) is thinner and peaks closer to 0 than our two estimates from spectral line broadening. Therefore, from the data we estimate \( v \sin i_* = 0.2 \pm 0.5 \) km s\(^{-1}\). This implies that the star’s most likely rotation period is 260 days (> 22 days with 3\( \sigma \) confidence; > 40 days only considering coplanar solutions).

To test the robustness of our analyses, we explored the impact of different priors. When replacing our two \( v \sin i_* \) priors with the value estimated in Valenti & Fischer (2005), two symmetrical solutions, on polar orbits, are preferred: \( \beta = +90^\circ \) and \( -90^\circ \) (such a Rossiter–McLaughlin effect would have a semi-amplitude of 23 cm s\(^{-1}\)). A similar situation occurred for the spin–orbit angle measurement of WASP-80b (Triaud et al. 2013), which depends entirely on the value of \( v \sin i_* \). Using no priors on \( v \sin i_* \), the posterior is qualitatively similar, but both spikes are thinner and \( v \sin i_* \) tails to higher values, as would be expected. The same procedures, removing the additional 70 cm s\(^{-1}\) noise added to the errorbars, produced similar results (with shorter confidence intervals).

6. DOPPLER TOMOGRAPHY

Given the impossibility of detecting the Rossiter–McLaughlin effect of 55 Cnc e, we tried to detect the signal of the planet using Doppler tomography (e.g., Albrecht et al. 2007; Collier Cameron et al. 2010). Doppler tomography reveals the distortion of the stellar line profiles when the planet, during transit, blocks part of the stellar photosphere. This distortion is a tiny dip in the stellar absorption profile, scaled down in width according to the planet-to-star radius ratio. Additionally, the area of that dip corresponds to the planetary-to-stellar disks area ratio. As the planet moves across the stellar disk, the dip produces a trace in the time series of line profiles, which reveals the spin–orbit alignment between the star and planetary orbit.

For this analysis, we summed up all of the thousands of stellar absorption lines in each spectrum into one high S/N mean line profile. For this step, we employed a least-squares deconvolution (e.g. Collier Cameron et al. 2002) of the observed spectrum and theoretical lists of the stellar absorption lines from the Vienna Atomic Line Database (Kupka et al. 1999) for a star with \( T_{\text{eff}} = 5200 \) K and \( \log g = 4.5 \). The resulting line profiles were scaled so that their height was one, and were interpolated onto a velocity grid of 0.79 km s\(^{-1}\) increments, corresponding to the velocity range of one spectral pixel of HARPS-N at 550 nm. We then corrected the stellar line profiles for the RV of the host star and the barycentric velocity of the Earth. For each of the six runs, we summed up all the mean line profiles collected before and after the transit and subtracted the resulting profile from the in-transit ones. We then sorted the co-aligned line profiles of all the runs by orbital phase and combined the line profiles into one data set. Figure 3 shows the residuals of the line profiles and demonstrates that we are also unable to detect a trace of the transiting planet using this method. Our ability to detect the planet using Doppler tomography is in fact limited by the resolution of the spectra (~2.6 km s\(^{-1}\) per resolution element), given the very slow rotational velocity of the star.

7. CONCLUSIONS

Our data do not support a detection of the spectroscopic transit of 55 Cnc e, but they rule out with 3\( \sigma \) confidence
Figure 3. Residuals of all line profiles of 55 Cnc taken during the six transits as a function of velocity and orbital phase of the planet. The two vertical dashed lines depict the area of the stellar line profile (FWHM). The units of the gray scale are fractional deviation from the average out-of-transit line profile. We are unable to detect the planetary signature in the line profiles.

any signal with a semi-amplitude larger than 35 cm s\(^{-1}\). The non-detection can be explained by one of three scenarios: either
55 Cnc rotates more slowly than the average G-K main-sequence
star (\(\sim 2.4\) km s\(^{-1}\); Valenti & Fischer 2005), the orbital plane
of the planets is perpendicular to the equatorial plane of the
star, or the spin axis of the star is highly inclined with respect
to us. Dragomir et al. (2014) report no variability associated
with stellar spot rotation on a 42 day continuous monitoring
of 55 Cnc with MOST. von Braun et al. (2011) estimated the
system age at 10.2 \(\pm\) 2.5 Gyr. Therefore, the star is likely a very
slow rotator, which is confirmed by our chromospheric activity
measurements and stellar line broadening. Our conclusion is
also consistent with a photometric modulation of 42.7 \(\pm\) 2.5
days reported by Fischer et al. (2008), which they interpreted
as stellar rotation. Because of the slow stellar rotation, reliably
determining the projected spin–orbit angle of 55 Cnc e, or the
inclination of its host’s spin axis, may remain out of reach.
The slow stellar rotation also implies a weaker tidal coupling
between 55 Cnc e and its host than what was presumed by Boué
& Fabrycky (2014). Following Kaib et al. (2011), that would
increase the probability of a spin–orbit misalignment.

While the detection of such a misalignment currently remains
out of reach, our analysis confirms the capacity of the HARPS
technology to reach a few tens of cm s\(^{-1}\). These RV time series
are the most constraining yet in precision and they reveal the
suitability of HARPS and HARPS-N for follow-up and confirmation
of small planets to be detected by missions like TESS.
Such a level of RV precision will also be routinely reached
by ESPRESSO on the Very Large Telescope. ESPRESSO will
increase the probability of a spin–orbit misalignment.

Finally, Bouvier & Hébrard (2014) recently reported a
detection of the Rossiter–McLaughlin effect of 55 Cnc e,
with an amplitude of \(\sim 60\) cm s\(^{-1}\). While such RV variations
could be attributed to stellar surface physical phenomena (e.g.,
granulation or faculae), we argue that they are not produced by
the Rossiter–McLaughlin effect, since the necessary \(v\ \sin\ i_e\ \sim
3.3\) km s\(^{-1}\) is incompatible with the \(v\ \sin\ i_e\), \(P_{\text{rot}}\), age, and \(R_{\text{HK}}\)
activity index values we measure in Section 4. That \(v\ \sin\ i_e\)
is also incompatible with the \(\sim 10\) Gyr stellar age derived by
von Braun et al. (2011), and with the \(P_{\text{rot}} > 40\) days rotational
period estimates from Fischer et al. (2008) and Dragomir et al.
(2014).
