ABSTRACT

Future weak lensing surveys potentially hold the highest statistical power for constraining cosmological parameters compared to other cosmological probes. The statistical power of a weak lensing survey is determined by the sky coverage, the inverse of the noise in shear measurements and the galaxy number density. The combination of the latter two factors is often expressed in terms of $n_{\text{eff}}$ – the ‘effective number density of galaxies used for weak lensing measurements’. In this work, we estimate $n_{\text{eff}}$ for the Large Synoptic Survey Telescope (LSST) project, the most powerful ground-based lensing survey planned for the next two decades. We investigate how the following factors affect the resulting $n_{\text{eff}}$ of the survey with detailed simulations: (1) survey time, (2) shear measurement algorithm, (3) algorithm for combining multiple exposures, (4) inclusion of data from multiple filter bands, (5) redshift distribution of the galaxies and (6) masking and blending. For the first time, we quantify in a general weak lensing analysis pipeline the sensitivity of $n_{\text{eff}}$ to the above factors.

We find that with current weak lensing algorithms, expected distributions of observing parameters, and all lensing data ($r$ and $i$ band, covering 18 000 degree$^2$ of sky) for LSST, $n_{\text{eff}} \approx 37$ arcmin$^{-2}$ before considering blending and masking, $n_{\text{eff}} \approx 31$ arcmin$^{-2}$ when rejecting seriously blended galaxies and $n_{\text{eff}} \approx 26$ arcmin$^{-2}$ when considering an additional 15 per cent loss of galaxies due to masking. With future improvements in weak lensing algorithms, these values could be expected to increase by up to 20 per cent. Throughout the paper, we also stress the ways in which $n_{\text{eff}}$ depends on our ability to understand and control systematic effects in the measurements.

Key words: methods: data analysis – cosmology: observations.

1 INTRODUCTION

Weak lensing is one of the most powerful tools for probing the dark matter distribution in our Universe and constraining dark energy parameters (Weinberg et al. 2012). Gravitational fields due to the large-scale matter distribution perturb light rays travelling from distant galaxies, causing the observed galaxy shapes to be slightly distorted compared to their true shapes. Since the original shapes are unknown, these weak distortions cannot be discovered by observations of individual galaxies. They can only be inferred via statistical approaches, e.g. correlations of galaxy shape parameters as a function of angular separation (see, e.g. Bartelmann & Schneider 2001).

The ultimate statistical power for deriving cosmological parameters with weak lensing depends on the total sky coverage and the number density of galaxies with accurate shear measurements in a survey. One reduces the statistical uncertainties from weak lensing by surveying wider and deeper fields. This has been the driver behind all ongoing and future weak lensing surveys [e.g. The Kilo Degree Survey1 (KiDS), the Hyper Suprime-Cam Survey2 (HSC), the Dark Energy Survey3 (DES), the Large Synoptic

Survey Telescope (LSST), the Euclid mission and the Wide-Field Infrared Survey Telescope (WFIRST)].

Using the weak lensing Fisher-matrix calculation introduced by Albrecht et al. (2006, hereafter A06), the statistical uncertainty of a weak lensing survey is determined by the combined quantity $f_{\delta} = \sigma_\delta^2$, where $f_{\delta}$ is the fraction of sky covered by the survey and $\sigma_\delta$ is the uncertainty on the mean shear in unit area. The sky coverage $f_{\delta}$ is limited by the accessible sky from a ground-based telescope. $\sigma_\delta$, however, cannot be straightforwardly calculated, since it contains not only the designed survey depth (the number of galaxies we see given the design of the survey), but also the performance of the entire analysis pipeline one uses to measure these distortions (the amount of the information we can actually extract from each galaxy given the measurement methods).

In A06, the question of calculating $\sigma_\delta$ is rephrased in terms of calculating $n_{\text{eff}}$, the effective number density of galaxies used for weak lensing measurements. A06 defined $n_{\text{eff}}$ to be the number density of perfectly measured galaxies that would contribute the same amount of shear noise as the (imperfectly) measured ensemble of galaxies. The standard deviation in each component of the ellipticity for the perfectly measured galaxy population (commonly known as ‘shape noise’), $\sigma_{\text{SN}}$, is assumed to be fixed at 0.25 in A06. The term ‘noise’ refers to the fact that the intrinsic galaxy shapes introduce uncertainty in the shear inferred from these galaxies. Most studies to date have adopted the formulae and model parameters in A06 to estimate the performance of future weak lensing surveys. However, the ways in which $n_{\text{eff}}$ is quoted in the literature are often inconsistent, causing confusion in the field. The main goal of this paper is to clearly define $n_{\text{eff}}$, estimate $n_{\text{eff}}$ for LSST and quantitatively evaluate the sensitivity of $n_{\text{eff}}$ to different assumptions about the survey plan and analysis pipeline. Our methodology for calculating $n_{\text{eff}}$ is general and can be applied to other surveys given the basic survey and analysis information.

In Section 2, we first review briefly the weak lensing notation and definition of $n_{\text{eff}}$. We also discuss the relevant information about the data set and the analysis pipeline required to calculate $n_{\text{eff}}$. We introduce the input galaxy catalogue and the $\sigma_{\text{SN}}$ value for this work in Section 3. Then, we show step by step in Section 4 how the shear measurement noise is estimated depending on different analysis methods and galaxy selection. We calculate in Section 5 the $n_{\text{eff}}$ values for LSST under different scenarios and discuss in depth the different factors that affect $n_{\text{eff}}$. Finally, we estimate in Section 6 how $n_{\text{eff}}$ degrades when practical effects such as masking and blending are introduced. The same calculation is then applied to an existing survey in Section 7 to demonstrate the generality of our approach. We summarize our results in Section 8.

2 OVERVIEW OF THE PROBLEM

2.1 Weak lensing notation

Throughout the paper, we measure object shapes using the two-component ellipticity spinor:

$$\epsilon = \epsilon_1 + i\epsilon_2,$$

(1)

where

$$\epsilon_1 = \frac{I_{11} - I_{22}}{I_{11} + I_{22} + 2\sqrt{I_{11}I_{22} - I_{12}^2}},$$

$$\epsilon_2 = \frac{2I_{12}}{I_{11} + I_{22} + 2\sqrt{I_{11}I_{22} - I_{12}^2}}.$$  

(2)

The $I_{ij}$ are the normalized moments of the object’s light intensity profile $I(x_1, x_2)$:

$$I_{ij} = \int \int dx_1 dx_2 I(x_1, x_2) x_1^i x_2^j, \quad i, j = 1, 2.$$  

(3)

Under this definition, the measured ellipticity $\epsilon$ changes accordingly in the presence of shear $\gamma = \gamma_1 + i\gamma_2$ and convergence $\kappa$ (see, e.g. Bartelmann & Schneider 2001):

$$\epsilon = \left\{ \begin{array}{ll}
(\epsilon^I + g)(1 + g^*\epsilon^I)^{-1} & |g| \leq 1 \\
(1 + g^*\epsilon^I)(\epsilon^I + g^*)^{-1} & |g| > 1
\end{array} \right.$$  

(4)

where $\epsilon^I = \epsilon_1 + i\epsilon_2$ refers to the intrinsic ellipticity of the galaxy before shearing, the asterisk denotes the complex conjugate and $g = g_1 + ig_2$ is the ‘reduced shear’ defined by

$$g = \gamma / (1 - \kappa).$$  

(5)

Here, we have adopted the approximation that $\gamma \approx g$ in the limit of weak lensing where $\kappa \ll 1$.

In the presence of noise, a weighting function $W(x_1, x_2)$ is included in the integrands in equation (3) to reduce the fluctuations in ellipticity measurements. The width of $W(x_1, x_2)$ is approximately the size of the observed object – this yields the maximum signal-to-noise ratio for each individual object. Due to imperfect point spread function (PSF) models and this weighting function, the shear measurement needs to be further calibrated from simulations (Heymans et al. 2006; Massey et al. 2007; Bridle et al. 2010).

2.2 Relation between shear noise and $n_{\text{eff}}$

As mentioned earlier, the relevant quantity in measuring the statistical power of a survey is the uncertainty on the mean shear per unit area, or $\sigma_\gamma$, (given fixed $f_{\delta}$). For each galaxy, since the shear noise results from the intrinsic shape noise as well as measurement noise, we can write

$$\sigma_{\gamma,i}^2 = \sigma_{\text{SN}}^2 + \sigma_{n,i}^2,$$  

(6)

where we have assumed that shape noise is uncorrelated with measurement noise. The subscript $i$ indicates this is the shear noise for the $i$th galaxy and the subscript $m$ refers to the measurement noise. $\sigma$ indicates the root-mean-square (rms) of the distribution. Note that measurement noise depends on the galaxy’s shape, size and brightness, while shape noise is usually taken to be constant for the entire galaxy sample (however, see discussion in Section 3).

If we assume that the mean shear estimation $\bar{\gamma}$ is calculated by the weighted mean of the shear over the entire sample, where the weight is just the inverse variance in each measurement, then we have

$$\bar{\gamma} = \frac{\sum_i N_i \gamma_i}{\sum_i N_i \sigma_{\gamma,i}^{-2}}.$$  

(7)
\( \sigma_{ij}^{2} = \Omega \text{Var}(\hat{\gamma}) + \Omega \left[ \sum_{n} \frac{1}{\sigma_{ij,n}^{2}} \right]^{-1} = \frac{\Omega \sigma_{SN}^{2}}{N_{\text{eff}}} \frac{\sigma_{SN}}{n_{\text{eff}}}. \)  

(8)

where \( N \) is the total number of galaxies used in the lensing analysis and \( \Omega \) is the total sky coverage. The last two factors in equation (8) provide the operational definition of \( n_{\text{eff}} \), where we have defined \( N_{\text{eff}} \) to be the effective number of weak lensing galaxies corresponding to this galaxy sample and \( n_{\text{eff}} = N_{\text{eff}}/\Omega \). Rearranging the terms in equation (8) and using equation (6) leads to the following relation:

\[
N_{\text{eff}} = \frac{\sigma_{SN}^{2}}{\sigma_{\gamma,i}^{2}} = \frac{1}{\Omega} \sum_{n} \frac{\sigma_{SN}^{2}}{\sigma_{\gamma,i}^{2}} = \frac{1}{\Omega} \sum_{n} N_{n} \frac{\sigma_{SN}^{2}}{\sigma_{SN}^{2} + \sigma_{m,i}^{2}}.
\]

(9)

Recall the measured weak lensing power spectrum can be written as (Amara & Réfrégier 2008)

\[
C_{ij}^{\ell}(\ell) = P_{ij}^{\ell}(\ell) + \delta_{ij} \sigma_{\gamma}^{2} + C_{ij}^{\gamma \gamma \text{SYS}}(\ell).
\]

(10)

where \( i \) and \( j \) denote two redshift bins, \( C_{ij}^{\ell}(\ell) \) is the measured lensing power spectrum, \( P_{ij}^{\ell}(\ell) \) is the true lensing power spectrum, \( \delta_{ij} \) is the Kronecker delta function and \( C_{ij}^{\gamma \gamma \text{SYS}}(\ell) \) is the systematic error in the shear power spectrum measurement. The uncertainty in the measured weak lensing power spectrum can be written as

\[
\Delta P_{ij}^{\ell}(\ell) = \sqrt{\frac{2}{(2\ell + 1) f_{\text{sky}}} \left[ P_{ij}^{\ell}(\ell) + \delta_{ij} \sigma_{\gamma}^{2} + C_{ij}^{\gamma \gamma \text{SYS}}(\ell) \right]}.
\]

(11)

This clearly displays what was mentioned earlier – the statistical uncertainty in cosmic shear measurements (the second term in the square brackets) is determined by the factor \( f_{\text{sky}}^{-0.5} \sigma_{\gamma}^{2} \), or equivalently, \( f_{\text{sky}}^{-0.5} \sigma_{SN} \sigma_{\text{eff}}^{-1} \).

From equation (9), we observe that calculating \( n_{\text{eff}} \) for LSST involves a combination of considerations. First, we need an understanding of the intrinsic distribution of galaxies in the multidimensional space (e.g. size, magnitude, redshift, shape, etc.), given the depth of the LSST data set. Secondly, we need to understand the expected shear measurement error for each galaxy, which depends on the characteristics of the galaxy, the measurement algorithm, how multiple measurements of the same galaxy are combined and considerations of systematic errors in the measurement. We address the first part of the problem (the intrinsic galaxy distribution) in Section 3 and the second part (the shear measurement error) in Section 4. It is important to realize that even for the same data set, it is possible to get different \( n_{\text{eff}} \) values depending on the different choices one makes with the analysis pipeline. Thus, one needs to be careful when quoting or comparing these numbers, to give enough information on the assumptions involved.

We also note that in equation (11) we have intentionally separated the systematic errors from the statistical errors in the \( n_{\text{eff}} \) calculation for simplicity. However, as we discuss in Section 4, \( n_{\text{eff}} \) depends on several factors in the analysis pipeline that are set by requirements on systematic errors in shear measurements. As a result, \( n_{\text{eff}} \) can be coupled with the systematic errors in an indirect way. The exact tradeoff between systematic and statistical errors for cosmic shear measurements, and the effect on \( n_{\text{eff}} \) is algorithm dependent and beyond the scope of this paper.

### 3 SHAPE NOISE AND THE INTRINSIC GALAXY DISTRIBUTION

To start, we need a realistic galaxy catalogue that contains the primary characteristics (redshift, size, magnitude and shape) of the galaxies expected to be seen in a 10-yr LSST weak lensing data set. The LSST weak lensing survey is expected to image 18 000 square degrees (Ivezic & the LSST Science Council 2011) of the sky in six filter bands (ugrizy) to a median redshift of \( \sim 1.2 \) and depth of \( \sim 27.5 \) and \( i \sim 26.8 \) (Ivezic et al. 2008a). For this study, we use a typical simulated galaxy catalogue generated by the LSST Catalogue Simulator (CATSIM; Connolly et al., in preparation).

We briefly describe here the key steps and references for creating the galaxy catalogue to help readers understand the results of this work. First, galaxies in the simulated galaxy catalogue from De Lucia et al. (2006) are matched with the dark matter peaks in the Millennium Simulation (Springel et al. 2005). Each galaxy in the De Lucia et al. (2006) catalogue is characterized by a list of parameters for the bulge and the disc component of the galaxy separately. A sophisticated fitting program then finds the best-fitting Spectral Energy Distribution parameters and galaxy extinction that reproduce the colour information for each galaxy. CATSIM generates galaxy catalogues with realistic galaxy morphologies, apparent colours and spatial distributions, and redshifts extending up to 5 on an area of \( 4.5 \times 4.5 \) square degrees. The simulations include galaxies with \( r\)-band AB magnitudes brighter than 28. In Connolly et al. (in preparation), the galaxy number density as a function of magnitude and redshift in the CATSIM catalogue is shown to be well matched to observations in the DEEP2 Redshift Survey (Davis et al. 2003; Coil et al. 2004). The magnitude and size of each galaxy will be used to calculate the signal-to-noise ratio (equation 14) and effective size (equation 15) of each measurement (see Appendix A). These two quantities determine the measurement noise, \( \sigma_{\text{m}} \), for each galaxy (see Section 4).

Finally, we assign shapes or apparent ellipticities to each galaxy according to those measured in the Cosmic Evolution Survey (COSMOS) data set (Leauthaud et al. 2007, private communication). These galaxy shapes have been corrected for measurement noise by excluding small and faint galaxies (Leauthaud et al. 2007). In Fig. 1, we show the redshift, apparent \( r \)- and \( i \)-band (the two main lensing bands) AB magnitude, size and ellipticity (\( \epsilon_{1}, \epsilon_{2} \)) distributions of the galaxy population used in this study. The rms width of Fig. 1 (e) gives \( \sigma_{\text{SN}} \approx 0.26 \) for equation (9). Finally, we note that the distribution of the absolute ellipticity (\( \epsilon = \sqrt{\epsilon_{1}^{2} + \epsilon_{2}^{2}} \), as shown in Fig. 1 (f), agrees well with that derived in Miller et al. (2013), which is based on the Sloan Digital Sky Survey data set.

Although we assume shape noise to be independent of galaxy morphology, redshift, size and magnitude in our calculations, this is not strictly true. Hwang & Park (2009), for example, showed that the ratio of early-type (elliptical) to late-type (spiral and irregular) galaxies at low redshift is higher compared to that at high redshift. This could in principle introduce a redshift-dependent shape noise. However, as shown in Leauthaud et al. (2007), Joachimi et al. (2013)

\[ \text{这种幅度限制可以被看作是} \quad r \text{-band AB magnitude at}\ 5\sigma \text{ for a point source.} \]

\[ \text{这些参数包括红移，颜色（} B, V, R, I \text{和} K \text{-band magnitudes），}

size（星系大小），estimates and stellar population age estimates.

\[ \text{这些星系被描绘为Sersic（Sersic 1968; Häuβler et al. 2013），其中的bulge和disc components have Sersic index 4和1，}

respectively.

\[ \text{http://deep.ps.uci.edu/}

\[ \text{Since we are extracting the distribution from the COSMOS measurements directly，the ellipticity we assign to the galaxies include the}

galaxy intrinsic shape and cosmic shear. However，we note that the level of cosmic shear is over an order of magnitude smaller than the level of the galaxies’ intrinsic shape noise; i.e. Figs 1(e) and (f) are dominated by shape noise.
Figure 1. Distributions of (a) redshift, (b) $r$- and $i$-band magnitude, (c) size and (e) single-component ellipticity in the galaxy catalogue used for this study. All histograms are normalized to unit area. The sizes of the galaxies are measured by the second-moment radius, which can be derived from the half-light radius of the bulge and disc component and the bulge-to-disc flux ratio (Appendix A1). In (d), we show how the half-light radius of the bulge and disc component and the bulge-to-disc flux ratio are distributed in the galaxy catalogue. Notice that there are bulge-only and disc-only galaxies, which lie on the two axes in the plot. In (f), we compare the distribution of the absolute ellipticity with that derived in Miller et al. (2013).

and Heymans et al. (2013), the estimated shape noise as a function of galaxy redshift, size and magnitude is consistent with being flat within measurement noise in the COSMOS data. As a result, we choose to make the first-order approximation in this work that shape noise is constant as measured in Leauthaud et al. (2007). A non-constant $\sigma_{\text{SN}}$ correction to this approximation will require further investigation with deep space-based data (e.g. Jee & Tyson 2011) and better shear measurement algorithms.
4 THE SHEAR MEASUREMENT NOISE

In this section, we estimate the shear measurement noise, \( \sigma_{m} \), for a large range of galaxies under realistic observing conditions using high-fidelity simulations. We then select the galaxies used for weak lensing measurements.

4.1 Simulation and shear measurement

We invoke the LSST Photon Simulator v3.2\(^{12}\) (\texttt{PHOSIM}; Peterson et al. in preparation) to generate high-fidelity images with realistic noise and instrumental/atmospheric effects. We also use the LSST Operations Simulator\(^{13}\) (\texttt{OPSIM}; Delgado et al. 2006) catalogue v3.61 to derive the expected distribution of observing conditions. \texttt{PHOSIM} is a fast Monte Carlo photon ray-tracing code that simulates all the major physical effects from the atmosphere down to the CCD readout. It adopts an atmospheric model with seven Kolmogorov turbulent screens distributed from a few metres to a few tens of kilometres above the telescope. Each screen is described by several parameters associated with the wind speed/direction and turbulence strength. The optics model in \texttt{PHOSIM} is based on the most up-to-date engineering design, with optical errors (e.g. optics element mis-alignment, mirror surface perturbation, tracking errors, etc.) at the level set by engineering specifications. \texttt{OPSIM}, on the other hand, models the telescope configuration, slewing mechanism, weather and sky conditions at the LSST site in a 10-yr period. Fig. 2 shows the atmospheric seeing\(^{14}\) and sky background distribution in \( r \) and \( i \) band from the \texttt{OPSIM} catalogue used in this paper. Due to the wavelength-dependent nature of the system throughput and PSF size, the best possible image quality (maximum signal-to-noise ratio + minimum PSF size) is usually achieved in the \( r \) - and \( i \) -band images. For optimal results in weak lensing measurements, the \texttt{OPSIM} algorithm would thus preferentially choose to image in one of these ‘lensing bands’ when the observing conditions are good.

With the input galaxy catalogue from \texttt{CATSIM} and the observing parameters from \texttt{OPSIM}, we use \texttt{PHOSIM} to generate a set of 1000 simulated 15-s \( r \)-band LSST exposures\(^{15}\) on a single LSST CCD sensor. For the 1000 exposures, we simulate galaxies with the redshift, size, magnitude and shape distributions\(^{16}\) in Fig. 1, and randomly assign observing conditions based on the distributions in Fig. 2. We select 10 random locations on the LSST focal plane for these simulations to capture realistic PSF effects across the field of view. For each exposure, we make two images. The first image contains galaxies from \texttt{CATSIM}, while the second image is identical to the first, except that we replace each of the galaxies with a bright star that effectively samples the PSF of its galaxy counterpart in the first image.

For each simulated image, we detect objects using the Source Extractor software (Bertin & Arnouts 1996) and measure shear using the \texttt{IMCAT} software package.\(^{17}\) The shear measurement algorithm \texttt{IMCAT} performs the following steps: First, the shapes of both stars and galaxies are measured. Then, for each galaxy in the first image, the PSF effects are corrected using the corresponding bright star in the second image. Finally, a shear value is calculated for each galaxy. The difference between the measured shear and the input shear is the shear measurement error, or

\[
\delta \gamma = \gamma_{\text{measured}} - \gamma_{\text{input}}. \tag{12}
\]

We use \texttt{IMCAT} for the shape/shear measurement because it is one of the most commonly used methods for weak lensing studies. The results from this paper will thus be directly relevant to the ongoing and future surveys. But given recent improvements in the shear measurement methods (Bridle et al. 2009; Kitching et al. 2012a,b; Bernstein & Armstrong 2013; Miller et al. 2013; Zuntz et al. 2013), our results are conservative in this regard.

---

\(^{12}\) http://dev.lsstcorp.org/trac/wiki/ls_phosim
\(^{13}\) http://ssg.astro.washington.edu/lsst/opsim.shtml
\(^{14}\) On top of the atmospheric seeing, we add the instrumental PSF \( \approx 0.4 \) arcsec in quadrature to get the total PSF size used in later calculations.
\(^{15}\) In the nominal survey plan for LSST, the telescope will take two 15-s exposures separated by 2–3-s readout with all instrument configurations held fix. This full sequence is called a ‘visit’, which is effectively a continuous 30-s exposure. To model this, we estimate \( \sigma_{m} \) in single 15-s exposures from the simulations and assign identical observing parameters for the two exposure in the same visit.
\(^{16}\) We sample galaxy parameters from the 3D redshift-size-magnitude distribution, and assign a random ellipticity from Fig. 1(d).
\(^{17}\) http://www.ifa.hawaii.edu/ kaiser/imcat/. The shear measurement algorithm in \texttt{IMCAT} is based on the KSB algorithm developed by Kaiser, Squires & Broadhurst (1995); Luppino & Kaiser (1997) and Hoekstra et al. (1998).
Note that in this analysis framework we have ignored several effects from a realistic stellar population. First, we choose to estimate \( n_{\text{eff}} \) for a typical weak lensing field, with Galactic latitude of \( |b| \sim 60^\circ \). The stellar density in these fields is relatively low (\( \approx 1 \text{ arcmin}^{-2} \)), such that significant blending from stars can be ignored. Secondly, by simulating the ‘true’ PSF for each galaxy via simulations (in the second image), we have avoided the process of PSF modelling. This includes selecting well-measured stars and modelling the PSF by interpolating shape parameters of these stars. The effect of imperfect star selection is expected to be small, since the bright stars used for PSF modelling are generally easy to identify without much contamination from the galaxies. The effect of interpolating shape parameters from stars depends on the interpolation scheme. In Appendix B, we show that using a conventional interpolation method for PSF modelling yields only a small (3–6 per cent) degradation in \( n_{\text{eff}} \) compared to the case for which the PSF is known exactly.

Our approach of estimating shear measurement noise from PHOSIM is very similar to that used in Bard et al. (2013). The major differences between the simulations described here and that in Bard et al. (2013) are: (1) we simulate single-exposure depths instead of the expected full survey depth and (2) we do not include shape noise in our definition of measurement errors.

### 4.2 Single exposure shear measurement noise for a single galaxy

To characterize the shear measurement noise \( \sigma_m \), we follow the procedure suggested by Bernstein & Jarvis (2002), and assume that shear measurement noise \( \sigma_m \) is mainly determined by the signal-to-noise ratio \( (\nu) \) and the effective size \( (R) \) of the measured galaxy via the following form:

\[
\sigma_m(\nu, R) = \frac{a}{\nu} \left( 1 + \frac{b}{R} \right)^c,
\]

where \((a, b, c)\) are coefficients depending on the shear algorithm and the image quality.

Here, the galaxy’s signal-to-noise ratio \( (\nu) \) is defined as

\[
\nu = \frac{S}{\sqrt{S + B}},
\]

where \( S \) is the source photon counts and \( B \) is the background photon counts.\(^{18}\) And the galaxy’s effective size \( (R) \) is defined to be the relative size of the galaxy to the PSF, or

\[
R = \frac{r_{\text{gal}}^2}{r_{\text{PSF}}^2}.
\]

Here, \( r_{\text{gal}} \) and \( r_{\text{PSF}} \) are the second-moment radii (see equation A5) of the galaxy and the PSF’s light distribution. In Appendix A, we show how \( \nu \) and \( R \) can be calculated from observational quantities as well as the generic galaxy model described in Section 3 and observational parameters.

The main task of this section is to determine the coefficients in equation (13) from the shear measurements in Section 4.1. To do this, we first calculate the \( \nu \) and \( R \) values for all galaxies measured in Section 4.1 and bin them into \((\nu, R)\) bins. Then, for all galaxies in each \((\nu, R)\) bin, we calculate the rms of the shear measurement errors \( \delta \gamma \) (equation 12). This provides an estimate for \( \sigma_m \) for that bin. We then fit the \( \sigma_m(\nu, R) \) surface and determine the \((a, b, c)\) coefficients.

We use 30 logarithmic bins in \( \nu \) ranging from 3 to 650 and 30 logarithmic bins in \( R \) ranging from 0.2 to 43, which covers all the galaxies measured in these simulations. Since each bin contains a different number of galaxies, an uncertainty estimate of \( \sigma_m/\sqrt{N_{\text{bins}}} \) is used for each bin during the fit, where \( N_{\text{bins}} \) is the number of galaxies in that bin. The distributions of the \( \nu \) (for any \( R \)) and of \( R \) (for any \( \nu \)) measured from single-exposure simulations are shown in Fig. 3, and a typical histogram for one of the bins is shown in Fig. 4. As can be seen, the shear measurement error is slightly non-Gaussian with some low-level wings.

We derive the best-fitting coefficients of equation (13) from the above procedure to be \((a, b, c) = (1.58, 5.03, 0.39)\). The rms difference between the fit and the measured values (weighted by \( N_{\text{bins}} \)) is \( \sim 0.1 \). The fitted surface is shown in Fig. 5. In general, the behaviour

of the measurement noise is intuitive—small and faint galaxies have noisier measurements and large, bright galaxies are well measured.

We can now estimate the shear measurement noise ($\sigma_m$) for each galaxy in each exposure by plugging the $\nu$ and $R$ values (for each galaxy in each exposure) into equation (13). In this calculation, four parameters from the CATSIM catalogue (the apparent magnitude, the galaxy bulge and disc half-light radii and the bulge-to-total flux ratio) and two parameters from the OPsim catalogue (the seeing and sky background in each exposure) are used. Note that we have derived the model of shear measurement noise ($\sigma_m$) via galaxies in a certain $\nu$ and $R$ range that can be detected and measured in single-exposure simulations (Fig. 3). For galaxy measurements with $\nu$ and $R$ values outside this range, our estimation of $\sigma_m$ would be an extrapolation.

### 4.3 Combining multiple shear measurements of a single galaxy

Shear measurements from the same galaxy imaged in multiple exposures are combined to give a single estimate of shear per galaxy. For LSST, this is a crucial step because the number of exposures of each galaxy is typically an order of magnitude larger than for previous surveys. That is, the algorithm one uses to combine these shear measurements is important.

Different approaches have been suggested to deal with such multi-epoch data sets. Conventionally, one would create co-added images and carry out the full analysis on the co-add. This is not an optimal approach, for one throws away information obtained in the sharpest images and furthermore, correlates the noise in the pixels and creates biases in the shear estimates. Bernstein & Jarvis (2002) and more recently Miller et al. (2007) and Tyson et al. (2008) have suggested taking the approach of joint fitting, where the individual exposures are kept separate throughout the analysis. The detections would still be made on a co-added image to maximize signal-to-noise ratio in the detection process. But then the shape measurement would involve a joint fit using all the original pixels from the individual exposures, making it possible to weight the measurement in different exposures according to the noise on that particular exposure. That is, we extract more information from good images and less information from bad images. The latter approach is optimal when the image quality varies across exposures.

First, we consider the case for which the shear is estimated jointly using all the original (individual) images. In this case, the optimal joint estimator will have a net measurement error, $\sigma_{m,\text{joint}}$, of

$$
\sigma_{m,\text{joint}} = \left[ \sum_j N_{\text{exp}} \frac{1}{\sigma_{m,j}} \right]^{-0.5}, \quad (16)
$$

where $\sigma_{m,j}$ is the measurement error estimate from equation (13) for each exposure $j$ out of the $N_{\text{exp}}$ total exposures.

For the second case of combining the images and then measuring shear from the co-added image, we can calculate the effective $\nu$ and $R$ values using the total signal and background and an estimate of the net PSF size from adding the $N_{\text{exp}}$ exposures:

$$
S_{\text{tot}} = \sum_j N_{\text{exp}} S = N_{\text{exp}} S, \quad B_{\text{tot}} = \sum_j N_{\text{exp}} B_j,
$$

$$
\frac{1}{r^2_{\text{PSF,eff}}} = \frac{1}{N_{\text{exp}}} \sum_j N_{\text{exp}} \frac{1}{r^2_{\text{PSF,j}}}, \quad v_{\text{eff}} = \frac{S_{\text{tot}}}{\sqrt{S_{\text{tot}} + B_{\text{tot}}}}, \quad R_{\text{eff}} = \frac{r^2_{\text{gal}}}{r^2_{\text{PSF,eff}}}, \quad (17)
$$

and

$$
\sigma_{m,\text{co-add}} = \frac{a'}{v_{\text{eff}}} \left[ 1 + \left( \frac{b'}{R_{\text{eff}}} \right)^c \right]. \quad (18)
$$

In principle, $(a', b', c)$ and $(a, b, c)$ need not be identical. The difference can be due to the specific PSF modelling technique one uses. This means that the fit shown in Fig. 5 (based on single exposure measurements) may no longer be appropriate in the case of co-added images. Nevertheless, for the purpose of this analysis, we avoided most PSF-related issues and specifically explored a wide range of reasonable $(\nu, R)$ values. As a result, we will make the approximation $(a', b', c') \approx (a, b, c)$, effectively generalizing equation (13) to all $(\nu, R)$ values.

We first consider the case for which only $r$-band images are used and then consider the case for which both $r$- and $i$-band images
are used. For LSST, we expect a similar number (≈368) of $r$- and $i$-band 15-s exposures in the full 10-yr data set. Note that the technical difficulties of combining images for different bands still need to be assessed (see also discussion in Section 5.4).

### 4.4 Galaxy selection

In all weak lensing analyses to date, one does not use all the galaxies that are detected and identified as galaxies to conduct cosmic shear measurements. Instead, only galaxies that pass certain criteria make it into the final summation in equation (9). Although noisy galaxies naturally have low weights in equation (9), there are several practical reasons that one rejects part of the galaxy population: First, most shear measurement algorithms become numerically unstable when working with noisy galaxies. Secondly, these noisy galaxies are subject to noise bias (Refregier et al. 2012; Melchior & Viola 2012) and can increase the systematic errors significantly. Finally, assuming one were to calibrate these systematic errors with simulations (Kacprzak et al. 2012), the calibration process becomes challenging and unstable as the measurement noise increases.

Given the reasoning above, a natural route to select galaxies is to base the selection on the relative level of the shear measurement errors ($\sigma_m$) and the shape noise ($\sigma_{SN}$). In other words, we use only galaxies that satisfy:

$$\sigma_m < k \sigma_{SN}, \quad (19)$$

where $k$ is of order unity and depends on the performance of the shear measurement algorithm. In the main analysis of this paper, we choose three $k$ values based on studies in Bridle et al. (2010) and Kitching et al. (2012a). These studies have shown that most current shear measurement algorithms perform well on objects with $(\nu, R) \approx (40, 1.5)$, operate with moderate accuracy on objects with $(\nu, R) \approx (20, 1)$, and tend to fail on objects with $(\nu, R) \approx (10, 0.5)$. These three cases roughly correspond to $k = (2.0, 1.0$ and $0.5)$ if we assume the shear measurement noise follows Fig. 5. In the rest of this paper, we will thus consider these three galaxy selection cuts, where $k = 1.0$ corresponds to the fiducial case, $k = 2.0$ corresponds to the optimistic case, and $k = 0.5$ corresponds to the conservative case. The fiducial case corresponds to using a shear measurement algorithm with accuracy similar to current state-of-the-art methods.

We note that a more common approach in existing weak lensing analysis pipelines is to select galaxies based on a 2D cut in the $\nu$–$R$ plane. However, we argue that galaxy selection based on such a cut is not necessarily optimal. As illustrated in Fig. 5, the two galaxy samples selected by the $k = 1$ contour and the dashed rectangle (equivalent to a 2D cut of $\nu > 20, R > 0.75$) have the same allowed maximum measurement noise. But the dashed line clearly removes less parameter space than the $k = 1$ contour, thus leading to smaller $n_{\text{eff}}$. This simple illustration demonstrates that if the measurement noise can be properly estimated, the most efficient way to select galaxies for weak lensing measurements is to base the selection on the measurement noise directly [equation (19)].

Finally, we consider the range of redshifts for galaxies used in the analysis. It is common for lensing analyses to only consider a limited redshift range since objects at very high redshift will have photometric redshifts that are poorly estimated, while objects at very low redshift do not provide much cosmological information. We assume that the LSST photometric redshift uncertainties are consistent with those given in LSST Science Collaboration (2009) and consider only galaxies in the redshift range 0.1–3.

### 5 ESTIMATION OF $n_{\text{eff}}$ FOR LSST

We now estimate $n_{\text{eff}}$ by combining the analyses from Sections 3 and 4 into equation (9): First, we estimate the shear measurement error on each galaxy in the galaxy catalogue after combining $N_{\text{exp}}$ exposures. Then we reject galaxies with measurement errors and redshift values that fail the selection criteria set in Section 4.4. The remaining galaxies are used to calculate $n_{\text{eff}}$ using equation (9) and $\sigma_{SN} = 0.26$. We consider two combining approaches (co-add and joint-fit), and also the possibility of combining $r$- and $i$-band data. Table 1 and Fig. 6 summarize the results of our analysis. We discuss below several issues related to estimating $n_{\text{eff}}$.

#### 5.1 Time dependence of $n_{\text{eff}}$

In Fig. 6, we show $n_{\text{eff}}$ as a function of number of exposures combined, or, equivalently, survey time. Fig. 6(a) shows the $n_{\text{eff}}$ behaviour for $r$-band only and for different $k$ values as described in Section 4.4. Fig. 6(b) shows, for the fiducial case ($k = 1.0$), how the result will change as one considers combining multiple exposures differently and when $i$-band data are included. The general trends for all plots are similar: $n_{\text{eff}}$ increases monotonically and does so faster in the beginning of the survey. In all cases studied here, the curves do not plateau during the survey.

As the exposure time increases, the same object will be measured with larger signal-to-noise ratio on the combined image and is more likely to survive the $\sigma_m$ cut. Given that the number of galaxies increases dramatically as one goes to the fainter end of the galaxy population (see Fig. 1c), we can expect a sharp increase in $n_{\text{eff}}$ over time. However, as the number density of galaxies surviving the $\sigma_m$ cut increases, blending may become an issue. We estimate in Section 6 the possible effect of blending on $n_{\text{eff}}$. We also note that the rate of increase of $n_{\text{eff}}$ is slower than the naive expectation of $\sqrt{N_{\text{exp}}}$. This is because we place a cut on $\sigma_m$ and not simply $\sigma_{SN}$.

---

**Table 1.** Summary of the effective number of galaxies per square arcminute used for weak lensing analyses, or $n_{\text{eff}}$, derived in Section 5 for the 10-yr data from LSST. The columns under $n$ list the raw galaxy number densities for different galaxy selection cuts (equation 19), while the columns under $n_{\text{eff}}$ list the corresponding effective galaxy number densities. In the first row, we use $r$-band images only and combine the multiple exposures via joint fitting. The second row shows how the numbers change as we adopt a co-add approach instead. The last row shows the case for which both $r$- and $i$-band images are used. The bold face values are used later in Section 6.

| $k$      | $n$  | $n_{\text{eff}}$ |
|----------|------|------------------|
|          | $r$ / joint fit | $r$ / co-add     |
| $k = 2.0$ | 26   | 19               |
| $k = 1.0$ | 40   | 30               |
| $k = 0.5$ | 67   | 42               |

---

$^{19}$ The question of whether near-infrared observations will be required to achieve this level of accuracy or if advanced methods such as those proposed by Newman (2008) will be sufficient is beyond the scope of this paper.
we expect the source flux becomes more pronounced as one collects more data. When including multiple exposures via a joint-fit method rather than a co-add method. This improvement comes from the fact that for a co-add method, only galaxies well measured in the ‘average’ exposure are used, while this is not necessarily true for the joint-fit method. It is possible to use galaxies that are not well measured in the ‘average’ exposure in a joint-fit method, as long as the galaxies are sufficiently well measured in some of the exposures. We have estimated in Table 1 a small decrease in \( n_{\text{eff}} \) (\( \sim 7 \) per cent) going from a joint-fit to a co-add approach. We note that in this calculation, our \( n_{\text{eff}} \) estimation for the co-add approach is less accurate than that for the joint-fit approach. This is because, as noted in Section 4.3, we have extrapolated Fig. 5 from single-exposure results to the co-add regime. In the co-add images, not only does the photon noise in the galaxies decrease,
the stars also become better measured and the PSF model becomes smoother and easier to model. But since we have avoided PSF estimation in this analysis, Fig. 5 should be a good approximation for both the single exposure and the co-added image.

5.4 Combining data from multiple bands

In most existing weak lensing analyses, only single-band data are used, as the surveys are usually designed to have the best image quality data in a single band. For LSST, both i- and r-band data should be sufficiently good for lensing analyses. We thus consider the case for which both i- and r-band images are used. Comparing the first and the last row in Table 1, we see that the addition of i-band data results in a ~20% percent growth in \( n_{\text{eff}} \) and not a naive square-root factor increase (Jarvis & Jain 2008). This is because i-band images generally have lower signal-to-noise ratio (higher background as seen in Fig. 2) and thus higher measurement noise. We also estimate \( n_{\text{eff}} \) for the case of combining all six filter bands using the same method. We find that \( n_{\text{eff}} \approx 71, 55, 36 \) arcmin\(^{-2} \) for the optimistic, fiducial and conservative scenarios, respectively. That is, \( n_{\text{eff}} \) increases by a factor of \( \sim 1.8 \) going from one filter \( r \) to six filters and \( \sim 1.5 \) going from two filters \( r+i \) to six filters. Again, the gain is smaller than \( \sqrt{6} \approx 2.4 \) and \( \sqrt{3} \approx 1.7 \). In addition to the fact that all other bands are shallower than \( r \) band, the average seeing in other bands is generally similar or worse than the \( r \)- and i-band seeing.

In the estimation of \( n_{\text{eff}} \) above for multiband data sets, we have made several assumptions. First, we assumed that individual galaxy shapes are the same in the different filter bands. This is a good assumption according to Jarvis & Jain (2008), who showed that the shape measurements in deep multiband data are highly correlated between different filter bands. Secondly, we have assumed that the measurement noise in each band depends on the galaxy's signal-to-noise and effective size in the same way as the r-band images (i.e. the coefficients of equation (13) are the same). This assumption could fail if, for example, the PSF modelling algorithm does not perform equally well in all bands. However, since we have minimized the effect from the PSF modelling procedure in our analysis, this should be a good assumption. Finally, we made the assumption that the joint-fitting algorithm is capable of operating on the multiband data set.

Given the assumptions discussed above, a more detailed study is required to understand the actual quantitative gain in combining data from multiple filter bands. Nevertheless, we point out here that it is in principle possible to achieve large \( n_{\text{eff}} \) values by combining data from all the available filters, even if some filters are not optimized for lensing. This conclusion is consistent with that found in Jarvis & Jain (2008).

5.5 Redshift distribution of \( n_{\text{eff}} \)

Finally, we look at the redshift distribution of \( n_{\text{eff}} \). In Fig. 7, we plot \( n_{\text{eff}} \) in 16 redshift bins from redshift 0 to 4 for the optimistic, fiducial and conservative scenarios. Also plotted is the raw galaxy number density \( n \) before any galaxy selection cut is applied, normalized to similar level as the other curves for qualitative comparison. We see that the true galaxy redshift distribution peaks at a redshift approximately 0.35-0.5 greater than the \( n_{\text{eff}} \) redshift distribution. This is because the high-redshift galaxies are usually poorly measured and contribute less to \( n_{\text{eff}} \), causing the \( n_{\text{eff}} \) redshift distribution to shift towards lower redshift. We fit the \( n_{\text{eff}} \) redshift distribution with the following functional form, which is often used to characterize the galaxy redshift distribution,

\[
P(z) = z^\alpha \exp \left[ -\left( \frac{z}{z_0} \right)^\beta \right],
\]

and list the fitted coefficients in the first three rows of Table 2. The median redshift \( z_m \) extracted from the curves in Fig. 7 is also listed in Table 2. The shape of the distribution is somewhat different from that measured in low-redshift galaxies, where \( \alpha \approx 2 \) and \( \beta \approx 1.5 \) (Smail et al. 1995).

Fig. 7 and Table 2 show the first attempt to date to quantitatively calculate the redshift distribution of \( n_{\text{eff}} \). This distribution can be used for more realistic Fisher-matrix forecasting and simulations of cosmic shear surveys. Previous calculations (Hu 1999; Takada & Jain 2004; Amara & Réfrégier 2007) adopt the raw galaxy redshift distribution for these applications, which could lead to an overestimation of the constraining power of the cosmic shear surveys.

### Table 2. Best-fitting coefficients for equation (21)

| \( k \)  | 2.0  | 1.0  | 0.5  | \( n \) |
|------|------|------|------|------|
| \( \alpha \) | 1.26 | 1.27 | 1.47 | 1.25 |
| \( z_0 \) | 0.57 | 0.50 | 0.30 | 1.0  |
| \( \beta \) | 1.05 | 1.02 | 0.89 | 1.26 |
| \( z_m \) | 0.89 | 0.82 | 0.71 | 1.22 |

6 EFFECTS OF OTHER PRACTICALITIES

In addition to the considerations discussed above, several practical factors affect \( n_{\text{eff}} \) at levels that cannot be neglected. We roughly
estimate the level of these effects. The results of this section are summarized in Table 4.

(1) Blending: after the selection cut, depending on the galaxy number density, a fraction of the galaxies will be rejected because they are blended with other close-by objects. At the low galaxy number density in existing data, this effect is not severe. As a result, the effect of blending has not been studied in detail for previous weak lensing analyses. However, given the high galaxy number density expected for LSST (Table 1), the effect can be significant. We estimate below roughly the effect of blending for LSST. A more detailed study will be presented in Kirkby et al. (in preparation).

First, we assume a galaxy is ‘blended’ when there are other objects with centre positions within a radius \( d \) of the galaxy’s centre, where \( d \) depends on the capability of the de-blending algorithm assumed. In other words, galaxies with neighbours closer than \( d \) will be rejected by a certain de-blending algorithm because attempting to de-blend these objects will introduce significant systematic errors on their shape measurements. Next, we use the same galaxy catalogue introduced in Section 3 and plot the fraction of blended galaxies as a function of galaxy number density in Fig. 8 for three \( d \) values. For de-blending treatments in existing data sets, conservative approaches at the level of \( d \approx 3 \) arcsec are used (see Section 7). We expect that when the LSST survey begins, de-blending algorithms will be improved, and objects separated by approximately twice the width of the PSF, or \( \approx 2 \) arcsec, could be properly de-blended. \( d \approx 1 \) arcsec represents an optimistic case for which the de-blending algorithm is capable of dealing with objects separated by approximately the width of the PSF.

The blending fraction \( F_{\text{blend}} \) in Fig. 8 can be well described by the functional form

\[
F_{\text{blend}}(n) = \eta \ln(1 + \mu n),
\]

where \( \eta \) and \( \mu \) are coefficients to fit for, and \( n \) is the galaxy number density. We list the best-fitting coefficients in Table 3 and overlay the best-fitting function to the points in Fig. 8. In this simplistic blending model, \( n_{\text{eff}} \) is degraded to \( (1 - F_{\text{blend}}) n_{\text{eff}} \), given a certain \( d \) value. Note that the degradation of \( n_{\text{eff}} \) from blending, or \( F_{\text{blend}} \), depends on the raw galaxy number density \( n \) and not \( n_{\text{eff}} \). We list the resulting \( n_{\text{eff}} \) for \( d = 2 \) arcsec in the second row of Table 4.

(2) Masking: parts of the images will be masked due to bright stars (generating diffraction spikes, saturated columns and large diffuse haloes) and edge effects. Masking can be combined into the \( n_{\text{eff}} \) calculation or simply accounted for by claiming a smaller optimistic \( k \) and conservative \( k \) galaxy selection cuts. These effective number densities are calculated for the last row in Table 1 (\( r \) and \( i \)-band data, combined through joint fitting).

### Table 3. Best-fitting coefficients for equation (22) that describes the fraction of galaxies blended as a function of galaxy number density. The fit is evaluated assuming different de-blending algorithms. The three \( d \) values correspond to conservative \((d = 3 \text{ arcsec})\), fiducial \((d = 2 \text{ arcsec})\) and optimistic \((d = 1 \text{ arcsec})\) assumptions for the performance of de-blending algorithms in LSST.

| \( d \)     | \( \eta \) | \( \mu \)   |
|------------|------------|-------------|
| 1 arcsec   | 0.50       | 1.9 \times 10^{-3} |
| 2 arcsec   | 0.68       | 5.5 \times 10^{-3}  |
| 3 arcsec   | 0.62       | 1.4 \times 10^{-2}  |

### Table 4. Estimation of the \( n_{\text{eff}} \) accounting for degradation caused by practical effects in data such as blending and masking, for the optimistic \((k = 2.0)\), fiducial \((k = 1.0)\) and conservative \((k = 0.5)\) galaxy selection cuts. This table assumes the galaxy number density expected for LSST and the effect can be significant.

| \( k \) | \( n_{\text{eff}} \) |
|--------|---------------------|
| raw \( n_{\text{eff}} \) | 48 37 24 |
| +blending \((d = 2 \text{ arcsec})\) | 36 31 22 |
| +masking \((15 \text{ per cent})\) | 31 26 18 |

**Figure 8.** Fraction of galaxies that have neighbours with a ‘centre-to-centre’ distance less than \( d \), or blended, as a function of the galaxy number density \( n \). The data points are overlaid by the best-fitting function (equation 22, Table 3) for the three \( d \) values with the black dashed curve. The three cases plotted here correspond to conservative \((d = 3 \text{ arcsec})\), fiducial \((d = 2 \text{ arcsec})\) and optimistic \((d = 1 \text{ arcsec})\) assumptions for the performance of de-blending algorithms in LSST. The orange star indicates the galaxy number density and fraction of blended galaxies in the CFHTLenS data set. The de-blending algorithm used in CFHTLenS corresponds to \( d \approx 2.7 \text{ arcsec} \) in our simple model.

### 7 CASE STUDY – \( n_{\text{eff}} \) FOR CFHTLENS

To demonstrate the generality of our approach, we perform the same \( n_{\text{eff}} \) calculation for the most recent the Canada-France Hawaii Telescope Lensing Survey (CFHTLenS) data set. We base the major parameters on the CFHTLenS summary paper (Heymans et al. 2012b, H12), the paper describing the shear measurement pipeline.
First, we point out that in H12, a different definition of the ‘effective number density of weak lensing galaxies’ is used. To avoid confusion, we will refer to this definition as \( n_{\text{eff}} \), where

\[
n_{\text{eff}} = \frac{1}{\Omega^2} \left( \frac{\sum w_i^2}{\sum w_i} \right)^2.
\]

H12 defined \( \Omega^2 \) to be the total area of the survey, excluding masked regions and the weighting factor \( w_i \) is a measure of the shear measurement error, defined as

\[
w_i = \left[ \frac{\sigma_i^2 e_i^2}{e_{\text{max}}^2 - 2\sigma_i^2} + \sigma_{\text{SN}}^2 \right]^{-1},
\]

where \( \sigma_i^2 \) is the 1D variance in ellipticity of the likelihood surface estimate in lensfit\(^{20}\) and \( e_{\text{max}} \) is the maximum allowed ellipticity. In the limit \( e_{\text{max}} \rightarrow \infty \), the first term in the bracket, \( (\sigma_i^2 e_i^2)/(e_{\text{max}}^2 - 2\sigma_i^2) \), reduces to \( \sigma_i^2 \), which can be associated with \( \sigma_i^2 \) in our work. In H12, the \( n_{\text{eff}} \) for the main lensing sample is calculated to be 11 arcmin\(^{-2} \), but \( n_{\text{eff}} \) (as defined in equation 9) is not calculated. Conceptually, these two quantities measure slightly different things: \( n_{\text{eff}} \) is a measure of the fraction of all the galaxies used that have measurement noise large compared to average measurement noise. \( n_{\text{eff}} \) is equal to the raw number density of galaxies selected when all the weights are the same and decreases as the distribution of the weights becomes broader. On the other hand, \( n_{\text{eff}} \) is defined specifically to measure the absolute statistical power of a weak lensing data set and is always smaller than the raw number density of galaxies even when all the galaxies have the same non-zero measurement noise. In the case of a very conservative cut, where most galaxies selected have low measurement noise and similar weighting factor, \( n_{\text{eff}} \) can be close to \( n_{\text{eff}} \) since they both approach the raw number density of galaxies.

The CFHTLenS data set covers an area of 154 square degrees, at approximately uniform depth. Each patch of sky is imaged six to seven times with the exposure time in each image being 600 – 700 s. For simplicity, we assume that all fields are imaged seven times, for 615 s each, making the total exposure time for each galaxy close to the actual total exposure time of \( \approx 4300 \) s. Lensing analyses are performed only in the \( i \) band, where the seeing conditions are particularly good – the mean seeing is 0.64 arcsec and all images have seeing better than 0.8 arcsec. We assume the seven exposures have the following equally spaced seeing values: \( [0.48, 0.53, 0.59, 0.64, 0.69, 0.75, 0.80] \) arcsec. We also assume that the sky background is constant at 20.0 mag arcsec\(^{-2} \). A magnitude cut of \( i_{\text{AB}} < 24.7 \) is placed to ensure the shape measurements are accurate; we replace the \( \sigma_i \) cut with this magnitude cut. There is no explicit cut in galaxy size in the shear measurement algorithm used in CFHTLenS,\(^{21}\) but since the galaxy models have a prior on the scalelength set to a minimum of 0.3 pixels, we use that as a measure of the implicit size cut. Using the mean seeing 0.64 arcsec (0.187 arcsec pixel\(^{-1} \)) = 3.5 pixels, we have \( R_{\text{cut}} \approx (0.3/3.5)^2 \approx 0.007 \). An additional redshift cut \( (0.2 < z < 1.3) \) is applied to the galaxy sample used for the lensing analysis to ensure accurate photometric redshift estimates. 20 per cent of the galaxies are rejected due to serious blending. 19 per cent of the survey is masked due to bright stars. A total of 39 per cent of the area is rejected when including the above masking and systematics diagnostics. The main survey quantities of CFHTLenS used in this study is summarized in Table 5.

The number density of galaxies with shape and redshift measurements, that was used in the CFHTLenS calculation of \( n_{\text{eff}} \) is \( \sim 17 \) arcmin\(^{-2} \). Note that this is much lower than the raw number density of galaxies at \( i_{\text{AB}} < 24.7 \) (\( \sim 35 \) arcmin\(^{-2} \), estimated from the CATSIM catalogue). Several effects contribute to the reduced galaxy number density (Miller, Heymans, Hildebrandt, private communication): (1) the redshift cut at \( 0.2 < z < 1.3 \), (2) incompleteness in the photometric redshift data, (3) incompleteness in detection due to low surface brightness, (4) rejection of large galaxies that are larger than the size of the postage stamps (\( \sim 9 \) arcsec on a side) and (5) rejection of blended galaxies. Given the expected raw number density of galaxies (\( \sim 35 \) arcmin\(^{-2} \)) and the final fraction of blended galaxies (20 per cent), we calculate that the effective blending criteria used in CFHTLenS corresponds to \( d \approx 2.7 \) arcsec in Fig. 8.

Putting in the above numbers, we calculate that without any blending rejection and masking, we have \( n_{\text{eff}} \approx 13 \) arcmin\(^{-2} \), a factor of \( \approx 3 \) fewer than the LSST \( n_{\text{eff}} \) for \( r \) band and the fiducial galaxy selection cut. Taking into account a 20 per cent blending rejection, we have \( n_{\text{eff}} \approx 10 \) arcmin\(^{-2} \). As expected for the rather conservative galaxy selection cut, this \( n_{\text{eff}} \) value is close to the \( n_{\text{eff}} \approx 11 \) arcmin\(^{-2} \) calculated in H12. Finally, taking into account the 39 per cent rejected area, which is avoided in H12 by considering the un-rejected area only, we have \( n_{\text{eff}} \approx 6 \) arcmin\(^{-2} \). This number, together with a shape noise of \( \sigma_{\text{SN}} \approx 0.26 \) and 154 square degree survey area make up a self-consistent set of parameters that quantifies the statistical errors in the CFHTLenS cosmic shear measurement. Note that one should be careful not to compare the two numbers, \( n_{\text{eff}} \) and \( n_{\text{eff}} \), directly as they measure slightly different properties of the galaxy population.

### Table 5. Main survey and analysis parameters from CFHTLenS related to the \( n_{\text{eff}} \) calculation. The asterisks indicate that the values are estimated or approximated from the real parameters in the survey. When applicable, the parameters are specified for the CFHT \( i \) band.

| Parameter                      | Value                      |
|--------------------------------|----------------------------|
| Total survey area              | 154 (deg\(^2\))           |
| Number of exposures*           | 7                          |
| Exposure time per exposure*    | 615 (s)                    |
| Seeing distribution*           | [0.48, 0.53, 0.59, 0.64, 0.69, 0.75, 0.80] (arcsec) |
| Sky background*               | 20 (mag arcsec\(^{-2} \))   |
| Wavelength range               | 685–840 (nm)               |
| Pixel scale                    | 0.187 (arcsec pixel\(^{-1} \)) |
| Redshift range                 | 0.2–1.3                    |
| Magnitude range                | \( i_{\text{AB}} < 24.7 \) |
| Size cut*                     | 0.007                      |
| Fraction of galaxies rejected due to blending | 20 per cent |
| Fraction of area rejected      | 39 per cent                |

---

20 CFHTLenS uses lensfit (Miller et al. 2007; Kitching et al. 2008; Miller et al. 2013) as the main shear measurement algorithm.

21 lensfit attempts to fit all detected objects with star and galaxy models and then classifies them as stars or galaxies according to which model gives a higher posterior probability.
calculate $n_{\text{eff}}$ for LSST. Our analysis considers all major components in a weak lensing pipeline including the galaxy population of interest, the distribution of observing conditions, the measurement errors, the galaxy selection procedure, the approach for combining multiple exposures and blending/masking effects. By using realistic simulations, we estimate that with current weak lensing algorithms (the fiducial scenario), $n_{\text{eff}} \approx 37 \text{ arcmin}^{-2}$ before considering masking and blending, $n_{\text{eff}} \approx 31 \text{ arcmin}^{-2}$ when rejecting the blended galaxies and $n_{\text{eff}} \approx 26 \text{ arcmin}^{-2}$ when factoring in a 15 per cent masked area. This is estimated for LSST after combining all the $r$- and $i$-band data in the full 10 yr survey on a 18 000 degree$^2$ survey area. With improvement in the weak lensing analysis algorithms, we can expect (optimistically) $n_{\text{eff}} \approx 48 \text{ arcmin}^{-2}$ before accounting for masking and blending, $n_{\text{eff}} \approx 36 \text{ arcmin}^{-2}$ when blended galaxies are rejected and $n_{\text{eff}} \approx 31 \text{ arcmin}^{-2}$ with 15 per cent of the area masked. (Table 4). We have shown quantitatively how improvement in the weak lensing algorithm as well as de-blending/masking techniques can lead to large improvements in $n_{\text{eff}}$.

Different schemes for combining multiple exposures are discussed in this paper. We find that using a co-add method reduces $n_{\text{eff}}$ by 7 per cent compared to a joint-fit method and optimally combining data from all six filters could increase $n_{\text{eff}}$ by a factor of 1.5 compared to using only the $r$- and $i$-band (lensing-optimized) data. We also quantify for the first time the redshift distribution of $n_{\text{eff}}$, which has a median redshift 0.35–0.5 lower than the raw galaxy distribution (Fig. 7). Finally, we demonstrate how the same methodology could be applied to current weak lensing surveys and show that the results are reasonable.

Now we review and compare our results to the $n_{\text{eff}}$ values that have been estimated in previous studies. Before comparing our results with the different studies, it is important to realize two issues regarding the definition of $n_{\text{eff}}$. First, many other papers define and quote differently the ‘effective number density of galaxies used for weak lensing measurements’. H12 is an example, described earlier (equation 23), that has an entirely different definition and underlying meaning of $n_{\text{eff}}$. Huterer et al. (2006) and Paulin-Henriksson et al. (2008), on the other hand, use the number $n_{\text{g}} \approx 30 \text{ arcmin}^{-2}$ in their analyses, where $n_{\text{g}}$ is the raw number of galaxies instead of the weighted $n_{\text{eff}}$. Secondly, most previous studies do not consider the masked area in the $n_{\text{eff}}$ calculation. To perform a fair comparison, we will thus compare our $n_{\text{eff}}$ estimation before masking (second row in Table 4) with other studies. That is, we have $n_{\text{eff}} \approx 36 \text{ arcmin}^{-2}$ (optimistic), $n_{\text{eff}} \approx 31 \text{ arcmin}^{-2}$ (fiducial) and $n_{\text{eff}} \approx 22 \text{ arcmin}^{-2}$ (conservative). Under this definition, one needs to specify an additional estimate of the masked survey area to fully characterize the statistical power in weak lensing for LSST.

In LSST Science Collaboration (2009), $n_{\text{eff}} \approx 40 \text{ arcmin}^{-2}$ was estimated for LSST. This estimate was based on scaling the measurement in Clowe et al. (2006) to the LSST depth and includes both $r$- and $i$-band images, with a rough estimate of blending. To perform a fair comparison, we note that at the time when the analysis of Clowe et al. (2006) was conducted, it was common to use a shear measurement algorithm that is subject to either the ‘conservative’ or the ‘fiducial’ scenario in this paper. This suggests that our estimates in this work, $n_{\text{eff}} \approx 31 \text{ arcmin}^{-2}$ and $36 \text{ arcmin}^{-2}$, are relatively lower. We attribute this to the fact that first the Clowe study is based on a relatively small area of sky; thus, the conclusions may not be general. Secondly, their blending estimation may be overly optimistic. Similarly, an independent group approached the problem by comparing Hubble Space Telescope and Subaru observations of the same field and combining multiple exposures with algorithms that take into account the PSF variation over time (Jee & Tyson 2011, Tyson, Dawson and Jee, private communication). They conclude $n_{\text{eff}} \approx 36 \text{ arcmin}^{-2}$ for the full LSST $r$- and $i$-band data set, consistent with our optimistic estimate. In A06, $n_{\text{eff}}$ was estimated to be $\approx 30 \text{ arcmin}^{-2}$ in the pessimistic scenario and $\approx 40 \text{ arcmin}^{-2}$ in the optimistic scenario. This is fairly consistent with what we have estimated for the ‘fiducial’ and ‘optimistic’ scenarios. With the detailed study in this paper we have a much better understanding of the origin of $n_{\text{eff}}$ and the multiple factors that can affect its level. Assumptions about these factors should be specified when stating any $n_{\text{eff}}$ estimate.

Although the focus of this paper is the statistical errors for future lensing surveys, it is important to realize that in many cases systematic errors are inevitably coupled with the statistical errors in lensing measurements. In Section 4.4, for example, we select galaxies with measurement noise lower than a certain threshold for cosmic shear measurement. The main purpose of this selection cut is to avoid systematic errors in shear measurements, which become large for faint and small galaxies. Similarly, in Section 6 we reject galaxies that have close neighbours. This is to avoid shear measurement biases from errors in the de-blending process. Finally, incorporating data from filters that are not optimized for lensing does not increase $n_{\text{eff}}$ significantly, but multicolour data is potentially useful for identifying and quantifying systematic uncertainties. The balance between statistical and systematic errors is the key issue to address when designing lensing pipelines in the next generation surveys. After all, it is the combination of the statistical and systematic errors that determine the ultimate uncertainties in the cosmological parameters.

ACKNOWLEDGEMENTS

We thank Gary Bernstein for helpful discussions. We thank Alexie Leauthaud for providing us with the COSMOS galaxy catalogue. We thank Jon Thaler and Seth Digel for useful comments which have helped improve this paper substantially.

Partial funding for MJ and BJ came from the Department of Energy award grant number DE-SC0007901. AJC acknowledges support from the Department of Energy award grant number DE-SC0002607. LSST project activities are supported in part by the National Science Foundation through Governing Cooperative Agreement 0809409 managed by the Association of Universities for Research in Astronomy (AURA), and the Department of Energy under contract DE-AC02-76-SFO0515 with the SLAC National Accelerator Laboratory. Additional LSST funding comes from private donations, grants to universities and in-kind support from LSSTC Institutional Members.

APPENDIX A: CALCULATING THE SIGNAL-TO-NOISE RATIO (v) AND EFFECTIVE SIZE (R) OF GALAXIES

For the analysis in this paper, we need to connect the input galaxy and observational parameters with the quantities measured from real images. This conversion is essential for calculating the signal-to-noise ratio (v) and effective size (R) of galaxies in our analysis.

A1 Conversion of galaxy model parameters to observable quantities

For the bulge+disc galaxy model provided by CATSIM, we are given the half-light radius of the bulge and the disc separately, the total magnitude and the ratio of flux in the bulge to the total flux (see Fig. 1). The bulge and disc are modelled by Sérsic profiles with Sérsic index n = 4 and n = 1, respectively. When measuring the galaxy parameters in real data, the galaxy is measured as a whole (bulge+disc). Moreover, sizes of galaxies are often measured through moments of the light distribution rather than half-light radius. Here, we attempt to connect the two conventions. Imagine a galaxy with the following profile:

\[ I(r) = I_{\text{gal}} \left[ f_b e^{-\frac{r}{r_h^b}} + (1 - f_b) e^{-\frac{r}{r_h^d}} \right], \]

where the subscript 'b' and 'd' indicates the bulge and disc, respectively, and \( r_h, r_d \) are the scalelength for the bulge and disc component.

First, we can calculate numerically the relation between the scalelengths and the half-light radii, \( r_{h,b} \) and \( r_{h,d} \), for the individual components:

\[ r_{h,b} \approx 3459r_b, \]
\[ r_{h,d} \approx 1.68r_d. \]

Next, we solve analytically for the second-moment radius of these two components:

\[ r_{sec,b} \approx 16108r_b \approx 4.66r_{h,b}, \]
\[ r_{sec,d} \approx 2.45r_d \approx 1.46r_{h,d}, \]

where the second-moment radius is defined by

\[ r_{sec} = \left[ \frac{\int_0^{2\pi} \int_0^{r_\text{max}} r^2 I(r)r \, dr \, d\theta}{\int_0^{2\pi} \int_0^{r_\text{max}} I(r)r \, dr \, d\theta} \right]^{0.5}. \]

Since the moments are additive component-wise, we have:

\[ r_{sec} = \sqrt{f_b r_{sec,b}^2 + (1 - f_b) r_{sec,d}^2} = \sqrt{f_b(4.66r_{h,b})^2 + (1 - f_b)(1.46r_{h,d})^2}. \]

A2 Connecting input and measured signal-to-noise ratio (v) and effective size (R)

Now we can calculate equations (14) and (15) from the input catalogue as well as the measured images.

From the input galaxy catalogue, we first calculate the galaxy’s effective size \( R \) by finding \( r_{gal} \) and \( r_{PSF} \) separately. We use the second line of equation (A6) to calculate \( r_{PSF} = r_{sec} \), and then calculate \( r_{PSF} \) from

\[ r_{PSF} = \frac{2r_{sec}}{2 + \ln 2}. \]
where the ‘$r_{\text{seeing}}$’ factor is usually expressed in terms of the 1D full width at half-maximum (FWHM) size, and the $\sqrt{2}$ in the numerator is to convert the 1D quantity to 2D. Next, to calculate the signal-to-noise ratio $\nu$, we first derive the second-moment radius of the convolved galaxy image using

$$r^2 = r^2_{g} + r^2_{\text{PSF}}.$$  \hfill (A8)

We then need the aperture radius $r_{ap}$ for the convolved galaxy. In Kron (1980), $r_{ap}$ is defined to be

$$r_{ap} = 2r_{\text{final}} = 2\int_0^{\infty} \int_0^{\infty} I'(r) r \, dr \, d\theta,$$  \hfill (A9)

where $I'(r)$ is the radial profile of the convolved galaxy. Instead of calculating this from the catalogue, which is complicated by the PSF convolution, we find empirically the relation between the second-moment radius and the aperture radius in typical galaxies in the simulations used in Section 4.1. Fig. A1 shows that for the galaxy sample with measurement noise cut $\sigma_m < \sigma_{SN}$, we find a simple linear relation between $r$, the convolved galaxy second-moment radius and $r_{ap}$, the aperture radius:

$$r_{ap} \approx 1.64r.$$  \hfill (A10)

Varying the measurement noise cut changes the relation, but for the galaxy sample of interest here, $r_{ap}$ is generally 1.5–2 times the second-moment radius $r$. In the main analysis of this paper, we use the fiducial cut ($k = 1.0$) and assume $r_{ap} \approx 1.64r$. In the worse-case scenario, where $r_{ap} \approx 2r$ (corresponding to $k = 0.5$), we have $\sim 17$ per cent decrease in $n_{\text{eff}}$. The source count in this aperture is estimated as 90 per cent of the source count derived by the total source magnitude, while the background count is just the area of the aperture times the background flux, which is calculated from OPSIM. Both source and background counts will need to be multiplied by the throughput of the system in the filter used. We use the average throughput at airmass 1.2 for LSST listed in Table A1.

From the measured image, we identify the IMCAT output parameters ‘$r_{g}$’ as the second-moment radius (equation A5) of the measured objects. The effective radius $R = r^2_{gal}/r^2_{\text{PSF}}$ is then calculated from

$$r_{\text{PSF}} = r_{\text{PSF,star}},$$  \hfill (A11)

and

$$r_{gal} = \sqrt{r^2_{g} - r^2_{\text{PSF}}}. \hfill (A12)$$

The aperture flux ($S$) and noise ($\sqrt{S + B}$) are outputs of the Source Extractor catalogue (‘FLUX_BEST’ and ‘FLUXERR_BEST’). We follow the convention of Leauthaud et al. (2007) and divide the two parameters to get the signal-to-noise ratio ($\nu$) of galaxies.

### APPENDIX B: EFFECT OF PSF INTERPOLATION

In the main analysis of this paper we used a rather idealized PSF model to avoid the PSF estimation problems that can vary significantly from pipeline to pipeline. Here, we demonstrate how $n_{\text{eff}}$ changes if we consider a more realistic case for PSF interpolation.

PSF interpolation refers to the procedure where we interpolate the PSF model parameters from the stellar positions to the galaxy positions. Conventionally, one would use a smooth low-order polynomial to fit each parameter over the field. This interpolation scheme, however, has been shown to be problematic when there are high spatial frequency PSF variations from the atmosphere in short exposures (Chang et al. 2012; Heymans et al. 2012a). We examine below how this imperfect PSF model degrades $n_{\text{eff}}$.

We generate 1000 simulated images similar to that described in Section 4.1. In this set of images, we include a realistic distribution of stars based on Ivezčić et al. (2008b). We then interpolate the shape parameters of the stellar images to the galaxy positions and perform the same PSF correction and shear measurement analysis as before, using these interpolated PSF models. The measurement surface noise as a function of $\nu$ and $R$ looks very similar to the corresponding interpolated PSF version, but with slightly lower levels. We fix $c$ in equation (13) and get $a = 2.28$, $b = 1.1$ when fitted to the measurements. This increase in measurement error yields a very slight decrease in $n_{\text{eff}}$ as listed in Table B1. This implies that the actual PSF interpolation method used does not seriously affect $n_{\text{eff}}$.

| $k$ | 2.0 | 1.0 | 0.5 |
|-----|-----|-----|-----|
| True PSF | 48 | 37 | 24 |
| Interpolated PSF | 46 | 36 | 23 |

This paper has been typeset from a $\LaTeX$/$\LaTeX$ file prepared by the author.
