(Dated: December 7, 2018)

We study symmetry-protected topological (SPT) phases of matter in 2D protected by symmetries acting on fractal subsystems of a certain type. Despite the total symmetry group of such systems being subextensively large, we show that only a small number of phases are actually realizable by local Hamiltonians. Which phases are possible depends crucially on the spatial structure of the symmetries, and we show that in many cases no non-trivial SPT phases are possible at all. In cases where non-trivial SPT phases do exist, we give an exhaustive enumeration of them in terms of their locality.

I. INTRODUCTION

Understanding and classifying the possible phases of matter has been a long running goal of condensed matter physics. In systems without any symmetries, one can have topological ordered phases which are long range entangled. With symmetries present, there are many more possibilities: the symmetry may be spontaneously broken, it may enrich an existing topological order, or it may lead to non-trivial short range entangled phases called symmetry-protected topological (SPT) phases.\(^1\)

Recently, a new type of symmetry, called “subsystem symmetries”, has been gaining interest for a number of reasons. These are symmetries which act on only a rigid (subextensive) subsystem of the full system, for example, along only a row or a column of a square lattice. Systems with such symmetries show up in a variety of contexts.\(^2\) Note that there is a distinction between subsystem symmetries and higher-form symmetries\(^3\) which act on deformable manifolds. One reason for the recent interest is due to their connection to fracton topological order.\(^4\) Namely, systems in \(D = 3\) dimensions with subsystem symmetries of along \(d = 2\) planes exhibit a gauge duality to (type-I) fracton topological ordered phase.\(^5\)\(^6\) More generally, this can be extended to systems with dimensions \(D \geq 3\) and symmetries along regular \(1 < d < D\) subsystems, whose gauge dual exhibits a generalized fracton topological order. The case \(d = D\) is simply the duality of a model with some global symmetry and a (non-fracton) topologically ordered state, e.g. the gauge dual of the \(Z_2\) symmetric Ising model in \(D \geq 2\) is a \(Z_2\) topological order. The case where \(d = 1\) is another extreme case, whose gauge dual does not correspond to a topological order. These should be thought of in analogy to the \(D = d = 1\) Ising chain, which is dual to another Ising model under the gauge duality. In the presence of a symmetry group \(G\), it is now well known that bosonic \(D = d = 1\) chains may be classified according to the second cohomology group \(H^2(G, U(1))\), and may be understood in terms of how the symmetry acts as a projective representation on the edges or under symmetry twists.\(^7\)\(^8\)

Going to one higher dimension, \(D = 2, d = 1\), we have two dimensional systems with symmetries acting along rigid lines. It was recently appreciated that such symmetries could protect non-trivial SPT phases, called subsystem SPT phases.\(^9\) An example of such a phase is the 2D cluster state on the square lattice,\(^10\) where it is shown that any state within this subsystem SPT phase is useful as a resource for universal measurement based quantum computing (MBQC)\(^11\), providing a generalization of the connection between MBQC and SPT phases from one dimension.\(^12\)\(^13\)\(^14\) A classification of such subsystem SPT phases was realized recently in Ref\(^16\) by the present author and colleagues, and relied on the definition of a modified (weaker) equivalence relation between phases. The reason this was needed in this case is due to the existence of “subsystem phases”: cases where two states which differ along only a subsystem may belong to distinct phases of matter. For instance, consider a \(D = 2\) trivial symmetric state, but along some of the \(d = 1\) subsystems, we place a 1D SPT (in such a way that all symmetries are still respected). This, now, as a whole represents a non-trivial 2D phase of matter protected by the subsystem symmetries, despite looking trivial in most of the bulk. Furthermore, the existence of such phases means that in the thermodynamic limit where system size is taken to infinity, there are an infinite number of subsystems, and so an infinite number of possible phases. The problem with this is that it now takes a subextensive (growing as \(O(L)\) in local systems of size \(L \times L\)) amount of information to convey exactly what phase a system is in, without assuming any form of translation invariance. In Ref\(^16\) it was shown that there existed some intrinsic global “data”, which we call \(\beta\), which is insensitive to the presence of subsystem phases. All the infinite phases of such a system could therefore be grouped into equivalence classes and classified according to \(\beta\). This classification has the nice interpretation of being a classification of phases \textit{modulo} lower-dimensional SPT phases, and is related to the problem of classifying 3D (type-I) fracton topological orders modulo 2D topological orders.\(^17\)\(^18\)\(^19\)\(^20\)\(^21\)\(^22\)\(^23\) There is also a connection between this classification and the appearance of a spurious topological entanglement entropy.\(^24\)\(^25\)\(^26\) The key idea is that a new tool, in this case the modified phase equivalence relation, was necessary in the classification of these subsystem SPT phases.
The topic of interest in this paper is another type of subsystem symmetry: fractal subsystem symmetries. In 2D, these may be thought of as “in-between” system symmetry: fractal subsystem symmetries. In 2D, d-to models with regular square lattice example) has been shown to be useful for cluster state on the honeycomb lattice, which (like the non-trivial SPT phases have also recently been shown to be able to protect for their information storage capacity as a translation invariant toy model of glassiness. Here, we wish to ask the more general question of what SPT phases are even possible in such systems with fractal symmetries. Note that in higher dimensions (D ≥ 3), similar to models with regular d-dimensional subsystem symmetries, the gauge dual of a fractal symmetric model may also result in (type-II) fracton topological order. 

Our main finding is that systems with fractal subsystem symmetries are free from subsystem phases and the associated problems that existed for line-like d = 1 subsystem SPTs. The key factor at play here is locality. Although the total number of phases is still infinite (a result of the total symmetry group being infinitely large), the vast majority of these phases are highly non-local and therefore unphysical. If we fix a degree of locality (what we mean by this will be explained) then the number of allowed phases remains finite in the thermodynamic limit. This allows for the classification of phases directly, without needing to define equivalence classes of phases like before (essentially due to the lack of any “weak” subsystem SPT phases).

We first begin by reviewing some necessary preliminary topics in Sec II. We then define fractal symmetries in Sec III and discuss the possible local SPT phases in Sec IV. In Sec V we give a explicit constructions for local models realizing an arbitrary local SPT phase. Sec VI deals with irreversible fractal symmetries and introduces the concept of pseudo-symmetries and pseudo-SPTs. A summary and discussion of the results is presented in Sec VII. Finally, a technical proof of the main result is given in Sec VIII.

II. PRELIMINARIES

A. Linear Cellular Automata

We first describe a class of fractal structures which determine the spatial structure of all our symmetries in this work (see Ref 24 for a nice introduction to such fractals and their polynomial representation). These fractal structures, which are embedded on to a 2D lattice, are generated by the space-time evolution of a 1D cellular automaton (CA). In particular, the update rule for this 1D cellular automaton will be linear, translation invariant, local, and reversible. These terms will all be explained shortly.

Let \( a_i^{(j)} \in \mathbb{F}_p \) denote the state of the cell at spatial index i at time index j. Each \( a_i^{(j)} \) can take on values 0, . . . , p − 1 for some prime p (p = 2 in the cases with Ising degrees of freedom). We take periodic boundary conditions in i such that \( 0 ≤ i < L_x \), and define \( a_i^{(j+1)} = a_i^{(j)} \). The state of the full cellular automaton at a time \( j \) is given by the vector \( \mathbf{a}_j \in \mathbb{F}_p^{L_x} \) with elements \( (\mathbf{a}_j)_i = a_i^{(j)} \). We will use the notation \( v_p \) to denote the ith element of a vector \( \mathbf{v} \). Bold lowercase letters will denote vectors, while bold uppercase letters will denote matrices.

The key ingredient of the cellular automaton is its update rule: given the state \( \mathbf{a}_j \) at time \( j \), how is the state \( \mathbf{a}_j^{(j+1)} \) at the next time step calculated? We will consider only the family of update rules of the form

\[
\mathbf{a}_i^{(j+1)} = \sum_{k=|a_0-1|}^{k=a_0} c_k a_{i-k}^{(j)}
\]

where \( c_k \in \mathbb{F}_p \) is a set of coefficients only non-zero for \( k_a ≤ k ≤ k_b \). Note that all addition and multiplication is modulo \( p \), following the algebraic structure of \( \mathbb{F}_p \). Linearity refers to the fact that each \( a_i^{(j+1)} \) is determined by a linear sum of \( a_i^{(j)} \). Thus, we may represent Eq 1 as

\[
\mathbf{a}_i^{(j+1)} = \mathbf{F} \mathbf{a}_i^{(j)}
\]

where \( \mathbf{F} \in \mathbb{F}_p^{L_x \times L_x} \) is an \( L_x \times L_x \) matrix with elements given by \( F_{i,j} = c_{i-j} \). For a given initial state \( \mathbf{a}_0 \), the state at any time \( j ≥ 0 \) is simply given by \( \mathbf{a}_j = \mathbf{F}^j \mathbf{a}_0 \).

Translation invariance refer to the fact that the update rules do not depend on the location \( i \), only on the relative location: \( \mathbf{F}_i = \mathbf{F}_{i+n} \). Locality means that \( F_{i,j} \) is only non-zero for small \( |i - j| \) of order 1. In our case, this means that \( |k_a| \) and \( |k_b| \) should be small \( O(1) \) values. Finally, reversibility means that only one \( \mathbf{a}_j \) can give rise to a \( \mathbf{a}_{j+1} \). In other words, the kernel of the linear map induced by \( \mathbf{F} \) is empty, and one can define an inverse \( \mathbf{F}^{-1} \) (which will generically be highly non-local) such that \( \mathbf{F}^{-1} \mathbf{F} = \mathbf{F} \mathbf{F}^{-1} = \mathbf{I} \). This is a rather special property which will depend on the particular update rule as well as choice of \( L_x \).

While we assume reversibility for much of this paper, we note that fractal SPTs exist even when the underlying CA is irreversible. We call such phases pseudo-SPT phases, and are discussed in Sec VI.

B. Polynomials over finite fields

Cellular automata with these update rules may also be represented elegantly in terms of polynomials with coefficients in \( \mathbb{F}_p \). By this we mean polynomials \( q(x) \)
over a dummy variable $x$ of the form
\[ q(x) = \sum_{i=0}^{\delta_q} q_i x^i \]
\hspace{1cm} (3)
where each $q_i \in \mathbb{F}_p$, and the degree $\delta_q \equiv \deg q(x)$ is finite. The space of all such polynomials is denoted by the polynomial ring $\mathbb{F}_p[x]$. A state $a^{(j)}$ of the cellular automaton may be described by such a polynomial, $a^{(j)}(x)$,
\[ a^{(j)}(x) = \sum_{i=0}^{L_x-1} a^{(j)}_i x^i. \] \hspace{1cm} (4)
In the case of periodic boundary conditions one should also work with the identity $x^{L_x} = 1$.

Application of the update rule is expressed most simply in the language of polynomials. Let us define $f(x)$ to be a Laurent polynomial, i.e. $f(x) = \tilde{f}(x)x^{k_a}$ where $\tilde{f}(x) \in \mathbb{F}_p[x]$ is a polynomial (and $k_a$ may be negative), given by
\[ f(x) = \sum_{k=k_a}^{k_b} c_k x^k \] \hspace{1cm} (5)
after which the update rule may be expressed simply as multiplication
\[ a^{(j+1)}(x) = f(x) a^{(j)}(x) \] \hspace{1cm} (6)
Given an initial state $a^{(0)}(x)$ then, the state at any future time is simply given by $a^{(j)}(x) = f(x)^j a^{(0)}(x)$. We will assume $c_{k_a}$ and $c_{k_b}$ are non-zero, and $k_b \neq k_a$ (so that $f(x)$ is not a monomial).

The key property of such polynomials that guarantees fractal structures is that for $q(x) \in \mathbb{F}_p[x]$, one has that
\[ q(x)^{p^n} = q(x^{p^n}) \] \hspace{1cm} (7)
also known as the “freshman’s dream”. Suppose we start off with the initial state $a^{(0)}(x) = 1$. After some possibly large time $p^n$, the state has evolved to
\[ a^{(p^n)}(x) = f(x)^{p^n} = f(x^{p^n}) = \sum_{k=k_a}^{k_b} c_k x^{k p^n} \] \hspace{1cm} (8)
which is simply the initial state at positions separated by distances $p^n$. At time $p^{n+1}$, this repeats but at an even larger scale. Thus, the space-time trajectory, $a^{(j)}$, of this cellular automaton always gives rise to self-similar fractal structures.

There are various other useful properties that will be used in the proof of Sec VIII, one of which is that any polynomial $q(x) \in \mathbb{F}_p[x]$ (without periodic boundary conditions) may be uniquely factorized up to constant factors as
\[ q(x) = q_1(x)q_2(x) \ldots q_n(x) \] \hspace{1cm} (9)
where each $q_i(x)$ is an irreducible polynomial of positive degree. A polynomial is irreducible if it cannot be written as a product of two polynomials of positive degree. This may be thought of as a “prime factorization” for polynomials.

### C. Projective Representations

The final topic which should be introduced are projective representation of finite abelian groups. Bosonic SPTs in 1D are classified by the projective representations of their symmetry group on the edg.\cite{28} Similarly, subsystem SPTs for which the subsystems terminate locally on the edges (i.e. line-like subsystems) may also be described by projective representations of a subextensively large group on the edg.$^{38,46}$ The same is true for fractal subsystem symmetries.$^{53}$

Let $G$ by a finite abelian group. A non-projective (also called linear) representation of $G$ is a set of matrices $V(g)$ for $g \in G$ that realize the group structure: $V(g_1)V(g_2) = V(g_1g_2)$ for all $g_1, g_2 \in G$. A projective representation is one such that this is only satisfied up to a phase factor,
\[ V(g_1)V(g_2) = \omega(g_1, g_2)V(g_1g_2) \] \hspace{1cm} (10)
where $\omega(g_1, g_2) \in U(1)$ is called the factor system of the projective representation, and must satisfies the properties
\[ \omega(g_1, g_2)\omega(g_1g_2, g_3) = \omega(g_1, g_2g_3)\omega(g_2, g_3) \]
\[ \omega(1, g_1) = \omega(g_1, 1) = 1 \] \hspace{1cm} (11)
for all $g_1, g_2, g_3 \in G$. A difference choice of $U(1)$ prefactors, $V'(g) = \alpha(g)V(g)$ leads to the factor system
\[ \omega'(g_1, g_2) = \frac{\alpha(g_1g_2)}{\alpha(g_1)\alpha(g_2)}\omega(g_1, g_2). \] \hspace{1cm} (12)
for $V'(g)$. Two factor systems related in such a way are said to be equivalent, and belong to the same equivalence class $\omega$.

Suppose we have a factor system $\omega_1(g_1, g_2)$ of equivalence class $\omega_1$, and a factor system $\omega_2(g_1, g_2)$ of class $\omega_2$. A new factor system can be obtained as $\omega(g_1, g_2) = \omega_1(g_1, g_2)\omega_2(g_1, g_2)$, which is of class $\omega \equiv \omega_1\omega_2$. This gives them a group structure: equivalence classes are in one-to-one correspondence with elements of the second cohomology group $H^2[G, U(1)]$, and exhibit the group structure under multiplication.

In the case of finite abelian groups, a much simpler picture may be obtained in terms of the quantities
\[ \Omega(g_1, g_2) = \frac{\omega(g_1, g_2)}{\omega(g_2, g_1)} \] \hspace{1cm} (13)
which is explicitly invariant under the transformations of Eq\cite{12} They have a nice interpretation of being the commutative phases of the projective representation
\[ V(g_1)V(g_2) = \Omega(g_1, g_2)V(g_2)V(g_1). \] \hspace{1cm} (14)
the case of 2D fractal symmetries

twists
stance, by looking at edges or matrix product state
are various ways this connection can be made, for in-
sentations to the classification of 1D SPT phases. There
whole projective representation.

symmetry in the sense that

\begin{align}
\Omega(g_1, g_2) &= \Omega(g_1, g_3)\Omega(g_2, g_3) \\
\Omega(g_1, g_2 g_3) &= \Omega(g_1, g_2)\Omega(g_1, g_3) \\
\Omega(g_1, g_2) &= \Omega(g_2, g_1)^{-1}
\end{align}

These properties mean that \( \Omega(g_1, g_2) \) is completely determined by its value on all pairs of generators of \( G \). Suppose \( a_1, a_2 \in G \) are two independent generators with orders \( n_1, n_2 \), respectively. Then, one can show that \( \Omega(a_1, a_2)_{n_1} = \Omega(a_1, a_2)_{n_2} = 1 \), and so \( \Omega(a_1, a_2) = e^{2\pi i w / \gcd(a_1, a_2)} \) for integer \( w \). The value of \( w \) for every pair of generators provides a complete description of the projective representation, and each of them may be chosen independently.

By the fundamental theorem of finite abelian groups, \( G \) may be written as a direct product

\[ G = \mathbb{Z}_{n_1} \times \mathbb{Z}_{n_2} \times \cdots \times \mathbb{Z}_{n_N} \]

where each \( n_i \) are prime powers. Let \( a_i \) be the generator of the \( i \)th direct product of \( G \) with order \( n_i \), and define \( m_{ij} \) through \( \Omega(a_i, a_j) = e^{2\pi i m_{ij} / \gcd(n_i, n_j)} \). Each choice of \( 0 \leq m_{ij} < \gcd(n_i, n_j) \) for \( i < j \) corresponds to a distinct projective representation. Indeed, applying the Kunneth formula, one can compute the second cohomology group

\[ H^2[G, U(1)] = \prod_{i < j} \mathbb{Z}_{\gcd(n_i, n_j)} \]

There is therefore a one-to-one correspondence between choices of \( \{m_{ij}\} \) and elements of \( H^2[G, U(1)] \).

Hence, we may simply refer to the commutative phases \( \Omega(g_1, g_2) \) of the generators, \( \{m_{ij}\} \), as a proxy for the whole projective representation.

D. 1D SPTs and twist phases

Let us now connect our discussion of projective representations to the classification of 1D SPT phases. There are various ways this connection can be made, for instance, by looking at edges or matrix product state representations\[^{15}\]. Here, we will be using symmetry twists\[^{24,48}\], which turn out to be a natural probe in the case of 2D fractal symmetries\[^{35}\].

Suppose we have a 1D SPT described by the unique ground state of the local Hamiltonian \( H \) and global on-site symmetry group \( G \). Let us take the chain to be of length \( L_x \) (taken to be large) with periodic boundary conditions. The symmetry acts on the system as

\[ S(g) = \prod_{i=0}^{L_x-1} u_i(g) \]

for \( g \in G \), where \( u_i(g) \) is the on-site unitary linear representation of the symmetry element \( g \) on site \( i \), and \([H, S(g)] = 0\). A local Hamiltonian may always be written as

\[ H = \sum_{i=0}^{L_x-1} H_i \]

where the sum is over local terms \( H_i \) with support only within some \( O(1) \) distance of \( i \).

The twisting procedure begins by constructing a new Hamiltonian, \( H_{\text{twist}}(g) \), for a given \( g \in G \). We pick a cut across which to apply the twist, \( x_{\text{cut}} \), which can be arbitrary. Then, define the truncated symmetry operator

\[ S_{\geq}(g) = \prod_{i=x_{\text{cut}}}^{x_{\text{cut}}+R} u_i(g) \]

for some \( 1 < R < L_x \). The twisted Hamiltonian is given by

\[ H_{\text{twist}}(g) = \sum_{i=0}^{L_x-1} \begin{cases} S_{\geq}(g)H_iS_{\geq}(g)^\dagger & \text{if } H_i \text{ crosses } x_{\text{cut}} \\ H_i & \text{else} \end{cases} \]

thus, the Hamiltonian is modified for \( H_i \) near \( x_{\text{cut}} \), but remains the same elsewhere.

We can now define the twist phase

\[ T(g_1, g_2) = \frac{\langle S(g_1) \rangle_{H_{\text{twist}}(g_2)}}{\langle S(g_1) \rangle_H} \]

which is a pure phase representing the charge of the symmetry \( g_1 \) in the ground state of the \( g_2 \) twisted Hamiltonian, relative to in the untwisted Hamiltonian. Here, \( \langle O \rangle_H \) means that expectation value of the operator \( O \) in the ground state of the Hamiltonian \( H \). It is straightforward to show that \( T(g_1, g_2) \) does not depend on where we place the cut, \( x_{\text{cut}} \) (this fact will be used to our advantage when twisting fractal symmetries). The set of twist phases \( T(g_1, g_2) \) is a complete characterization of the state. Indeed, the correspondence of the twist phases to the projective representation characterizing a phase can be made by simply

\[ \Omega(g_1, g_2) = T(g_1, g_2). \]

as such, we refer to \( \Omega(g_1, g_2) \) itself as the twist phases.

An alternate, but equivalent, view is to examine the action of \( S_{\geq}(g_2) \) on the ground state \( |\psi\rangle \). The action of \( S_{\geq}(g_2) |\psi\rangle \) must act as identity on the majority of the system, except near \( x_{\text{cut}} \) and \( x_{\text{cut}} + R \), where it may act as some unitary operation,

\[ S_{\geq}(g_2) |\psi\rangle = U_{g_2} \tilde{U}_{g_2} |\psi\rangle. \]

where \( U_{g_2} \) acts near \( x_{\text{cut}} \), and \( \tilde{U}_{g_2} \) acts near \( x_{\text{cut}} + M \). Then, the twisted Hamiltonian acting on the ground state can be thought of as

\[ H_{\text{twist}}(g_2) |\psi\rangle = U_{g_2} H U_{g_2}^\dagger |\psi\rangle \]
such that the ground state of $H_{\text{twist}}(g_2)$ is given by $U_{g_2} |\psi\rangle$. The twist phase is then given by

$$
\Omega(g_1, g_2) = \frac{\langle \psi | U_{g_2}^\dagger S(g_1) U_{g_2} | \psi \rangle}{\langle \psi | S(g_1) | \psi \rangle}
$$

which measures the charge of the excitation created by $U_{g_2}$ under the symmetry $S(g_1)$. Thus, all information regarding the phase is contained within this local unitary matrix $U_{g_2}$ that appears due to a truncated symmetry operator.

### III. Fractal Symmetries

We can now discuss fractal symmetries. The fractal symmetries we consider may be thought of as a combination of an on-site symmetry group imbedd with some spatial structure.

Let us first consider a system with one fractal symmetry, described by the cellular automaton polynomial $f(x)$ over $U_p$, which we will denote by

$$
G = \mathbb{Z}_p^{(f,y)}
$$

which means that the on-site symmetry group is $\mathbb{Z}_p$, while the superscript, $(f,y)$, denotes the associated spatial structure: $f$ denotes a cellular automaton described by the polynomial $f(x)$, and $y$ denotes the positive “time” direction of this cellular automaton (in this case, the positive $y$ direction).

Our systems have degrees of freedom placed on the sites of an $L_x \times L_y$ square lattice with periodic boundary conditions. Each site is labeled by its index along the $x$ and $y$ direction, $(i,j)$, and transforms as an on-site linear representation $u_{ij}(g)$ under $G$. For simplicity, we will only consider the cases where $L_x = p^N$ is a power of $p$, and $L_y$ chosen such that $f(x)^{L_y} = 1$. The latter is not difficult to accomplish, as $f(x)^{L_x} = f(x^{L_x}) = f(1)$, so we may simply choose $L_y = kL_x > 0$ such that $f(1)^k = 1$. Note that reversibility of $f(x)$ implies $f(1) \neq 0$.

The symmetries of the system are in one-to-one correspondence with valid space-time histories of the cellular automaton. The choices of $L_x$ and $L_y$ made earlier means that any state $a^{(0)}(0)$ (on a ring of circumference $L_x$) is cyclic in time with period dividing $L_y$: $a^{(L_y)} = a^{(0)}$.

Given a valid trajectory $a^{(j)}$, the operator $\prod_{ij} u_{ij}(g^{a^{(j)}})$ for $g \in G$ represents a valid symmetry operator. The entire space-time trajectory $a^{(j)}$ is determined solely by its state at a particular time $j_0$, $a^{(j_0)}$, which can be in any of $p^{L_x}$ states. The total symmetry group will therefore be given by $G_{\text{tot}} = (\mathbb{Z}_p)^{L_x}$.

Let us identify a particular element $g$ as a generator for $\mathbb{Z}_p$. Then, let a set of $L_x$ generators for $G_{\text{tot}} = \mathbb{Z}_p^{L_x}$, defined with respect to $j_0$, be $\{g_i^{(j_0)}\}_{0 \leq i < L_x}$. We may then define a vectorial representation of group elements via the one-to-one mapping from vectors $v \in \mathbb{F}_p^{L_x}$ to group elements,

$$
g^{(j_0)}[v] = \prod_{i=0}^{L_x-1} (g_i^{(j_0)})^{v_i} \in G_{\text{tot}}
$$

The action of each of these symmetry elements on the system is defined as

$$
S(g^{(j_0)}[v]) = \prod_{j=0}^{L_x-1} u_{ij}[g; \bar{F}^{j-j_0}v]
$$

where we have introduced the vectorial representation for $u_{ij}(g)$ on a row $j$,

$$
u_{ij}[g; v] \equiv \prod_{i=0}^{L_x-1} u_{ij}(g^{v_i})
$$

Thus, $S(g^{(j_0)}[v])$ is the unique symmetry operator that acts as $u_{ij}(g)[v]$ on the row $j_0$. It can be viewed as the symmetry operation corresponding to the space-time trajectory of a CA which is in the state $v$ at time $j_0$. Because $f(x)^{L_y} = 1$ due to our choice of $L_x$ and $L_y$, any initial state is guaranteed to come back to itself after time $L_y$, representing a valid cyclic space-time trajectory.

We may choose as a generating set the operators defined with respect to row $j_0$,

$$
S(g^{(j_0)}[e_i]) = S(g^{(j_0)}_{i_{j_0}})
$$

where $e_i$ is the unit vector $(e_i)_{j'} = \delta_{ij'}$. These act on only a single site on the row $j_0$, and an example of which is
shown in Figure 1 (top). However, notice that this choice of basis is only “most natural” when viewed on the row \( j_0 \). Suppose we wanted to change the row which we have defined our generators with respect to from \( j_0 \) to \( j_1 \). How are the new operators related to our old ones? Well, one can readily show that

\[
S(g^{(j_1)}[v]) = \prod_j u_j [g; F^{j-j_1} v] = \prod_j u_j [g; F^{j-j_0} F^{j_0-j_1} v] = S(g^{(j_0)}[F^{j_0-j_1} v])
\]

is simply related via multiplication of \( v \) by powers of \( F \). Thus,

\[
g^{(j_1)}[v] = g^{(j_0)}[F^{j_0-j_1} v]
\]

In general, we can have systems with multiple sets of fractal symmetries. The other main situation we consider is the case of two fractal symmetries of the form

\[
G = \mathbb{Z}_p^{(f,y)} \times \mathbb{Z}_p^{(\bar{f},\bar{y})}
\]

where \( \bar{x} \equiv x^{-1} \) and \( \bar{f}(x) \equiv f(\bar{x}) \). This is the form of fractal symmetry known to protect non-trivial fractal SPTs. The first fractal represents a CA evolving in the positive \( y \) direction with the rule \( f(x) \), and the second represents a CA evolving in the opposite \( y \) direction with the rule \( \bar{f}(x) \) (they are spatial inversions of one another). In this case, we have one generator from each \( \mathbb{Z}_p \), \( g^{(a)} \) and \( g^{(b)} \), and we can define two sets of fractal symmetry generators as above with respect to a row \( j_0 \). Let us call the two sets of generators \( \{g^{(a,j_0)}\}_i \) and \( \{g^{(b,j_0)}\}_i \), and define their corresponding vectorial representation. A general \( a \) or \( b \) type symmetry acts as

\[
S(g^{(a,j_0)}[v]) = \prod_{j=0}^{L_x-1} u_j [g^{(a)}; F^{j-j_0} v]
\]

\[
S(g^{(b,j_0)}[v]) = \prod_{j=0}^{L_x-1} u_j [g^{(b)}; (F^T)^{j-j_0} v]
\]

IV. LOCAL PHASES

Consider performing the symmetry twisting experiment on a system with fractal symmetries. We can view the system as a cylinder with circumference \( L_x \) and consider twisting the symmetry as discussed in Sec IID. We separately discuss the cases of one or two fractal symmetries of a specific form first, and then go on to more general combinations.

A. One fractal symmetry

Let us take \( G = \mathbb{Z}_p^{(f,y)} \) and consider twisting by a particular element \( g^{(j_0)} \in G_{\text{tot}} \). Since the twist phase doesn’t depend on the position of the cut, we can choose to make the cut on the row \( j_{\text{cut}} = j_0 \). The twisted Hamiltonian \( H_{\text{twist}}(g^{(j_0)}) \) is then obtained by conjugating terms in the Hamiltonian which cross \( j_{\text{cut}} \) by the truncated symmetry operator \( S_T(g^{(j_0)}) \).

Let the Hamiltonian be written as a sum

\[
H = \sum_{i,j} H_{ij}
\]

where each \( H_{ij} \) is a local term with support near site \((i,j)\). Now, consider twisting the Hamiltonian by \( g^{(j_0)} \) across the cut which also goes along the row \( j_0 \). As can be seen in Figure 2 (left), \( S_T(g^{(j_0)}) \) acts differently from an actual symmetry operator at the point \((i,j_0)\) (and on some row \( j_0 + R \) far away). Thus, the twisted Hamiltonian may be written as

\[
H_{\text{twist}}(g^{(j_0)}) \psi = U_{g^{(j_0)}} H U_{g^{(j_0)}}^\dagger \psi
\]

when acting on the ground state \( \psi \), for some unitary \( U_{g^{(j_0)}} \) with support near the site \((i,j_0)\). Note that there is always some freedom in choosing this unitary.

Then, consider measuring the charge of a symmetry \( g^{(j_0-l_y)} \) in response to this twist, as in Eq 28. Clearly, only those symmetry operators whose support overlaps with the support of \( U_{g^{(j_0)}} \) may have picked up a charge. Suppose the support of every \( U_{g^{(j_0)}} \) is bounded within some \((2l_x + 1) \times (2l_y + 1) \) box centered about \((i,j_0)\), such that only sites \((i', j')\) with \(|i' - i| \leq l_x \) and \(|j' - j_0| \leq l_y \) lie in the support. As can be seen in Figure 2 (left), \( S_T(g^{(j_0-l_y)}) \) only overlaps with this box for \( i' \) in the range

\[
-l_x - 2l_y k_a \leq i' - i \leq l_x - 2l_y k_a
\]

and therefore, \( \Omega(g^{(j_0-l_y)}, g^{(j_0)}) \) may only be non-trivial if \( i' - i \) is within some small range. This places a constraint on the allowed twist phases. In addition, this must be true for all choices of \( j_0 \). It turns out this is a very strong constraint, and eliminates all but the trivial phase in the case of \( G = \mathbb{Z}_p^{(f,y)} \), and only allows a finite number of specific solutions for the case \( G = \mathbb{Z}_p^{(f,y)} \times \mathbb{Z}_p^{(\bar{f},\bar{y})} \), as we will show.
We also do not strictly require that the support of
U_{j_0(k_0)} be bounded in a box. This will generally not be the case, as the operator may have an exponentially decaying tail. Consider a unitary U which has some nontrivial charge e^{i\phi} \neq 1 under S, meaning

$$SU^\dagger S = e^{i\phi} U$$

(44)

when acting on the ground state. Clearly, if the support of U and S are disjoint, this cannot be true. Next, consider any decomposition of U into a sum of matrices U_k, U = \sum_k U_k, and suppose that some of the U_k had disjoint support with S. Then, we may write

$$U = \sum_{k \in D} U_k + \sum_{k \in \bar{D}} U_k$$

(45)

where k \in D are all the k for which U_k and S have disjoint support, and k \in \bar{D} are all the k for which they do not. But then

$$SU^\dagger S = \sum_{k \in D} SU^\dagger S_k + \sum_{k \in \bar{D}} U_k$$

\neq e^{i\phi} U

(46)

as the disjoint component has not picked up a phase e^{i\phi}, and SU^\dagger S_k for k \in D cannot have disjoint support with S (since only identity maps to identity under unitary transformations) and so can’t affect the disjoint component of U. Thus, let us define a subset of sites, \mathcal{A}(U), defined as

$$\mathcal{A}(U) = \bigcap_{U = \sum_k U_k} \bigcap_{k \in D} \text{Supp}(U_k)$$

(48)

where the first intersection is over all possible decompositions U = \sum_k U_k, and \text{Supp}(U_k) is the support of U_k (the subset of sites for which it acts as non-identity). U can only have nontrivial charge under S if \mathcal{A}(U) overlaps with the support of S. In our case, l_x and l_y should actually be chosen such that \mathcal{A}(U_{j_0(k_0)}) may always be contained within the (2l_x + 1, 2l_y + 1) box. An exponentially decaying tail of U is therefore completely irrelevant, as \mathcal{A}(U) only cares about the smallest part, before the decay begins. The exact value of l_x or l_y is not too important — what is important is that it is finite and small.

We also note that the twist phases obtained when twisting along a cut in the y direction will be different, but are not independent of our twist phases for a cut along the x direction. The reason for this is that they are both fully determined by the charges of excitations created by truncated symmetry operators under all other fractal symmetries. Thus, it is sufficient to examine only the set of twist phases for a cut parallel to x, as we have been discussing. As we chose y to be the “time” direction of our CA, twisting along the x direction is far more natural.

Let us make some definitions which will simplify this discussion. Notice that \Omega(g^{j_0}[v], g^{k_0}[w]) may be described by the bilinear form \mathbb{F}_p^{L_x} \times \mathbb{F}_p^{L_y} \rightarrow \mathbb{F}_p represented by the skew-symmetric matrix W^{(j_0,k_0)} \in \mathbb{F}_p^{L_x \times L_x} defined according to

$$\Omega(g^{j_0}[v], g^{k_0}[w]) = e^{2\pi i v^T W^{(j_0,k_0)} w}$$

(49)

and that W^{(j_0,k_0)} for any (j_0, k_0) contains full information of the twist phases. Furthermore, since g^{j_0}[v] = g^{j_0}[F^{j_0} v, v], we can deduce that W transforms under this change of basis as

$$W^{(j_0,k_0)} = (F^{j_0} f)^T W^{(j_0,k_0)} (F^{j_0} f)$$

(50)

We say that a matrix W^{(j_0,l_y,j_0)} for a particular choice of j_0, is local if its only non-zero elements W^{(j_0,l_y,j_0)} \neq 0 are within a small diagonal band given by Eq 43. A stronger statement, which will call consistent locality, is that this is true for all j_0. The matrix W^{(j_0,l_y,j_0)} for a physical state must be consistently local.

Let us adopt a polynomial notation which will be useful to perform computations. We may represent the matrix W^{(j_0,k_0)} by a polynomial W^{(j_0,k_0)}(u,v) over \mathbb{F}_p as

$$W^{(j_0,k_0)}(u,v) = \sum_{i \in D} W^{(j_0,k_0)} u^i v^{i'}$$

(51)

with periodic boundary conditions u^{L_x} = u, v^{L_y} = 1. Locality is simply the statement that the powers of v in this polynomial must be bounded by Eq 43 (modulo L_x). Now, consider what happens to this polynomial as we transform our basis choice from j_0 \rightarrow j_0 - n,

$$W^{(j_0 - n - l_y,j_0 - n)}(u,v) = f(v)^n f(u \bar{v})^n W^{(j_0 - l_y,j_0)}(u,v)$$

(52)

which must be local for all n if W^{(j_0 - l_y,j_0)}(u,v) is to be consistently local.

Let us start with j_0 = 0, and suppose that we have some W^{(-l_y,0)}(u,v) that is non-zero and local. By locality, W^{(-l_y,0)}(u,v) may always be brought to a form where the powers of v are all within the range given by Eq 43. Let a^0 and b^0 be the smallest and largest powers of v in W^{(l_y,0)}(u,v) once brought to this form, which must satisfy

$$- l_x - 2l_y k_a \leq a \leq b \leq l_x - 2l_y k_a$$

(53)

Now, consider W^{(-l_y-n,-n)}(u,v) for small n,

$$W^{(-l_y-n,-n)}(u,v) = f(v)^n f(u \bar{v})^n W^{(l_y,0)}(u,v)$$

(54)

which (by adding degrees) will have a^{n-n \delta_f} and b^{n+\delta_f} as the smallest and largest powers of v, where \delta_f = \deg(z^{-k_a f(x)}) > 0. The smallest and largest powers will therefore keep getting smaller and larger, respectively, as we increase n. Thus, there will always be some finite n beyond which locality is violated, and so W^{(-l_y,0)}(u,v) can never be consistently local. The only consistently local solution is therefore given by W^{(-l_y,0)}(u,v) = 0, which corresponds to the trivial phase. We have therefore shown that no non-trivial local SPT phase can exist protected by only G = \mathbb{Z}_p^{(f,v)} symmetry.
around box of size \((2l + 1)\times (2l + 1)\) about \((i, j_0)\). This implies that the twist phase must be trivial for \(i'\) outside of a small region around \(i\), a property which we call locality. However, this must be true for all choices of \(j_0\), which greatly constrains the allowed twist phases. In the case of twist phases between the same type of symmetry (left), only the trivial set of twist phases, all \(\Omega(g_{i,0}^{(a,j_0)}, g_{i}^{(a,j_0)}) = 1\) is allowed. Between an \(a\) and a \(b\) type symmetry (right), we show that only a finite number of solutions exist.

B. Two fractal symmetries

Let us now consider the more interesting case, \(G = \mathbb{Z}_p^f \times \mathbb{Z}_p^y\), for which we know non-trivial SPT phases can exist. In this case, we have the symmetry generators \(g_i^{(a,j_0)}\) for \(a \in \{a, b\}\), and \(0 \leq i < L_x\). As we showed in the previous section, the twist phase between two \(a\) or two \(b\) symmetries must be trivial. The new ingredient comes in the form of non-trivial twist phases between \(a\) and \(b\) symmetries.

As can be seen in Fig 2 by the same arguments as before, the twist phase

\[
\Omega(g_i^{(b,j_0)}, g_i^{(a,j_0)})
\]

may only be non-trivial if \(i' - i\) lies within some finite range,

\[
-l_x + 2l_y k_a \leq i' - i \leq l_x + 2l_y k_b.
\]

Let us again define the matrix \(W^{(k_0, j_0)}\), but this time only between the \(a\) and \(b\) symmetries via

\[
T(g_i^{(b,k_0)}|W_i|g_i^{(a,j_0)}|v\rangle) = e^{2\pi i \alpha_{ij}w^{T}w^{(k_0,j_0)}v}
\]

note that \(W^{(k_0, j_0)}\) need not be skew-symmetric like before. From Eq \ref{eq:40} the changing of basis is given by

\[
W^{(k_1, j_1)} = F^{k_1-k_0} W^{(j_0, j_1)} F^{j_0-j_1}
\]

We are looking for matrices \(W_i^{(j_0+l_y-j_0)}\) which are local (only non-zero within the diagonal band Eq \ref{eq:56}), and also consistently local, meaning that this is true for all \(j_0\). Starting with \(j_0 = 0\), then, we are searching for a local matrix \(W^{(l_y,0)}\), for which

\[
W^{(l_y,n)} = F^n W^{(l_y,0)} W^{(l_y,0)} F^{-n}
\]

is also itself local for all \(n\).

Let us again go to a polynomial representation

\[
W^{(l_y,0)}(u,v) = \sum_{\ell} W_{\ell}^{(l_y,0)} u^{\ell} v^{\ell-i}
\]

which leads to the relation

\[
W^{(l_y+n-n)}(u,v) = f(v)^{-n} f(uv) W^{(l_y,0)}(u,v)
\]

which must have only small (in magnitude) powers of \(v\) for all \(n\). However, \(f(v)^{-1} \equiv f(v)L_y^{-1}\) contains arbitrarily high powers of \(v\), and therefore simply adding degrees as before does not work and we may expect that a generic \(W^{(l_y,0)}(u,v)\) will become highly non-local immediately. Instead, what must be happening is that, at each step, \(f(uv)W^{(j_0+l_y-j_0)}(u,v)\) must contain some factor of \(f(v)\) (when viewed as a polynomial without periodic boundary conditions) such that the \(f(v)^{-1}\) can divide out this factor cleanly, producing a local \(W^{(j_0+l_y-j_0+1)}(u,v)\).

How does this work in the case of the known fractal SPT? In that case, \(W^{(0,0)}\) is already local and is
given by the identity matrix. Then, clearly $W^{(n,n)} = W^{(0,0)}$ as it is invariant under Eq 59 and remains local for all $n$. In the polynomial language, the identity matrix corresponds to the polynomial $W^{(0,0)}(u,v) = \sum_i u^i$, which has the property of translation invariance: $W^{(0,0)}(u,v) = u W^{(0,0)}(u,v)$. In this case, $f(u,v) W^{(0,0)}(u,v) = f(v) W^{(0,0)}(u,v)$, and so can be safely multiplied by $f(v)^{-1}$. In fact, any translation invariant solution, $W^{(0,0)}(u,v) = g(v) \sum_i u^i$ for any $g(v)$, is invariant under multiplying by $f(v)^{-1} f(u,v)$.

We now state the main result of this paper: a special choice of basis functions $v^k K_m(u,v)$ with the property that $W(u,v)$ is consistently local if and only if in the unique decomposition

$$W(u,v) = \sum_{k=0}^{L_x-1} \sum_{m=0}^{L_x-1} C_{k,m} v^k K_m(u,v)$$

where $C_{k,m} \in \mathbb{F}_p$ are constants, each $C_{k,m} v^k K_m(u,v)$ is itself individually local. $K_m(u,v)$ is given by

$$K_m(u,v) = (u+1)^{L_x-1-m} V_m(v)$$

$$V_m(v) = \prod_{i=0}^{N_f-1} f_i(v)^{p^{i+1}}$$

where $f_i(x)$ are the $N_f$ unique irreducible factors of the polynomial $f(x) \equiv x^{-k_a} f(x)$ appearing $r_i$ times, $f(x) = \prod_i f_i(x)^{p^{i+1}}$, and $p^{i+1}$ is the power of $p$ in the prime decomposition of $r_i$. The proof of this is rather technical and is delegated to Section VIII. Thus, any phase can simply be constructed by finding all $v^k K_m(u,v)$ that are local, and choosing their coefficients $C_{k,m}$ freely.

Let us go back to the matrix representation, and define the corresponding matrices $K^{(k,m)} \leftrightarrow v^k K_m(u,v)$, following the same mapping as Eq 60. The elements of the matrix $K^{(k,m)}_{i',i}$ are non-zero if and only if $k \leq i'-i \leq k + D_m$, where $D_m$ is the degree of $V_m(v)$. $D_m$ increases monotonically with $m$, and is bounded by $D_m \leq m \delta f$. This bound is saturated when $v^{-k_t} f(x)$ is a product of irreducible polynomials, each of which appear only once. Our main result (Theorem VIII.1) states that any consistently local $W^{(l_x,0)}$ can be written as a linear sum of local $K^{(l_x,0)}$. Thus, it is straightforward to enumerate all possible $W^{(l_x,0)}$, which is simply all matrices in the subspace of $\mathbb{F}_p^{L_x \times L_x}$ spanned by the set of local $K^{(k,m)}$ (note that the full set of $\{K^{(k,m)}\}_{k,m}$ for all $0 \leq k, m < L_x$ forms a complete basis for this space). Figure 3 shows $K^{(0,m)}$ for $m = 0,1,2,3$ for a specific example, and how they evolve from one row to the next while maintaining locality.

A property of the matrices $K^{(k,m)}$ that they are periodic with period $p^{N_m}$, meaning $K^{(k+m',m)}_{i',i} = K^{(k',m)}_{i',i}$, where $N_m \equiv \lfloor \log_p (m + 1) \rfloor$. They also have cycles of period $p^{N_m}$, meaning $K^{(k+m',m)}_{i',i} = F^{p^{N_m}} K^{(k,m)}_{i',i} F^{-p^{N_m}}$. Since $D_m$ increases monotonically with $m$, only $m$ up to some maximum value, $M$, are local and may be included in $W^{(l_x,0)}$. We therefore see that $W^{(l_x,0)}$ must be periodic with period $p^{N_m}$. Thus, locality enforces that the projective representation characterizing the phase, $W^{(l_x,0)}$, be $p^{N_m}$-translation invariant! This is a novel phenomenon that does not appear in, say, subsystem SPTs with line-like symmetries where the projective representation does not have to be periodic (and as a result there are an infinite number of distinct phases in the thermodynamic limit, even with a local model).

How many possible phases may exist for a given $(l_x, l_y)$? This is given by the number of $K^{(k,m)}$ that can fit within a diagonal band of width $\ell \equiv 1 + 2x + 4y \delta f$. For each $m$, $K^{(k,m)}$ is local if $0 \leq k < \ell - D_m$. Thus, there are $C_m \equiv \max(\ell - m D_m, 0)$ possible $k$ values for each $m$. The total number of local $K^{(k,m)}$ is then $\sum_m C_m$.

Consider the case where $f(x) = x^{k_a} f_1(x) f_2(x) \ldots$, where each unique irreducible factor $f_i(x)$ only appears once. Then, $D_m = m \delta f$. The total number of local $K^{(k,m)}$ is then

$$N_{loc} = \sum_{m=0}^{\infty} \max(\ell - m \delta f, 0)$$

$$= \frac{\delta f}{2} |C| (2C - |C| + 1)$$

where we have just summed $m$ to infinity since $\ell \ll L_x / \delta f$, and $C \equiv \ell / \delta f$. Notice that $N_{loc}$ only depends only on the combination $\ell$, and not specifically what $l_x$ and $l_y$ are. The $W^{(l_x,0)}$ describing each phase is therefore a linear sum of these $N_{loc}$ matrices $K^{(k,m)}$ and so the total number of possible phases is $p^{N_{loc}}$. These phases are in one-to-one correspondence with elements of the group $\mathbb{F}_p^{N_{loc}}$, and exhibit the group structure under stacking.

Note that this number is an upper bound on the number of possible phases with a given $(l_x, l_y)$.

Consider the example in Figure 3 which has $f(x) = x^{-1} + 1 + x$ and $p = 2$. Suppose we were interested in phases that have locality $(l_x, l_y) = (1,0)$, then the matrix $W^{(l_x,0)}$ may only be non-zero if $-1 \leq i' - i \leq 1$. The only local $K^{(k,m)}$ matrices are then $K^{(-1,0)}$, $K^{(0,0)}$, $K^{(1,0)}$, and $K^{(-1,1)}$. Then, our result (Theorem VIII.1) states that all consistently local $W^{(l_x,0)}$ matrices are a linear sum (with binary coefficients) of these four $K^{(k,m)}$ matrices. There are therefore only $2^4$ possible phases, and they all have twist phases that are periodic with a period of 2 sites (or 1 if the coefficient of $K^{(-1,1)}$ is zero).

C. More fractal symmetries

Beyond these two cases, we may imagine more general combinations of fractal symmetries of the form

$$G = \prod_{i=0}^{N-1} \mathbb{Z}(f_i, y^p)$$

where we have $N$ different fractals $f_i(x)$, which each have positive time direction $y^p$ given by $\eta_i = \pm 1$. We again
FIG. 3. Visualization of the matrices $K^{(k,m)}$ for the example of $f(x) = \bar{x} + 1 + x$ and $p = 2$, for $k = 0$ and $m = 0, 1, 2, 3$ (other $k$ can be obtained by shifting every element $k$ steps to the left). Each blue cell $(i', i)$, counting from the top left, represents a non-zero matrix element $K^{(0,m)}_{i',i} = 1$. The arrows indicate evolution by $K \rightarrow F K F^{-1}$, under which they exhibit cycles of period $2^\lceil \log_2 (m+1) \rceil$, as can be seen. Each of them are only non-zero about a small diagonal band (non-gray squares) of width given by $D_m = 1 + 2^m$. A $K^{(k,m)}$ is local if this white band fits inside some diagonal band (Eq 56). If a $K^{(k,m)}$ is local, then it can be seen that under evolution it retains locality (the white band never gets larger), a property which we call consistent locality. The main result of this paper is that any consistently local matrix can be written as a linear sum of local $K^{(k,m)}$.

Since there are only a finite number of local $K^{(k,m)}$, there are only a finite number of consistently local matrices that can be written, and therefore a finite number of distinct phases in the thermodynamic limit. The number will depend on the choice of $(l_x, l_y)$, i.e. how local the model is. Notice that consistent locality is non-generic: if we just pick a local matrix by filling in elements along the diagonal band at random, it will generically quickly become highly non-local after a few steps of evolution.

By an argument similar to that given in Sec [IV A] we may show that any twist phase between the two generators of $\mathbb{Z}_p^{(f_i, y^{\eta_i})}$ and $\mathbb{Z}_q^{(f_j, y^{\eta_j})}$ for which $\eta_i = \eta_j$ must be trivial. What about when $\eta_i \neq \eta_j$? In that case, we can show that there may only exist non-trivial twist phases between them if $f_i(x) = f_j(\bar{x})$.

Suppose we have some matrix $W^{(l_y,0)}$ describing twist phases between symmetry generators of $\mathbb{Z}_p^{(f_i, y^{\eta_i})}$ and $\mathbb{Z}_q^{(f_j, y^{\eta_j})}$. Going to a polynomial representation $W^{(l_y,0)}(u, v)$ (as in Eq 60), the change of basis to a different row is

$$W^{(l_y+n,m)}(u, v) = f_i(uv)^n f_j(v)^{-n} W^{(l_y,0)}(u, v)$$

which must be local for all $n$. Suppose that $W^{(l_y,0)}(u, v)$ is $p^k$-periodic, such that $u^{p^k} W^{(l_y,0)}(u, v) = W^{(l_y,0)}(u, v)$. Assume none of $f_i(x)$ are monomials. In this language, the previous case of two fractal symmetries is given by $N = 2$ with $f_0(x) = f_1(\bar{x}) = f(x)$, and $\eta_0 = -\eta_1 = 1$. Note that we could have allowed $p$ to vary among the fractals — the reason we do not consider this case is that the twist phases between generators of $\mathbb{Z}_p$ and $\mathbb{Z}_q$ are gcd($p, q$)th roots of unity, but since $p$ and $q$ are both prime, this phase must be trivial.

By an argument similar to that given in Sec [IV A] we may show that any twist phase between the two generators of $\mathbb{Z}_p^{(f_i, y^{\eta_i})}$ and $\mathbb{Z}_q^{(f_j, y^{\eta_j})}$ for which $\eta_i = \eta_j$ must be trivial. What about when $\eta_i \neq \eta_j$? In that case, we can show that there may only exist non-trivial twist phases between them if $f_i(x) = f_j(\bar{x})$.

Suppose we have some matrix $W^{(l_y,0)}$ describing twist phases between symmetry generators of $\mathbb{Z}_p^{(f_i, y^{\eta_i})}$ and $\mathbb{Z}_q^{(f_j, y^{\eta_j})}$. Going to a polynomial representation $W^{(l_y,0)}(u, v)$ (as in Eq 60), the change of basis to a different row is

$$W^{(l_y+n,m)}(u, v) = f_i(uv)^n f_j(v)^{-n} W^{(l_y,0)}(u, v)$$

which must be local for all $n$. Suppose that $W^{(l_y,0)}(u, v)$ is $p^k$-periodic, such that $u^{p^k} W^{(l_y,0)}(u, v) = W^{(l_y,0)}(u, v)$.
Then,

\[ W^{(l_v+n p^k, n p^k)}(u, v) = (f_i(v)^{p^k} f_j(v)^{-p^k})^n W^{(l_v, 0)}(u, v) \]

should also be local for all \( n \) (recall that locality in the polynomial language is a statement about the powers of \( v \) present). This implies that \( f_i(v)^{p^k} f_j(v)^{-p^k} = 1 \), or \( f_i(v)^{p^k} = f_j(v)^{p^k} \). If \( p^k \ll L_{xj} \), then this means that we must have \( f_i(x) = f_j(x) \). In the case where \( p^k \not\ll L_{xj} \), we may simply consider larger system sizes \( L_{xj}, L_y \rightarrow p^n L_{xj}, p^n L_y \), but with the same periodicity \( p^k \), and come to the same conclusion. Hence, there can only exist non-trivial twist phases between symmetries with \( f_i(x) = f_j(x) \) and \( \eta_i = -\eta_j \).

For the more general group \( G \) in Eq. (68) to find all the possible phases with a fixed locality \((l_x, l_y)\), we should simply find all pairs \((i, j)\) where \( \eta_i = -\eta_j \) and \( f_i(x) = f_j(x) \), and construct a local \( W^{(l_v, 0)} \) matrix for each such \((i, j)\) pair. Thus, the case with two fractal symmetries \( G = \mathcal{Z}_p^{(f, p)} \times \mathcal{Z}_p^{(f, p)} \) already contains all the essential physics.

V. CONSTRUCTING COMMUTING MODELS FOR ARBITRARY PHASES

In this section, we show that it is indeed possible to realize all the phases derived in the previous section for systems with two fractal symmetries, \( G = \mathcal{Z}_p^{(f, p)} \times \mathcal{Z}_p^{(f, p)} \), in local Hamiltonians. We show how to construct a Hamiltonian, composed of mutually commuting local terms, for an arbitrary phase parameterized by the matrix \( W^{(l_v, 0)} \). These Hamiltonians are certainly not the most local models that realize each phase, but they are quite conceptually simple and the construction works for any given \( W^{(l_v, 0)} \).

Let us define \( \mathcal{Z}_p \) generalizations of the Pauli matrices \( X \) and \( Z \) satisfying the following algebra,

\[
X^N = Z^N = 1 \quad (70)
\]

\[
XZ = e^{\frac{2\pi i}{p}} ZX \quad (71)
\]

and may be represented by a \( p \times p \) diagonal matrix \( Z \) whose diagonals are \( p \)-th roots of unity, and \( X \) as a cyclic raising operator in this basis.

The local Hilbert space on each site \((i, j)\) of the square lattice is taken to be two such \( p \)-state degrees of freedom, labeled \( a \) and \( b \), which are operated on by the operators \( Z^{(a)}_{ij} \) and \( X^{(a)}_{ij} \), for \( a \in \{a, b\} \). Each \( Z^{(a)}_{ij} \) only has non-trivial commutations with \( X^{(a)}_{ij} \) on the same site and \( a \).

Let us also define a vectorial representation of such operators: functions of vectors \( v \in \mathbb{F}_p^{L_v} \) to operators on the row \( j \) as

\[
Z^{(a)}_j[v] = \prod_{i=0}^{L_v-1} (Z^{(a)}_{ij})^{v_i} \quad (72)
\]

\[
X^{(a)}_j[v] = \prod_{i=0}^{L_v-1} (X^{(a)}_{ij})^{v_i} \quad (73)
\]

One can verify that the commutation relations in this representation are

\[
X^{(a)}_j[v] Z^{(a)}_j[w] = e^{\frac{2\pi i}{p} v^T} w Z^{(a)}_j[w] X^{(a)}_j[v] \quad (74)
\]

for two operators on the same row \( j \) with the same \( a \in \{a, b\} \), and trivial otherwise.

The onsite symmetry group is \( G = \mathcal{Z}_p^{(f, p)} \times \mathcal{Z}_p^{(f, p)} \). Let us label the first \( \mathcal{Z}_p \) factor as \( a \), and the second as \( b \), and let \( g^{(a)} \) and \( g^{(b)} \) be generators for the two. Then, we take the onsite representation

\[
\eta_{ij}(g^{(a)}) = X^{(a)}_{ij} \quad (75)
\]

As always, we take \( L_x \) to be a power of \( p \), and \( L_y \) such that \( f(x)^L_y = 1 \). The total symmetry group is \( G_{tot} = \mathcal{Z}_p^{L_x} \times \mathcal{Z}_p^{L_y} \). An arbitrary element of the first \( \mathcal{Z}_p^{L_x} \) factor, with basis defined with respect to row \( j_0 \), is given by

\[
S(g^{(a,j_0)})[v] = \prod_{j=0}^{L_y-1} X^{(a)}_j[(F^T)^{j_0-j}v] \quad (76)
\]

and of the second by

\[
S(g^{(b,j_0)})[v] = \prod_{j=0}^{L_y-1} X^{(b)}_j[(F^T)^{j_0-j}v] \quad (77)
\]

Suppose we are given a consistently local matrix \( W^{(l_v, 0)} \) representing the twist phase. For convenience, let us denote \( W_j \equiv W^{(l_v, j_0)} \). Recall that consistent locality implies \((W_j)_{ij} \) is only non-zero if \( i' - i \) is within some small range, for all \( j \). Then, let us define the operators

\[
A_{ij} = X^{(a)}_j[e_i] Z^{(b)}_{j+i}[-W_j e_i] Z^{(b)}_{j+i+1}[F W_j e_i] \quad (78)
\]

\[
B_{ij} = X^{(b)}_j[e_i] Z^{(a)}_{j-i}[-W^T_j e_i] Z^{(a)}_{j-i-1}[F^T W^T_j e_i] \quad (78)
\]

Notice that these are local operators, as \( W_j \) is consistently local. Consider the Hamiltonian

\[
H = - \sum_{ij} A_{ij} - \sum_{ij} B_{ij} \quad (79)
\]

which we will now show is symmetric, composed of mutually commuting terms, and has a unique ground state which realizes the desired twist phase \( W_j \).

First, let us show that \( A_{ij} \) and \( B_{ij} \) commute with all \( S(g^{(a,j_0)})[v] \) and \( S(g^{(b,j_0)})[v] \). Note that \( A_{ij} \) commutes with all \( a \) type symmetries, and \( B_{ij} \) commutes with all
where we have again used the evolution equation $H_j [\psi]$. Let us conjugate every term in the Hamiltonian crossing the $j = 0$ cut by the truncated symmetry operator $S_\geq (g^{(a,0)}[\psi])$. The only terms which are affected by this conjugation are $B_{i'0}$ for which $e_{i'}^T W_{i0}^T \psi = W_{i0}^{T(\psi_0)} \neq 0$, which are transformed as

$$B_{i'0} \rightarrow B_{i'0} = e^{-2\pi i W_{i0}^{T(\psi_0)}} B_{i'0}$$

(83)
on the zeroeth row, and $B_{i'j} = B_{i'j}$ on all other $j \neq 0$, in the twisted Hamiltonian. Now, we are curious about the charge of a symmetry $g^{(b,l_0)}[\psi]$ in the ground state of this twisted Hamiltonian, which acts as

$$S(\psi) = \prod_j B_j [(F^T)^j \psi]$$

(84)

$$= e^{2\pi i W_{i0}^{T(\psi_0)}} \prod_j B_j [(F^T)^j \psi]$$

(85)

since the symmetry only includes a single $B_{i'0}$ on the zeroeth row. Thus, the ground state of the twisted Hamiltonian (which has eigenvalue 1 under $B_{i'j}$), has picked up a nontrivial charge under the symmetry $S(\psi)$, relative to in the untwisted Hamiltonian. Indeed, this phase is

$$\Omega(g^{(b,l_0)}, g^{(a,0)}) = e^{2\pi i W_{i0}^{T(\psi_0)}}$$

(87)

which is exactly as desired. Thus, this model indeed realizes the correct projective representation and describes the desired phase of matter.

VI. IRREVERSIBILITY AND PSEUDOSYMMETRIES

In this section, we discuss fractal symmetries described by a non-reversible linear cellular automaton (for which fractal SPTs do still exist), or even originally reversible cellular automata that become irreversible when put on different system sizes (e.g. $L_x$ or $L_y$ that are not powers of $p$).

Fractal symmetries are drastically affected by the total system size. For example, consider the Sierpinski fractal SPT, which is generated by a non-reversible $f(x) = 1 + x$ with $p = 2$, on a lattice of size $L_x = L_y = 2^N$. In this scenario, there are no non-trivial symmetries at all! The total symmetry group $G_{\text{tot}} = \mathbb{Z}_1$ is simply the trivial group. Yet, we can still define large operators that in the bulk look like symmetries (i.e. they obey the local cellular automaton rules), but violate the rules only within some boundary region. The total symmetry group being trivial may be thought of as simply an incommensurability effect, whereby the space-time trajectory of the CA cannot form any closed cycles. Thus, there is still a sense in which this model obeys a symmetry locally. This effect is exemplified when one notices that, upon opening...
boundary conditions, there are no obstacles in defining fractal symmetries and non-trivial SPTs. In this way, it should still be possible to extract what the SPT phase “would have been” if the CA rules had been reversible or if the total system sizes had been chosen more appropriately such the total symmetry group had been non-trivial. To generalize away from the fixed point and to an actual phase, we must formulate what it means for a perturbation to be “symmetric” in a system with a potentially trivial total symmetry group. We will say that a perturbation to be “symmetric” in a system with a pseudo-symmetry, and be in a symmetry of the full system may not even exist. Thus, a system may respect a pseudosymmetry, and be in a symmetry of the full system. Notice that these only involve positive powers of $F$, as we do not assume an inverse exists. Thus, even in the extreme case where $G_{\text{tot}}$ is trivial, a Hamiltonian may still be symmetric under the fractal pseudo-symmetry $G$ in this way. In the opposite extreme case where $f(x)$ is reversible and $G_{\text{tot}} = G^{L_x}$ (as was the topic of the rest of this paper), $H_{ij}$ commuting with all pseudo-symmetries is equivalent to it commuting with all the fractal symmetries in $G_{\text{tot}}$. Thus, it is natural to expect that pseudo-symmetries may also protect non-trivial SPT phases.

Indeed, notice that one can perform a twist of a pseudo-symmetry. Given a cut, $j_0$, we may use the operator $\tilde{S}_i^{(a,j_0+R)}$, for some $1 \ll R \ll L_x$, in place of the truncated symmetry operator $S_{\beta}(g_{i}^{(a,j_0)})$ from Sec IV. This can be used to obtain a twisted Hamiltonian as before by conjugating each term

$$H_{ij} \rightarrow \tilde{S}_i^{(a,j_0+R)} H_{ij} (\tilde{S}_i^{(a,j_0+R)})^\dagger$$

for some $1 \ll R \ll L_x$ if $H_{ij}$ crosses $j_0$. Each $H_{ij}$ commuting with all their respective pseudo-symmetries (Eq 89) means that the only terms which may commute with $\tilde{S}_i^{(a,j_0+R)}$ are those near $(i, j_0)$ and those at the far-away row $j_0 + R$ which are not affected by the twisting process.

Measuring the charge of a pseudo-symmetry is a trickier process, since there is no “symmetry operator” which we can measure the charge of in the ground state. Hence, the charge of a pseudo-symmetry is not so well defined. However, we may still measure the charge relative to what it would be in the ground state on the untwisted Hamiltonian, $|\psi\rangle$, which turns out to be well defined. One approach is to again express the twisted process as the action of some local unitary near $(i, j_0)$, $H_{\text{twist}} |\psi\rangle = U H U^\dagger |\psi\rangle$, where as before $A(U)$ is contained within some $(2L_x + 1) \times (2L_y + 1)$ box ($A(U)$ is defined in Eq 18. If the support of $U$ were entirely in this box, then we could measure the change in the charge of a b type symmetry by

$$\Omega^{(j_0 + l_x, j_0)}_{i' i} = \langle \psi | S^U U^\dagger SU |\psi\rangle$$

where $S = \tilde{S}_i^{(b,j_0+lc)}$, and $|\psi\rangle$ is the ground state of $H$ (for convenience we have suppressed the dependence of $U$ and $S$ on $i, i'$, etc). However, if the support of $U$ is not confined to this box, this expectation value may not yield a pure phase. One solution is to use a family of larger pseudo-symmetry operators which act the same way within $A(U)$, and take the limit of the sizes going to infinity. For example, using $S(n)$ instead of $S$ in the above, defined as

$$S(n) \equiv \tilde{S}_i^{(b,j_0+lc+p^n,j_0-p^n)}$$

which is shown in Figure 4. For large $n$ and $i'$ within

$$-L_x \ll l_x \ll i' - i \ll L_x + k_n l_y$$

this operator acts in the same way as $S$ within $A(U)$, but is also a valid pseudo-symmetry operator elsewhere as well, except on rows $j_0 + l_x + p^n$ and $j_0 - p^n$ which are far away, as shown in Figure 4. Then, we may define

$$\Omega^{(j_0 + l_x, j_0)}_{i' i} \equiv \lim_{n \rightarrow \infty} \langle \psi | S(n)^U U^\dagger S(n) U |\psi\rangle$$

which, in the large $n$ limit (while keeping $p^n \ll L_x$), is a pure phase. In the case where $G_{\text{tot}} = G^{L_x}$, this will coincide with the twist phases

$$\Omega^{(j_0 + l_y, j_0)}_{i' i} = \Omega(g_{i'}^{(b,j_0+l_x,j_0)} g_{i}^{(a,j_0)})$$

discussed earlier. However, the key ingredient to showing that this pseudo-SPT phase is truly stable to local pseudo-symmetric perturbations is to show that $\Omega^{(j_0 + l_y, j_0)}_{i' i}$ for all $j_1$ is completely determined by its value at $j_0$. Define (like before) the matrix $W^{(j_1,j_0)} \in \mathbb{P}_p \times L_x$ by

$$\Omega^{(j_1,j_0)}_{i' i} = e^{2\pi i W^{(j_1,j_0)}}$$
To define $K^{(k,m)}$ for cases where $f(x)$ may not be reversible, we may simply note that each solution is $p^{N_m}$-periodic in both directions. Thus, it is straightforward to generalize $K^{(k,m)}$ for $m$ where $p^{N_m}$ divides $L_x$ and $L_y$. In the coming proof, we are careful to show that $f(x)$ is only ever divided out of polynomials of finite degree in $x$ which contained $f(x)$ as a factor anyway, so polynomial division by $f(x)$ is remainder-less and results in another polynomial. Thus, the results apply equally well for non-reversible $f(x)$, as long as $L_x$ and $L_y$ are commensurate with the periodicity. This commensurability requirement may greatly reduce the number of possible pseudo-SPT phases, for example, if $L_x$ or $L_y$ are coprime to $p$, then only $m = 0$ is allowed. Note that on such system sizes is also possible to have periodicity that is not a power of $p$ in non-generic cases, for example, the special case where $f(x) = g(x^\nu)$ is a function of only $x^\nu$ and $\nu$ is not a power of $p$.

VII. DISCUSSION

We have therefore asked and answered the question of what SPT phases can exist protected by fractal symmetries for the type $G = \mathbb{Z}_p^{(f,y)}$, $G = \mathbb{Z}_p^{(f,y)} \times \mathbb{Z}_p^{(f,y)}$, or combinations thereof. If we completely ignore locality along the $x$ direction, effectively compactifying our system into a quasi-1D cylinder with global symmetry group $G_{\text{tot}} = GL_x$, we would have found that the possible phases are classified by $H^2(G^{L_x}, U(1))$ which is infinitely large as $L_x \to \infty$. What we have shown, however, is that the vast majority of these phases require highly non-local correlations that cannot arise from a local Hamiltonian. In the case of $G = \mathbb{Z}_p^{(f,y)}$, locality disqualifies all but the trivial phase. In the case of $G = \mathbb{Z}_p^{(f,y)} \times \mathbb{Z}_p^{(f,y)}$ case, there exists multiple non-trivial phases that are allowed. If we restrict the twist phases to be local up to some degree, $(l_x, l_y)$, then there are only a finite number of possible phases, independent of total system size $L_x$ and $L_y$. The number of phases depends only on the combination $\ell \equiv 1 + 2l_x + 4l_y \delta f$, which is linear in both $l_x$ and $l_y$ (thus demonstrating a kind of holographic principle). For more general combinations of such fractal symmetries, we have shown that the classification of phases simply amounts to finding pairs of fractal symmetries of the form $(\mathbb{Z}_p^{(f,y)}, \mathbb{Z}_p^{(f,y)})$ and repeating the analysis above.

Suppose we are given an unknown system with $G = \mathbb{Z}_p^{(f,y)} \times \mathbb{Z}_p^{(f,y)}$, how do we determine what phase it belongs to and how do we convey compactly what phase it is in? Recall that for the case with line-like subsystem symmetries (the topic of Ref. [53]), to describe a specific phase required information growing with system size, and so a modified phase equivalence relation was introduced to deal with this. Such a modified phase equivalence was not needed in this case, and we will show that indeed a specific local phase may be described with a finite amount of information. Suppose we are given
an unknown Hamiltonian $H$. It is possible to compute the full set of twist phases and construct the $L_x \times L_x$ matrix $W^{(0,0)}$. If the only non-zero matrix elements of $W^{(0,0)}$ are within some diagonal band, then we are set. Otherwise, find the smallest integer $l_y \geq 0$ for which $W^{(l_y,0)} = F^{l_y} W^{(0,0)}$ is only non-zero within a diagonal band of width $\ell \sim O(1)$. This is guaranteed to be the case for some $l_y$ (also of $O(1)$) due to locality. Note that $\ell$ and $l_y$ are independent of which row we call the zeroth row. From the fact that $W^{(j_0 + l_y,j_0)}$ must also be non-zero only within this diagonal band for all $j_0$, our main result (Theorem VIII.1) states that $W^{(l_y,0)}$ must be a sum

$$W^{(l_y,0)} = \sum_{(k,m) \in \text{loc}} C_{km} K^{(k,m)}$$

(98)

where $C_{km} \in \mathbb{F}_p$, and loc is the finite set of all pairs $(k, m)$ where $K^{(k,m)}$ is also only non-zero within the same band of width $\ell$. Thus, this phase is specified fully by our choice of origin, $l_y$, and the finite set of non-zero $C_{km}$. Furthermore, this description does not depend on $L_x$ and $L_y$, and so it makes sense to say whether two systems of different sizes belong to the same phase.

Where do other previously discovered 2D systems with fractal symmetries fall into our picture? The quantum Newman-Moore paramagnet is described by the Hamiltonian

$$H_{NM} = -\sum_{ij} X_{ij} Z_{i,j+1} Z_{i-1,j-1} - h \sum_{ij} X_{ij}$$

(99)

$X_{ij}$, $Z_{ij}$, are Pauli matrices acting on the qubit degree of freedom on site $(i, j)$. The symmetry in our notation is given by $G = \mathbb{Z}_2^{(f,y)}$ with $f(x) = 1 + x$ (which is irreversible). $H_{NM}$ has a phase transition from a spontaneously symmetry-broken phase at $|h| < 1$ to a trivial symmetric paramagnet at $|h| > 1$. Our results would imply that there can be no non-trivial SPT phase in this system. Thus, all the possibilities in this model are different patterns of broken symmetry. Next, we have the explicit example of the 2D Sierpinski fractal SPT (which appeared at a gapped boundary in Ref 59). This model is isomorphic to the cluster model on the honeycomb lattice, and is described by symmetries $G = \mathbb{Z}_2^{(f,y)} \times \mathbb{Z}_2^{(f,y)}$ with $f(x) = 1 + x$. With proper choice of unit cell, the Hamiltonian is given by

$$H_{clus} = -\sum_{ij} X_{ij}^{(b)} Z_{i,j+1}^{(a)} Z_{i-1,j-1}^{(a)} + Z_{i,j+1}^{(b)} Z_{i,ij+1}^{(a)} Z_{i-1,j-1}^{(a)}$$

(100)

Notice that $f(x) = 1 + x$ with $p = 2$ is irreversible for all system sizes, thus these phases should be viewed as pseudo-SPT phases (and indeed every term commutes with all the pseudo-symmetries). Computing the pseudo-SPT twist phases for $H_{clus}$ gives $\Omega^{(1,1)}_{ij} = (-1)^{\delta_{ij}}$. Thus, we have simply $W^{(0,0)} = 1 = K^{(0,0)}$. A translation invariant model must simply be a sum of $K^{(k,0)}$ and this is indeed the case here. The family of 2D fractal SPT models described in Ref 58 all realize $W^{(0,0)} = 1$. Our results here imply the existence of a number of new local phases for which the Hamiltonian and twist phases are not strictly translation invariant with period 1. Sec IV gives a construction of such models, which works even when $f(x)$ is not reversible. The twist phases for these models may be translation invariant with a minimal period of $2^n$ sites along either $x$ or $y$, but in exchange will also require interactions of range $O(2^n)$.

VIII. PROOF OF RESULT

In this section, we will focus on proving the claim in Sec IV that any consistently local matrix $W$ must be a linear sum of $K^{(k,m)}$, each of which are local. We will say that the set of matrices satisfying this property, $\{K^{(k,m)}\}$, serve as an optimal basis (this term will be precisely defined soon). Recall that we are dealing with the case where $L_x = p^n$ is a power of $p$ and $L_y$ is chosen such that $f(x) |_{L_y} = 1$. We will simply use $L$ to refer to $L_x$ in this section for convenience.

A. Definition and statement

We will be using the polynomial representation exclusively. Let $W(u, v)$ be a Laurent polynomial over $\mathbb{F}_p$, in $u$ and $v$ representing the twist phases, defined according to Eq 60. Formally, periodic boundary conditions $u^L = v^L = 1$ means that we only care about the equivalence class of $W(u, v)$ in $\mathbb{F}_p[u, v]/(u^L - 1, v^L - 1)$, where $\langle u^L - 1, v^L - 1 \rangle$ is the ideal generated by these two polynomials. Rather than dealing with equivalence classes, we will instead deal with canonical form polynomials: a polynomial $q(u, v)$ is in canonical form if $\deg_u q(u, v) < L$ and $\deg_v q(u, v) < L$. Obviously, canonical form polynomials are in one-to-one correspondence with equivalence classes from $\mathbb{F}_p[u, v]/(u^L - 1, v^L - 1)$. Any polynomial with $u$ or $v$-degree larger than $L$ can be brought into canonical form via simply taking $u^a = u^a \mod L$ and $v^a = v^a \mod L$. From now on, we will implicitly assume all polynomials have been brought to their canonical form.

Let us now define what it means for a polynomial to be local.

Definition VIII.1. A Laurent polynomial $g(u, v)$ is $(a, b)$-local, for integers $a \leq b$, if

$$\deg_u v^{-a} g(u, v) \leq b - a$$

(101)

A Laurent polynomial $g(u, v)$ being $(a, b)$-local roughly means that the only non-zero powers of $v$ are $v^a$, $v^{a+1}$, \ldots, $v^b$ (powers mod $L$). As a shorthand, we will more often say that a polynomial is $\ell$-local to mean $(\ell, \ell)$-local.
which can be thought of as simply an upper bound on its \(v\) degree. Whenever something is said to be \(\ell\)-local, we are usually talking about \(\ell \ll L\) being some finite value of order 1. Some nice properties are that if \(g(u,v)\) is \((a,b)\)-local, then

1. \(v^kg(u,v)\) is \((a+k,b+k)\)-local;
2. \(g(u,v)g'(u,v)\) is \((a+a',b+b')\)-local, if \(g'(u,v)\) is \((a',b')\)-local.
3. \(g(u,v)^N\) is \((Na,Nb)\)-local;

Next, let us define the “evolution operator” \(t_h\) with respect to an (invertible) Laurent polynomial \(h(x)\) which operates on a polynomial \(W(u,v)\) as

\[
t_h : W(u,v) \rightarrow t_h(u,v)W(u,v); \tag{102}
\]

\[
t_h(u,v) = h(v)\text{ }^{-1}W(u,v) \tag{103}
\]

By invertible, we mean that there exists an inverse \(h(v)^{-1}\) with periodic boundary conditions, such that \(h(v)h(v)^{-1} = 1\). In the case of \(h(x) = f(x)\), \(t_f\) evolves the polynomial \(W^{(l,v)}(u,v) \rightarrow W^{(l+1,v)}(u,v)\). Notice that an overall shift, \(h(x) \rightarrow x^\ell h(x)\), results in \(t_h(u,v) \rightarrow u^\ell t_h(u,v)\), which does not affect the locality properties (which only depends on powers of \(v\)). For the purposes of this proof we will therefore simply work with (non-Laurent) polynomials \(h(x)\). We can now define consistent locality.

**Definition VIII.2.** A Laurent polynomial \(g(u,v)\) is consistently \((a,b)\)-local under \(t_h\) if \(t_h^n g(u,v)\) is \((a,b)\)-local for all \(n\).

Physically, the twist phases \(W^{(l,v)}(u,v)\) must be consistently \((-2\ell,2\ell)\)-local (from Eq. 100) under \(t_f\) in order to correspond to a physical phase obtained from a local Hamiltonian.

Let us define

\[
U_m(u) = (u-1)^{L-1-m} \tag{104}
\]

for \(m = 0, \ldots, L - 1\), which serves as a complete basis for all polynomials \(g(u) \in \mathbb{F}_p[v]\) with degree \(\deg_u g(u) \leq L\). Any polynomial \(W(u,v)\) may therefore be uniquely expanded as

\[
W(u,v) = \sum_{m=0}^{L-1} U_m(u) W_m(v) \tag{105}
\]

which we take to be our definition of \(W_m(v)\). Since \(U_m(u)\) are all independent, if \(W(u,v)\) is \(\ell\)-local, each \(W_m(v)\) must also be \(\ell\)-local.

**Definition VIII.3.** A set of polynomials \(\{V_m(v)\}\) indexed by \(m = 0, \ldots, L-1\) is said to generate an optimal basis for \(t_h\) if for every \(\ell\)-local \(W(u,v)\), \(W(u,v)\) is consistently \(\ell\)-local if and only if \(V_m(v) | W_m(v)\) for all \(m\). The basis set \(\{v^k V_m(u) V_m(v)\}\) is then called an optimal basis.

When we say \(V_m(v) | W_m(v)\), we mean that \(V_m(v)\) divides \(W_m(v)\) as polynomials in \(\mathbb{F}_p[v]\) without periodic boundary conditions, i.e., there exists a polynomial \(q(v)\) such that \(W_m(v) = q(v)V_m(v)\) and

\[
\deg_q q(v) = \deg_v W_m(v) - \deg_v V_m(v) \leq \ell - \deg_v V_m(v) \tag{106}
\]

which follows by addition of degrees, and since \(W_m(v)\) is \(\ell\)-local.

Suppose \(\{V_m(v)\}\) generates an optimal basis for \(t_h\). Assuming \(V_m(v)\) is invertible, \(\{v^k U_m(u) V_m(v)\}_{k,m}\) for \(0 \leq k, m < L\) generates a complete basis for canonical form polynomials. This basis is optimal with respect to \(t_h\) in the sense that all consistently \(\ell\)-local polynomials under \(t_h\) may be written as a linear sum of \(\ell\)-local basis elements. If there are only a finite number \(N_{\text{loc}}\) of \(\ell\)-local basis elements (as will be the case), then there are also only a finite number \(p^{N_{\text{loc}}}\) of consistently \(\ell\)-local \(W(u,v)\).

We can now restate our main theorem, the proof of which will be the remainder of this section.

**Theorem VIII.1.** The polynomials \(V_m(u,v),\) defined in Eq. 104, generate an optimal basis for \(t_f\).

**B. Proof**

Let us first list some relevant properties of \(U_m(u)\).

1. \((u-1)^n U_m(u) = U_{m-n}(u)\) for \(n \leq m\), or 0 for \(n > m\)
2. \(U_m(u)\) is \(p^N_m\)-periodic, meaning

\[
u^{p^N_m} U_m(u) = U_m(u) \tag{107}
\]

where \(N_m = \lceil \log_p (m+1) \rceil\). This follows from the fact that

\[
(u^{p^N_m} - 1) U_m(u) = (u-1)^{p^N_m} U_m(u) = 0 \tag{108}
\]

since \(p^N_m > m\), due to property 1.
3. \(U_m(u)\) is also cyclic under evolution by \(t_h\) with period dividing \(p^N_m\), \(t^{p^N_m}_h U_0(u) = U_0(u)\). This follows from the fact that \(u^{p^N_m} U_0(u) = U_0(u)\), and so

\[
t^{p^N_m}_h U_0(u) = h(v)^{-p^N_m} h(uv)^{p^N_m} U_0(u) = h(v)^{-p^N_m} h(v)^{p^N_m} U_0(u) = U_0(u) \tag{109}
\]

4. \(t_h U_m(u) = U_m(u) + \sum_{m' < m} q_{m'} U_{m'}(u)\). Under evolution by \(t_h\), \(t_h U_0(u)\) is given by simply \(U_0(u)\), plus a linear combination of \(U_m(u)\) for \(m' < m\).

Using property 1 It is therefore easy to extract each component \(W_m(v)\) in the expansion of Eq. 105 directly from \(W(u,v)\) in a straightforward way. Suppose the largest \(m\) for which \(W_m(v) \neq 0\) is \(m = M\). Then,
\[(u - 1)^MW(u, v) = W_M(v)U_0(u)\] gives only the \(m = M\)th component multiplying \(U_0(u)\). Then, we may take \(W'(u, v) \equiv W(u, v) - U_M(u)V_M(v)\), which has largest \(m\) given by \(M' < M\). This process can be repeated on \(W'(u, v)\) to fully obtain \(W_m(v)\) for all \(m\). From Property 2, we also find that \(W(u, v)\) is actually \(p^{N_m}\)-periodic.

Property 4 is the most important property (and what makes \(U_m(u)\) a special basis for this problem). It follows from Property 2 for \(m = 0\), \(t_hU_0(u) = U_0(u)\), and the fact that the \(m\)th component of \(t_hU_m(u)\) is obtained by

\[(u - 1)^m t_h(u, v)U_m(u) = t_h(u, v)U_0(u) = U_0(u)\] (110)

which remains unchanged under evolution by \(t_h\). Thus, supposing the expansion of \(W(u, v)\) has some largest \(m\) value \(M\), then defining \(\Delta_h W(u, v)\) according to

\[t_h W(u, v) = W(u, v) + \Delta_h W(u, v)\] (111)

we must have that \(\Delta_h W(u, v)\) has a largest \(m\) value \(M < M\). Alternatively, \((u - 1)^M \Delta_h W(u, v) = 0\). This fact will be used numerous times as it allows for a proof by recursion in \(M\) in many cases.

Let us first prove two minor Lemmas.

**Lemma VIII.2.** Suppose \(\{V_m(v)\}\) generates an optimal basis for some \(t_h\). Then, \(V_m(v) \mid V_{m'}(v)\) for all \(m' \geq m\) and \(V_0(v) = 1\).

**Proof.** First, any \(\ell\)-local \(W(u, v)\) that contains only an \(m = 0\) component, \(W(u, v) = U_0(u)W_0(v)\), is trivially also consistently \(\ell\)-local under any \(t_h\), since \(t_h U_0(u) = U_0(u)\). Thus, it must be that \(V_0(v) = 1\). Next, if \(W(u, v)\) is consistently \(\ell\)-local, then

\[(u - 1)^n W(u, v) = \sum_{m = n}^{L - 1} U_{m - n}(u)W_m(v)\] (112)

must also be consistently \(\ell\)-local for any \(n \geq 0\). However, this implies that \(V_m(v) \mid W_{m + n}(v)\). But all we know is that \(V_{m + n} \mid W_{m + n}(v)\). For this to always be satisfied, we must therefore have that \(V_m(v) \mid V_{m'}(v)\) for all \(m' \geq m\).

**Lemma VIII.3.** Let \(W(u, v)\) be \(\ell\)-local. Then, \(W(u, v)\) is consistently \(\ell\)-local under \(t_h\) if and only if \(\Delta_h W(u, v)\) is also consistently \(\ell\)-local.

**Proof.** Consider evolving \(W(u, v)\),

\[t_h W(u, v) = W + \Delta_h W\] (113)

\[t_h^2 W(u, v) = W + \Delta_h W + t_h \Delta W\] (114)

\[t_h^3 W(u, v) = W + \Delta_h W + t_h \Delta_h W + t_h^2 \Delta_h W\] (115)

and so on. By definition, if \(W(u, v)\) is consistently \(\ell\)-local, then \(t_h^m W(u, v)\) must all be \(\ell\)-local. But then, this means that each term added in increasing \(m\), \(t_h^{m-1} \Delta_h W(u, v)\), must also be \(\ell\)-local, meaning that \(\Delta_h W(u, v)\) is therefore consistently \(\ell\)-local. If \(W(u, v)\) is not consistently \(\ell\)-local, then that means that there must be some \(n\) such that \(t_h^n \Delta W(u, v)\) is not \(\ell\)-local, which therefore implies that \(\Delta_h W(u, v)\) is also not consistently \(\ell\)-local.

The next Lemma gives a family of a consistently \(\ell\)-local polynomials.

**Lemma VIII.4.** Let \(K_m^h(u, v) = U_m(u)h(v)^m\) for some \(0 \leq m < L\). Then, \(\deg V_0(v) = m\delta_h\) for all \(n\). It is therefore consistently \(m\delta_h\)-local under \(t_h\).

**Proof.** Let us prove by recursion in \(m\). The base case, \(m = 0\), is true since \(U_0(u) = 0\) is indeed consistently 0-local. Now, assume \(m > 0\) and we have proved this Lemma for all \(m' < m\).

Let us compute \(\Delta_h K_m^h(u, v)\).

\[\Delta_h K_m^h(u, v) = U_m(u)h(v)^m - 1\] (116)

\[= U_m(u)h(v)^m - 1\sum_{k=0}^{\delta_h} h_k v^k (u - 1)^n\] (117)

where \(h(x) = \sum_{k=0}^{\delta_h} h_k x^k\), and we have used Property 2 of \(U_m(u)\) to replace \(v^k \rightarrow u^k\), where \(\bar{k} \equiv (k \mod p^{N_m})\) is positive. Then, we may use the identity

\[u^k - 1 = \sum_{n=0}^{\bar{k}} \binom{n}{\bar{k}} (u - 1)^n\] (118)

to expand

\[\Delta_h K_m^h(u, v) = U_m(u)h(v)^m - 1\sum_{k=0}^{\delta_h} \sum_{n=0}^{\bar{k}} h_k v^k (u - 1)^n\] (119)

and note that by our recursion assumption, \(v^k h(v)^n K_m^{h-n}\) is consistently \((k, (m - 1)\delta_h + k)\)-local. Since \(0 \leq k \leq \delta_h\), each term is therefore consistently \(m\delta_h\)-local. Thus, \(\Delta_h K_m^h(u, v)\) is consistently \(m\delta_h\)-local. By Lemma VIII.3, \(K_m^h(u, v)\) is therefore also \(m\delta_h\)-local. Finally, the \(\bar{v}\)-degree of \(K_m^h(u, v)\) saturates \(m\delta_h\) since the \(m\)th component of \(t_h^n K_m^h(u, v)\) has \(\bar{v}\)-degree \(m\delta_h\) for all \(n\). The proof follows for all \(m\) by recursion.

Thus, a family of consistently \(\ell\)-local \(W(u, v)\) may be created by a linear sum over of \(\ell\)-local \(v^k K_m^h(u, v)\), over \(k\) and \(m\). However, this may not be exhaustive: there may be some consistently \(\ell\)-local \(W(u, v)\) that are not in this family. To show exhaustiveness, we need to show that \(\{V_m(v) = h(v)^m\}\) generates an optimal basis for \(t_h\). This is not true generally, but is true in the case that \(h(x)\) is irreducible, which our next lemma addresses. Notice that \(V_m(v) = h(v)^m\) are consistent with the properties of being generators of an optimal basis from Lemma VIII.2. \(V_0(v) = 1\) and \(V_m(v) \mid V_{m'}(v)\) for all \(m' \geq m\).

**Lemma VIII.5.** Suppose \(h(x)\) is an irreducible polynomial. Then, \(\{V_m(v) = h(v)^m\}\) generates an optimal basis for \(t_h\).
To prove that \( \{h(v)^m\} \) generates an optimal basis for \( t_h \), we need to show that for any \( \ell \)-local \( W(u, v) \), it is consistently \( \ell \)-local if and only if \( h(v)^m \mid W_m(v) \) must hold for all \( m \).

First, the reverse implication follows from Lemma VIII.4 if \( W(u, v) \) is \( \ell \)-local and each \( h(v)^m \mid W_m(v) \), then \( W(u, v) \) is also consistently \( \ell \)-local. We must now prove the forward implication.

Let \( W(u, v) \) by consistently \( \ell \)-local under \( t_h \), with the expansion

\[
W(u, v) = \sum_{m=0}^{M} U_m(u)W_m(v)
\]

where \( M \) is the largest \( m \) value in the expansion, and \( W_M(v) \neq 0 \). We need to prove that this implies that \( h(v)^m \mid W_m(v) \) for all \( m \). We now prove by recursion, and assume that this has been proven for all \( M' < M \). Note that for the base case \( M = 0 \), \( \{h(v)^m\} \) indeed generates an optimal basis for all \( M = 0 \) polynomials \( W(u, v) \). If \( h(v) = ev^k \) is a monomial, then this proof is also trivial, so we will assume this is not the case in the following.

Consider \( \Delta_h W(u, v) \), which by Lemma VIII.3 also has maximum \( m < M \) and is consistently \( \ell \)-local. Take the \( m = M - 1 \)th component of \( \Delta_h W(u, v) \), obtained by \( (u-1)\Delta_h W(u, v) \), which by a straightforward calculation is given by

\[
(u-1)^{M-1}\Delta_h W(u, v) = g(v)h(v)^{-1}W_M(v)U_0(u)
\]

where

\[
g(v) = \sum_{k=0}^{\delta_h} \bar{h}_k v^k
\]

\( \delta_h \equiv \deg_v h(v) \), \( h_k \) is defined through \( h(v) = \sum_k h_k v^k \), and \( \bar{h} \equiv (k \mod \overline{pN_M}) \). Note that since \( W(u, v) \) is \( \ell \)-local, despite Eq. 122 containing \( h(v)^{-1} \), is of \( v \)-degree bounded by \( \ell \). By our recursion assumption, \( h(v)^{M-1} \) must divide Eq. 122.

Let us prove that \( h(v) \mid g(v) \) and \( g(v) \neq 0 \). First, since \( \deg_v h(v) = \deg_v g(v) \) and \( h(v) \) is irreducible, if \( h(v) \) is to possible divide \( g(v) \), it must be that \( g(v) = const \cdot h(v) \). This can only be the case if \( (k \mod \overline{pN_M}) \equiv k_0 \) is the same for all \( k \). But then,

\[
h(v) = k_0 \sum_{i=0}^{i_{max}-1} h_{k_0+ipN_M} v^{k_0+ipN_M}
\]

while

\[
= k_0 v^{k_0} \left( \sum_{i=0}^{i_{max}-1} h_{k_0+ipN_M} v^i \right)^{p^N_M}
\]

which contradicts the fact that \( h(v) \) is irreducible, as \( i_{max} > 1 \) and \( p^N_M > 1 \) (which is the case here). The \( g(v) = 0 \) is the \( k_0 = 0 \) case of this. Thus, \( g(v) \neq 0 \) and \( h(v) \mid g(v) \).

Going back, we have that

\[
h(v)^{M-1} \mid g(v)h(v)^{-1}W_M(v) \]

\[
\implies h(v)^M \mid g(v)W_M(v)
\]

but since \( h(v) \nmid g(v) \), it must be the case that \( h(v)^M \mid W_M(v) \).

Now, consider \( W'(u, v) = W(u, v) - U_M(u)W_M(v) \), which is a sum of two consistently \( \ell \)-local polynomials (using Lemma VIII.4), and so is also consistently \( \ell \)-local. By our recursion assumption, it then follows that \( h(v)^m \mid W_m(v) \) for \( m < M \). Thus, \( h(v)^m \mid W_m(v) \) holds for all \( m \) in \( W(u, v) \).

By recursion in \( M \), we have therefore proved that for all \( W(u, v) \), \( h(v)^m \mid W_m(v) \) must be true for all \( m \). Thus, \( \{h(v)^m\} \) generates an optimal basis for \( t_h \).

If \( \tilde{f}(x) = x^{-k_0} f(x) \) is irreducible, then Lemma VIII.5 is sufficient to obtain all consistently \((a, b)\)-local \( W(u, v) \). To do so, we simply have to find all \((k, m)\) where the basis element \( v^k K_m^f(u, v) \) is \((a, b)\)-local, and take a linear combination of them. If there are \( N_{loc}(a, b) \) such basis elements, then the \( p^{N_{loc}(a, b)} \) possible linear combinations are exhaustive.

In the case that \( \tilde{f}(x) \) is not irreducible, there may be inconsistently \((a, b)\)-local polynomials that do not fall within this family. However, note that it is always possible to expand \( \tilde{f}(x) \) in terms of its unique irreducible factors

\[
\tilde{f}(x) = f_0(x)^{\gamma_0} f_1(x)^{\gamma_1} \cdots
\]

The next two Lemmas allows us to use this result construct an optimal basis for \( \tilde{f}(x) \), based on this factorization.

**Lemma VIII.6.** Let \( h(x) \) be an irreducible polynomial, and \( r > 0 \) an integer. Then, \( \{V_m(v) = h(v)^{\overline{m}}\} \) generates an optimal basis for \( t_h \), where \( \overline{m} = \lfloor m/p^N \rfloor \) and \( \alpha \) is the power of \( p \) in the prime factorization of \( r \).

**Proof.** First, note that if \( p \nmid r \), \( p \) is coprime to \( r \), then being consistently \( \ell \)-local under \( t_h \) is equivalent to being consistently \( \ell \)-local under \( t_h \). This follows from the fact that, if \( W(u, v) \) has maximum \( m \) value \( m = M \), then \( t_h^n M W(u, v) = W(u, v) \). If \( W(u, v) \) is consistently \( \ell \)-local under \( t_h \), then \( t_h^n M W(u, v) = t_h^n \mod pN_M \) \( W(u, v) \) is, by definition, \( \ell \)-local for all \( n \). If \( W(u, v) \) is instead consistently \( \ell \)-local under \( t_h \), then \( t_h^n W(u, v) = t_h^n \mod pN_M \) \( W(u, v) \) is \( \ell \)-local for all \( n \). But, \( r^n \) takes on all value mod \( pN_M \), and so these two conditions are equivalent. Thus, Lemma VIII.5 states that \( \{h(v)^{\overline{m}}\} \) generates an optimal basis for \( t_h \), which therefore also generates an optimal basis for \( t_h \). Indeed, if \( p \nmid r \), \( h(v)^{\overline{m}} = h(v)^m \) and the proof is complete.

Next, consider the case where \( r = p^\alpha \) is a power of \( p \). Notice that \( t_h^n(u, v) = t_h(a^\beta, v^\gamma) \) in this case is a function
of only \( w^{\tau} \) and \( v^{\tau} \). Let \( W(u, v) \) be \( \ell \)-local and decompose it as

\[
W(u, v) = \sum_{i=0}^{r-1} \sum_{j=0}^{r-1} (u^{r-1-i} v^j) W_{ij}(u^{\tau}, v^{\tau})
\]

(129)
such that each of the \( ij \) “block” does not mix under evolution by \( t^k \). Thus, each \( ij \) may be treated as an independent system in terms of variables \( u \equiv u^{\tau} \) and \( v \equiv v^{\tau} \), with \( L \equiv L/r \). Thus, by Lemma VIII.5, each \( ij \) component (and therefore \( W(u, v) \)) is only consistently \( \ell \)-local if and only if in the decomposition

\[
W_{ij}(u^{\tau}, v^{\tau}) = \sum_{\tilde{m}=0}^{L/r-1} (u^{r-1} - 1)^{i-j} \tilde{m} W_{ij, \tilde{m}}(v^{\tau})
\]

(130)

\[
h(v^{\tau}) \tilde{m} | W_{ij, \tilde{m}}(v^{\tau}) \text{ for all } i, j, \tilde{m}. \] Defining \( m \equiv i + \tilde{m} r \), \( W(u, v) \) may be written as

\[
W(u, v) = \sum_{m=0}^{L-1} \sum_{j=0}^{r-1} u^j v^j W_{ij, m}(u^{\tau}, v^{\tau})
\]

(131)

\[
= \sum_{m=0}^{L-1} U_m(u) W_m(v)
\]

(132)

where \( W_m(v) = \sum_{j=0}^{r-1} v^j W_{ij, m}(u^{\tau}, v^{\tau}) \), so \( W(u, v) \) is consistently \( \ell \)-local if and only if \( h(v^{\tau}) \tilde{m} | W_m(v) \). To eliminate reference to \( \tilde{m} \), we may use the fact that \( \tilde{m} = [m/r] \), such that \( \overline{m} = r \tilde{m} \). Therefore, \( W(u, v) \) is consistently \( \ell \)-local if and only if \( h(v) \overline{m} | W_m(v) \) for all \( m \), and \( \{h(v) \overline{m} \} \) generates an optimal basis for \( t_h^r \) when \( r = p^\alpha \) as well.

Finally, consider the general case \( r = \tilde{r} p^\alpha, \) where \( p \not| \tilde{r} \). We have just shown that \( \{h(v) \overline{m} \} \) generates an optimal basis for \( t_{h^r} \). Since \( \tilde{r} \) is coprime to \( p \), by our first argument, this also generates an optimal basis for \( t_{h^r} \).

**Lemma VIII.7.** Suppose \( \{V_1, m(v)\} \) and \( V_2, m(v) \) generate optimal bases for \( t_{h^r} \) and \( t_{h^r} \), respectively, and \( V_1, m(v) \) and \( V_2, m(v) \) share no common factors for all \( m \), \( m' \). Then, \( \{V_m(v) = V_1, m(v) V_2, m(v)\} \) generates an optimal basis for \( t_{h^r} \).

**Proof.** Let \( W(u, v) \) be \( \ell \)-local which we expand as

\[
W(u, v) = \sum_{m=0}^{M} U_m(u) W_m(v)
\]

(133)

where \( M \) is the largest \( m \) for which \( W_m(v) \neq 0 \). If \( V_1, m(v) V_2, m(v) | W_m(v) \), then \( W(u, v) \) is consistently \( \ell \)-local under \( t_{h^r} \) and \( t_{h^r} \), and therefore also under \( t_{h^r} \). We then need to prove the reverse implication, that \( W(u, v) \) being consistently \( \ell \)-local under \( t_{h^r} \) implies \( V_1, m(v) V_2, m(v) | W_m(v) \) for all \( m \). We will prove this by recursion in \( M \). The base case, \( M = 0 \), is trivial since \( V_0(v) = V_1, 0(v) V_2, 0(v) = 1 \) is a requirement from Lemma VIII.2. Now, suppose this has been proven for all \( M' < M \).

First, assume that \( W(u, v) \) is consistently \( \ell \)-local under \( t_h \), but not \( t_{h^2} \). Then, consider \( \Delta_{h, h^2} W(u, v) \), which has largest \( m < M \) and is consistently \( \ell \)-local under \( t_{h, h^2} \) by Lemma VIII.3. Our recursion assumption, then, implies that \( \Delta_{h, h^2} W(u, v) \) is also consistently \( \ell \)-local under \( t_{h^1} \) and \( t_{h^2} \) individually. Then,

\[
t_{h_{h^2}}^m W(u, v) = W(u, v) + \sum_{i=0}^{m-1} t_{h_{h^2}}^i \Delta_{h, h^2} W(u, v)
\]

(134)

and so

\[
t_{h_{h^2}}^m t_{h_{h^2}}^m W(u, v) = t_{h_{h^2}}^m W(u, v) + \sum_{i=0}^{m-1} t_{h_{h^2}}^i t_{h_{h^2}}^i \Delta_{h, h^2} W(u, v)
\]

(135)

which is \( \ell \)-local. But, if we choose \( n = (k-m \mod p^\alpha M) \), then we get that \( t_{h_{h^2}}^n W(u, v) \) is always \( \ell \)-local. Thus, \( W(u, v) \) is consistently \( \ell \)-local under \( t_{h^2} \) as well, which contradicts our initial assumption. Therefore, \( W(u, v) \) cannot be consistently \( \ell \)-local under \( t_{h^1} \) but not \( t_{h^2} \).

Next, assume \( W(u, v) \) is neither consistently \( \ell \)-local under \( t_{h^1} \) nor \( t_{h^2} \). Then, consider

\[
W'(u, v) \equiv V_{1, M}(v) W(u, v)
\]

(136)

which is consistently \( \ell + \deg V_{1, M}(v) \equiv \ell' \)-local under \( t_{h^1, h^2} \) (notice that if \( \ell \ll L \), then \( \ell' \ll L \) as well). \( W(u, v) \) is also \( \ell' \)-local under \( t_{h^1, h^2} \), since \( V_{1, m}(v) | V_{1, M}(v) \) for all \( m \leq M \) by Lemma VIII.2. However, since \( V_{1, M}(v) \) shares no common factors with \( V_{2, m}(v) \), \( W(u, v) \) is still not consistently \( \ell' \)-local under \( t_{h^1, h^2} \). But, we just showed previously that we cannot have a situation in which \( W(u, v) \) is \( \ell' \)-local under \( t_{h^1, h^2} \) and \( t_{h^1} \) but not \( t_{h^2} \), thus leading to a contradiction. \( W(u, v) \) must therefore be consistently \( \ell \)-local under both \( t_{h^1} \) and \( t_{h^2} \).

This means that \( V_{1, m}(v) | W_{m}(u, v) \) and \( V_{2, m}(v) | W_{m}(u, v) \) for all \( m \). Since \( V_{1, m}(v) \) and \( V_{2, m}(v) \) share no common factors, this means that \( V_{1, m}(v) V_{2, m}(v) \mid W_{m}(u, v) \). Thus, \( \{V_{m}(v) V_{2, m}(v)\} \) generates an optimal basis for \( t_{h^1, h^2} \).

We may now prove Theorem VIII.1. Let us factorize \( \tilde{f}(x) \) into its \( N_f \) unique irreducible polynomials,

\[
\tilde{f}(x) = \prod_{i=0}^{N_f} f_i(x)^{r_i}
\]

(137)

Using Lemma VIII.6, an optimal basis for \( t_{f_i}^{r_i} \), is generated by \( \{f_i(x)^{r_i}\} \), where \( m_i = [m/p^{\alpha_i}] p^{\alpha_i} \), and \( \alpha_i \) is the power of \( p \) in the prime factorization of \( r_i \). Since \( f_i(x)^{m_i} \) for different \( i \) share no common factors (as \( f_i(x) \) are irreducible), Lemma VIII.7 then says that \( \{f_0(x)^{m_0} f_1(x)^{m_1}\} \) generates an optimal basis for \( t_{f_0}^{r_0} t_{f_1}^{r_1} \). This may be iterated to construct an optimal basis for \( t_{f_0}^{r_0} t_{f_1}^{r_1} t_{f_2}^{r_2} \) and so on. Finally, one gets that \( \{\prod_{i=0}^{N_f} f_i(x)^{r_i}\} \) generates an optimal basis for \( t_f \), which is therefore also an optimal basis for \( t_f \). This is exactly \( \{V_{m}(v)\} \), and the proof is complete.
