ABSTRACT

Polyaniline salts were synthesized at room temperature (30°C) by electrochemical oxidation using primary dopants such as HCl, HNO₃, H₂SO₄ and CH₃COOH. All the synthesized PANI have resulted in emeraldine salt form as indicated by dark green colour of the salts. Various characterization techniques employed were UV-Vis spectroscopy, FT-IR and Cyclic voltammetry studies. All these techniques confirm the various properties of PANI. The characteristic peaks in the UV-Visible spectra of the samples indicate that effective doping has occurred in the synthesized polymer polymers. Quinoid and benzenoid bands at 1553-1596 cm⁻¹ and 1437 – 1496 cm⁻¹ respectively were observed in all the samples. The band gaps for all the samples were obtained using the absorption spectra and Stern relation. PANI-H₂SO₄ had the least band gap whereas PANI-CH₃COOH had the highest band gap. The voltammograph showed the various oxidation states during the electrochemical deposition at a potential of 0.8 V. Four probe Method was used to study the conductivity of both thin films deposited on ITO slides. The conductivity values for PANI-H₂SO₄ were found to be 3.424 S.cm⁻¹ for thin film. By comparing the four samples’ π - π* transition, from the strongest to the weakest were in the order: , PANI-H₂SO₄ followed by PANI-HCl then PANI-HNO₃ and the weakest been PANI-CH₃COOH. This suggests that polaron charge carriers are responsible for the high conductivity in H₂SO₄ doped PANI.

1. INTRODUCTION

Polyaniline (PANI) is one of the most studied conjugated polymers due to its widely tunable electrical conductivity (Cao et al., 1992) and environmental stability (Rannou and Nechtschein, 1997, DeLongchamp and Hammond, 2001). PANI can be readily synthesized...
from commercially available starting materials under gentle conditions by oxidation methods (Masters et al., 1991), (Wei et al., 1989). Polyaniline remains one of the most interesting materials due to its unique conduction mechanism and good environmental stability in the presence of oxygen and water vapour (Kumar et al., 1997).

The process ability, conductivity and stability are major requirements of any polymer for technological application (Chauhan et al., 2011). Modifications of the oxidation state, dopant and polymerization conditions are means of optimizing the process ability, conductivity and stability of PANI for technological application. Researchers are interested in improving properties such as the electrical conductivity of PANI through the choice of appropriate dopants (Alesary et al., 2018). Dopants create charge carriers in a conducting polymer which is responsible for the conductivity of the conducting polymer (Atassi et al., 2008).

A study on the effects of primary dopants on the properties of Polyaniline will help in the determination of the appropriate dopant to produce suitable material for technological applications.

2. METHODOLOGY

2.309 g of aniline was measured, and 0.05 ml of distilled water was added to it. The solution was stirred under a magnetic stirrer for 5 minutes. A 0.05 ml of the 1 M HCl solution was added to the aniline solution. This was stirred for 5 minutes to obtain uniform solution. The three electrodes [ITO (working), Platinum (counter) and Ag/AgCl (reference)] were placed into the solution and connected to the potentiostat [Fig. 1]. A voltage of 0.8 V was applied for deposition to be completed in 10 minutes for each sample. Cyclic voltammetry technique was selected from the interface using the EChem v2.1.12 software. The following parameters were used to perform the cyclic process. Scan rate of 100 mV/s, Step width of 20 ms, 1 cycle and rest time of 2 seconds were used. The procedure above was repeated for the other dopants. Voltamographs of I/mA and V/mV were obtained for each sample. The samples were dried at 60°C for 30 minutes.

![Figure 1 Electrochemical Deposition Setup](https://ssrn.com/abstract=3527296)
The cell consists of the electrodes, electrolyte and power supply. Electrochemical polymerization has many advantages over chemical synthesis of PANI, such as strict control of the oxidation potential applied during synthesis providing the unique ability to moderate the polymerization initiation and termination processes (Bhadra et al., 2007). Also, there is cleanness because no extraction from the monomer–solvent–oxidant mixture is necessary, doping and thickness control via electrode potential, simultaneous synthesis and deposition of PANI thin layer. The electrochemical behavior of polyaniline is dependent on the applied potential and the surface area of the electrodes (Song et al., 2013).

Cyclic voltammetry was used to study the qualitative information about the electrochemical process in synthesizing PANI by electrodeposition on an ITO glass with aqueous acids forming part of the electrolyte. Cyclic voltammograms obtained from the electrochemical process using the eDaQ software integrated into the POTENTIOSTAT 468 device that was used for this experiment.

3. RESULTS AND DISCUSSION

3.1. FTIR of Thin Films

The most dominant bands in the entire spectra which are clear characteristics of polyaniline were 3468 cm\(^{-1}\) – 3025.17 cm\(^{-1}\), 1593 cm\(^{-1}\) – 1553 cm\(^{-1}\), 1481 cm\(^{-1}\) – 1413 cm\(^{-1}\), 1300 cm\(^{-1}\) – 1239 cm\(^{-1}\), 1142 cm\(^{-1}\) -1022 cm\(^{-1}\) and 883 cm\(^{-1}\) – 880 cm\(^{-1}\). Below is a table for the various peaks recorded for the thin film samples.

| SAMPLE  | N-H stretching | C-H stretching | C = N stretching | Quinoid Bond | Benzenoid Bond | C-H out of plane |
|---------|----------------|----------------|------------------|--------------|----------------|-----------------|
| HCl     | -              | -              | 1670             | 1561         | 1481           | 787             |
| H\(_2\)SO\(_4\) | -              | -              | 1650             | 1561         | 1478           | 789             |
| HNO\(_3\) | 3468           | 3266           | 1673             | 1563         | 1500           | 827             |
| CH\(_3\)COOH | 3384           | 3050           | -                | 1553         | 1481           | 820             |

3.2. UV-Vis Spectra Thin Film Samples

The absorption observed for the thin films occurs between the ranges of 320-375, 400-480 and 600-720 nm. These wavelengths reveal the electron transition in the thin film samples. In all samples, there is first the \(\pi - \pi^*\) electron transition which occurs earliest in the weak acids between the wavelength 320-375 nm and then the polaron (transitions) typical of polyaniline occurring within the range of 400-480 nm. The electron transition between the benzenoid and quinoid rings occurs at 600-720 nm. The transitions occurring in the polaron, benzenoid and quinoid of the thin film occur in all the samples. The clear difference is in the \(\pi - \pi^*\) transition which for the PANI-HCl and PANI-H\(_2\)SO\(_4\) occurred at a much higher wavelength. In these films there was no shift from <300 nm to >300 nm. According to (Melad et al., 2016) such shifts are due to the steric effect which hinders charge transfer between chains and leads to low conductivity in the material.
3.3. Band Gap of Thin Film Samples

The Eg obtained were 3.00 eV, 2.60 eV, 3.36 eV and 4.1 eV for PANI-HCl, PANI-H\textsubscript{2}SO\textsubscript{4}, PANI-HNO\textsubscript{3} and PANI-CH\textsubscript{3}COOH respectively.

![Figure 3 Band Gap of Thin film samples](image)
3.4. Cyclic Voltammograms of Thin Films

The cyclic voltammogram (CV) shows two sets of distinct redox reaction. That is two pairs of anodic and cathodic current peaks with potential peaks also. This was observed in the voltammogram for HCl and CH₃COOH. A single current peak and potential peak are observed for both cathodic and anodic processes from the voltammogram. The CV curve for CH₃COOH shows a set of redox couple between the potential E= -0.29 V and +0.134 V using the Ag/AgCl as reference electrode. This is related to the conversion of fully reduced leucoemeraldine base to the partially oxidized emeraldine. The second set of redox couple occurs between the potentials E = +0.63 V and E = -0.25 V using Ag/AgCl can be related to the conversion of emeraldine to the fully oxidized pernigraniline.

For all the four samples it was observed that the oxidation peak and its corresponding reduction peak appeared to move to more negative values at the scan rate used which was 100 mV/s. This implies that the protons are involved in the reaction unlike the first peaks. The anodic peak observed at more positive potentials of E = +0.13 – 0.73 V for CH₃COOH, E =+0.22 – 0.74 V for H₂SO₄, E = +0.20 – 0.83 V for HCl and E = +0.41 – 0.77 V for HNO₃ was very strong in the first cycle of the anodic branch for the case of each electrolyte used in the experiment. This can be attributed to the initial monomer oxidation according to (Genies et al., 1987).

Almost all the monomer were oxidized between the potentials of E = +0.73 to +0.83 V/S.C.E and afterwards a redox equilibrium was installed at E = -0.20 v for CH₃COOH, H₂SO₄ and HCl except HNO₃ which was installed at a potential of E = +0.06 V. The voltammogram show a narrow anodic-cathodic peak of the polymer and according to (Genies and Ląpkowski, 1987) that shows the polyaniline synthesized is highly conductive. (Bejan et al., 1998) revealed that for a Pt as counter electrode, reduction will always prevail and that was experienced in all the four electrolytes used in this experiment.
4. CONCLUSION

Polyaniline, PANI-ES was synthesized by electrochemical oxidation using four different dopants (HCl, H₂SO₄, HNO₃ and CH₃COOH). UV-Vis spectroscopy was carried out on the samples prepared by the methods stated. Absorption peak was observed between the ranges of 300-350 nm which depicts the $\pi - \pi^*$ electron transition. Another peak between 450 – 540 nm was also noticed for in all the samples and can be attributed to the polaron and bipolaron transition in polyaniline. This observation was made in all the samples prepared by the different acids or dopants. The band gap for the thin film samples were in the range of 2.60-3.83 eV.
