The NA61/SHINE experiment aims to discover the Critical Point of strongly interacting matter and study the properties of the onset of deconfinement. These goals are to be achieved by performing a two-dimensional phase diagram ($T$-$\mu_B$) scan by measurements of hadron production properties in proton-proton, proton-nucleus and nucleus-nucleus interactions as a function of collision energy and system size. Close to the Critical Point an increase of fluctuations is predicted. This contribution presents preliminary results on transverse momentum and multiplicity fluctuations expressed in terms of strongly intensive quantities from the Be+Be energy scan. The data are fully corrected for contributions from non-target interactions. The Be+Be results are compared with NA61/SHINE measurements from the p+p energy scan, with NA49 results from central Pb+Pb collisions as well as with model predictions.

9th International Workshop on Critical Point and Onset of Deconfinement - CPOD2014,
17-21 November 2014

1. Introduction and motivation

NA61/SHINE [1] is a fixed-target experiment located at the Super Proton Synchrotron (SPS) in the North Area at CERN. It measures hadron production in proton-proton, proton-nucleus and nucleus-nucleus collisions at various beam momenta (13A – 158A GeV/c).

The main goal of the experiment is to discover the Critical Point of strongly interacting matter and study the properties of the onset of deconfinement.

One of the tools for studying the phase transition region and search for the Critical Point (CP) is the analysis of event-by-event fluctuations of multiplicity and kinematic characteristics. These fluctuations and correlations may serve as a signature of the onset of deconfinement (close to the phase transition the Equation of State changes rapidly which can impact the energy dependence of fluctuations) and can help to locate the CP of strongly interacting matter.

The NA49 collaboration [2] has studied proton-proton and nucleus-nucleus collisions. In their system-size scan with p, C, Si and Pb beams at 158A GeV/c [3] an increase of fluctuations for medium-size systems, consistent with CP predictions [4] has been observed.

NA61/SHINE is performing a systematic two-dimensional scan of the phase diagram (Fig. 1) in which the CP (if it exists) is expected to show up as a hill-like structure in the energy-system size dependence of fluctuations.

2. The analysis

Four data sets of $^7$Be+$^9$Be collisions recorded by NA61/SHINE in 2011 and the winter 2012/13 have been analyzed. Statistics are shown in Table 1.

A number of selection criteria were used to ensure good quality inelastic Be+Be collisions produced by a well-defined beam particle without other beam particles close in time. Reconstructed particles must originate from a well reconstructed main vertex and leave sufficient numbers of points inside the TPCs. Electrons and positrons were excluded. The analysis was limited to particles with transverse momentum less than 1.5 GeV/c.

Centrality was determined from the energy deposited in the NA61/SHINE forward calorimeter – the Particle Spectator Detector (PSD) (see E.Kaptur, this proceedings).
Table 1: Number of analyzed Be+Be interactions before and after quality cuts.

| $P_{beam}$ [GeV/c] | $\sqrt{s_{NN}}$ [GeV] | target inserted | target removed |
|---------------------|------------------------|-----------------|----------------|
|                     |                        | all selected    | all selected   |
| 20                  | 6.27                   | 3.2 M 1.2 M     | 305 k 2.5 k    |
| 40                  | 8.73                   | 3 M 0.9 M       | 319 k 1.8 k    |
| 75                  | 11.94                  | 4.2 M 1.2 M     | 433 k 2.4 k    |
| 150                 | 16.83                  | 2.5 M 0.9 M     | 283 k 2.4 k    |

Figure 2: Distribution of accepted particles in center-of-mass rapidity (top) and azimuthal angle (bottom) as a function of transverse momentum for Be+Be collisions at minimum (20A GeV/c, left) and maximum (150A GeV/c, right) beam momentum.

The fluctuation results are corrected for contributions from non-target interactions. For this purpose NA61/SHINE acquired data with both target inserted and removed. Then the contribution from non-target interactions is subtracted in the analysis.

Corrections for detector effects and trigger bias are estimated to be small but still under investigation.

3. Fluctuation Measures

As fluctuations in high-energy heavy-ion collisions may have different sources, it is important to select the fluctuations of interest. Despite a good PSD performance, it is impossible to determine exactly volume of the created matter on an event-by-event basis. However, it is possible to construct fluctuation measures which do not depend on volume and its fluctuations (strongly intensive measures) in statistical models in the grand canonical ensemble (GCE).
3.1 Scaled variance

The most natural way to describe fluctuations of the quantity $A$ is to measure the variance of its distribution. This is an extensive quantity, i.e. proportional to the system size. However, the ratio of two extensive variables is independent of system size (intensive measure). So the scaled variance

$$\omega[A] = \frac{\text{Var}(A)}{\langle A \rangle} \quad (3.1)$$

does not depend on the average volume, but it depends on volume fluctuations.

The scaled variance is a measure of multiplicity fluctuations used extensively in the past and also studied by NA61/SHINE.

3.2 Strongly intensive measures

It is possible to define a combination of scaled variances of two quantities, $A$ and $B$, in such a way, that their dependence on average volume and volume fluctuations cancels out. Such a measure is called strongly intensive.

There are two families of strongly intensive fluctuation measures [6]:

$$\Delta[A,B] = \frac{1}{C_\Delta} \left[ \langle B \rangle \omega[A] - \langle A \rangle \omega[B] \right] \quad (3.2)$$

$$\Sigma[A,B] = \frac{1}{C_\Sigma} \left[ \langle B \rangle \omega[A] + \langle A \rangle \omega[B] - 2 \left( \langle AB \rangle - \langle A \rangle \langle B \rangle \right) \right] \quad (3.3)$$

In case of transverse momentum fluctuations:

$$A = p_T = \sum_{i=1}^{N} p_{Ti}, \quad B = N, \quad C_\Delta = C_\Sigma = \langle N \rangle \omega[p_T]$$

They are both equal to 0 if there are no fluctuations and they are both equal to 1 for the Independent Particle Model [7]. However, there is one important difference between the two measures – $\Sigma[p_T,N]$ contains a correlation term, $\langle AB \rangle$.

To compare with published NA49 data, the strongly intensive $\Phi_{p_T}$ measure [8] is used:

$$\Phi_{p_T} = \sqrt{\frac{p_T^2 \omega[p_T]}{\Sigma[p_T,N]}} \left[ \sqrt{\Sigma[p_T,N]} - 1 \right], \quad (3.4)$$

4. Results

Figure 3 presents results for the scaled variance of the multiplicity distribution from Be+Be collisions for four energies, compared with measurements of NA61/SHINE from the energy scan of inelastic p+p interactions. $\omega$ increases with energy – probably due to KNO scaling (variance of the multiplicity distribution increases faster than its mean). Larger values for Be+Be than for p+p collisions are probably due to volume fluctuations because $\omega$ is not a strongly intensive measure.

Figure 4 shows results for transverse momentum fluctuations measured by the strongly intensive measures $\Delta[p_T,N]$, $\Sigma[p_T,N]$ and $\Phi_{p_T}$ for Be+Be interactions of several collision centralities and energies. They are compared with measurements of NA61/SHINE from the energy scan of inelastic p+p interactions.
Transverse momentum fluctuations in Be+Be and p+p interactions show no structures which could be related to the CP. Be+Be results are close to those from inelastic p+p reactions. The weak dependence on centrality in Be+Be shows that the fluctuations do not depend on the collision volume. The difference between \( \Delta[P_T, N] \) and \( \Sigma[P_T, N] \) might be due to Bose-Einstein and/or \( P_T - N \) correlations [9].

4.1 Comparison with NA49

As it is impossible to correct fluctuations for the acceptance, additional cuts were applied to compare NA61/SHINE results on \( \Phi_{p_T} \) with the published NA49 measurements at 158A GeV/c beam energy. The NA49 analysis was limited to the forward rapidity region (1.1 < \( y_\pi < 2.6 \)) since the high density of tracks did not allow reliable measurements in the mid-rapidity region. Moreover, a common azimuthal angle acceptance was used for all systems.

The comparison is shown in Fig. 5. Results of NA61/SHINE from p+p interactions agree with corresponding measurements from NA49. Also the result for Be+Be collisions is consistent with the system size dependence suggested by NA49.

The ongoing Ar+Sc energy scan is expected to give more insight into the existence and location of the CP.
