Abstract

We study numerically the existence and character of bound states for positive and negative point charges shielded by the response of a two-dimensional homogeneous electron gas. The problem is related to many physical situations and has recently arisen in experiments for impurities on metal surfaces with Schockley surface states. Mathematical theorems ascertain a bound state for two-dimensional circularly symmetric potentials $V(r)$ with $\int_0^\infty dr V(r) \leq 0$. We find that a shielded potential with $\int_0^\infty dr V(r) > 0$ may also sustain a bound state. Moreover, on the same footing we study the electron-electron interactions in the two-dimensional electron gas finding a bound state with an energy minimum for a certain electron gas density.

I. INTRODUCTION AND MOTIVATION

The properties of the two-dimensional (2D) electron gas and in particular the phenomena induced by isolated or clustered impurities embedded in it have attracted a large volume of experimental and theoretical research. The interest stems from the increasingly more ideal realisations of the 2D electron gas, for example, at interfaces of semiconductor heterostructures, at semiconductor surface inversion layers, at (noble) metal surfaces as Schockley surface states or as quantum well states in metallic overlayers on insulators or on other metals. At the same time the development of different photoelectron and scanning tunneling spectroscopies has enabled an increasingly more accurate characterization of these systems\textsuperscript{1,2}.

Many experiments deal directly or indirectly with the existence of bound electron states in systems interacting with the 2D electron gas. The impurity-induced electron localization has been studied in the Schockley surface state systems\textsuperscript{3,4,5}. The quantum diffusion of hydrogen on metal surfaces reflects the coupling of the hydrogen with the metallic (possibly 2D) electron gas\textsuperscript{6,7}. Finally, a bound state between two electrons in a 2D electron gas has been proposed as an alternative pairing mechanism to the phonon coupling for high-temperature superconductivity\textsuperscript{8,9}. Remarkably, it was explicitly pointed out\textsuperscript{8} that the many-body ground state of a dilute gas of fermions is unstable to pairing if and only if a two-body bound state exists.

The background for the above-mentioned physics is laid by basic mathematical theorems. First, in two dimensions, for any everywhere attractive circularly symmetric potential, $V(r)$, there exists always a bound state no matter how weak the potential is. For the case of a shallow potential valley characterized by the $\int_0^\infty drrV(r) < 0$ condition, an explicit expression for the binding energy, $E_b$, was derived in the textbook by Landau\textsuperscript{10}. It turns out that the binding energy depends exponentially on the inverse of a negative constant (given by the condition) in the investigated weak-coupling limit. The theorem of Simon\textsuperscript{11} extends the conditions for a bound state to the $\int_0^\infty drrV(r) = 0$ case, i.e., to the not everywhere nonpositive or not everywhere nonnegative suitable potentials.

In this work we present a numerical analysis for the existence of a 2D bound state in potentials fulfilling the $\int drrV(r) = 0$ condition. The physically motivated effective potentials, $V_{\text{eff}}(r) = \Lambda V(r)$, will refer to the perfectly shielded fields of embedded attractive
or repulsive unit-charges in a 2D electron gas, and Λ plays the role of a convenient coupling constant to detailed numerics. In the repulsive case the screening is constrained by the fact that the maximum of the surrounding hole density is the uniform electron gas density. Beside the cases based on the mentioned standard condition, the overscreening and underscreening of unit-charges (with Λ = 1) shall be investigated as well. The corresponding potentials could mimic the shielding-dynamics in, for example, standing wave generation on surfaces in the presence of impurities. Slightly surprisingly we find a bound state also for the overscreened attractive and underscreened repulsive potentials. In order to treat also the electron-electron effective interaction we use in the Schrödinger equation the reduced mass $\mu = 1/2$. The energy of the ensuing bound electron pair has a minimum at a certain electron gas density.

The rest of the paper is organized as follows. In the next section, Sec. II, we shall deduce our physically motivated model potentials to numerical, 2D bound-state calculations. The results obtained are presented on illustrative figures, by considering relevant parameter-ranges in coupling, screening-tuning, and density of the electron gas. Finally, Sec. III is devoted to a short summary. Hartree atomic units, $\hbar = e^2 = m_e = 1$, will be used in the equations and discussion below.

II. MODELS AND RESULTS

A. Shielded potentials

We begin with few mathematical expressions. The 2D Fourier-Hankel (F-H) transformation of a $F(r)$ function is

$$F(q) = 2\pi \int_0^\infty dr \, r J_0(rq) F(r),$$

(1)

where $J_0(x)$ is the zeroth-order Bessel function. The inverse F-H transform has the form

$$F(r) = \frac{1}{2\pi} \int_0^\infty dq \, q J_0(qr) F(q).$$

(2)

These equations will be used below, in model-potential constructions.

The field of an embedded charged particle is shielded in the 2D electron gas. Thus instead
of the bare Coulomb form, \( v_c(q) = 2\pi/q \), one can write in momentum space

\[
V(q) = \pm v_c(q) [1 - \Delta n(q)],
\]
for the shielded field around unit-charges of different signs. Here \( \Delta n(q) \) is the screening density in momentum-space. With a unit-norm \( \Delta n(r) \) one obtains, via the above Eqs.(1) and (3), the \( V(q \to 0) \propto q \) limiting behaviour if the real-space density decays faster than \( r^{-4} \). This case corresponds to the \( \int dr r V(r) = 0 \) condition of Simon’s theorem.

Notice, that the well-known\textsuperscript{12} quasiclassical, Thomas-Fermi (TF) approximation for impurity screening in a 2D electron gas results in a monotonic potential

\[
V_{TF}(r) = \pm \int_0^\infty dq \frac{q}{q + 2} J_0(qr) = \pm \int_0^\infty dx \frac{xe^{-2}}{(x^2 + r^2)^{3/2}}.
\]

Negative and positive signs in Eq.(4) refer to embedded attractive and repulsive unit charges, respectively. At large distances \( (r \to \infty) \) the \( V_{TF}(r) \) potential falls of as \( \pm 1/(4r^3) \), and one gets the \( \int_0^\infty dr r V_{TF}(r) = \pm (1/2) \) condition. Therefore, this type of potential with negative sign belongs to the class analyzed by Landau\textsuperscript{10}.

We shall characterize the \( \Delta n(r) \) density directly by the properly normalized hydrogenic (H) and gaussian (G) forms, \( (\alpha^2/2\pi) \exp(-\alpha r) \) and \( (\beta^2/\pi) \exp(-\beta^2 r^2) \), respectively. The corresponding Fourier-Hankel transforms are \( \alpha^3/(\alpha^2 + q^2)^{3/2} \) and \( \exp[-q^2/(2\beta^2)] \), respectively. Using the former in Eq.(3) and applying Eq.(2), we get

\[
V_H(r) = \pm \frac{1}{r} \left(1 - 2u^2 [I_0(u)K_1(u) - I_1(u)K_0(u)]\right),
\]

in which \( u = \alpha r/2 \) for shorthand. The gaussian-form results in

\[
V_G(r) = \pm \frac{1}{r} \left(1 - \sqrt{2\pi z} I_0(z) e^{-z}\right),
\]

where \( z = \beta^2 r^2/2 \). In the above equations \( I_i(x) \) and \( K_i(x) \) are modified Bessel functions.

We stress that \( V(q = 0) = 0 \), i.e., \( \int_0^\infty dr r V(r) = 0 \) in these models. For long distances these shielded potentials decay as \( \mp 3/(2\alpha^2 r^3) \), and \( \mp 1/(4\beta^2 r^3) \), respectively. The attractive potentials are exhibited in Fig. 1, by fixing \( \alpha = 4 \) (solid curve) and \( \beta = 2\sqrt{2} \) (dashed curve). The \( \alpha = 4 \) value could correspond to a strictly atomistic, 1s-like in 2D, electron density. For a detailed comparison, two other potentials are also plotted. That is, the bare Coulomb one, \( V_c(r) = (-1/r) \), and the conventional Thomas-Fermi form, \( V_{TF}(r) \) of Eq.(4).
FIG. 1: (Color online) The shielded attractive potentials of Eq.(5) (solid blue curve) and Eq.(6) (dashed red curve) with $\alpha = 4$ and $\beta = 2\sqrt{2}$, respectively. The dotted black curve refers to a bare Coulomb potential, $-1/r$. The dash-dotted green curve is devoted to the attractive Thomas-Fermi form of Eq.(4).

In order to go beyond the $\int_0^{\infty} dr r V(r) = 0$ condition, one may multiply the shielding parts of Eqs.(5) and (6) by a $\lambda$ variable [See Eqs. (10) and (13) below]. In such a way we can investigate the overscreened ($\lambda > 1$) and underscreened ($\lambda < 1$) cases, for which $\int_0^{\infty} dr r V(r, \lambda) \neq 0$. Moreover, as discussed above the effective potentials have a multiplicative coupling constant $\Lambda$, $[V_{\text{eff}}(r) = \Lambda V(r, \lambda)]$. In our 2D numerics $\Lambda$ and $\lambda$ will serve as convenient parameters.

**B. Numerical solution of the 2D Schrödinger equation**

The bound-state energy levels ($E_b$) and wave functions [$\psi(r)$] satisfy the 2D Schrödinger equation

$$\left[ -\frac{1}{2\mu} \nabla^2 + V_{\text{eff}}(r) - E_b \right] \psi(r) = 0,$$

where $\mu$ is the reduced mass; it is unity for the impurity-electron case.

In circular symmetry the wave function separates as

$$\psi(r) = e^{im\phi} R_{mn}(r),$$

where $m = 0, \pm1, \pm2, \ldots$ is the azimuthal quantum number and $n = 1, 2, 3, \ldots$ is the radial
quantum number related to the number of radial nodes \((n - 1)\) of the radial wave function \(R_{mn}(r)\). In this work we are only interested in the values \(m = 0\) and \(n = 1\). Further, by making the substitution \(U_{mn}(r) = r^{1/2}R_{mn}(r)\) we obtain the differential equation

\[
\frac{d^2 U_{mn}(r)}{dr^2} + \left( 2\mu [E_b - V_{eff}(r)] - \frac{(m^2 - 1/4)}{r^2} \right) U_{mn}(r) = 0.
\] (9)

This is the same form as the radial equation studied in spherically symmetric problems. We solve the equation on an exponentially expanding radial mesh, \(r(j) = r_{\text{min}} \exp((j-1)\Delta x)\) with \(j=1\ldots N\). With a given guess for the eigenvalue \(E_b\) the function \(U_{mn}(r)\) is integrated outwards from origin and inwards from a large radius by starting with its asymptotic expansions. At a matching point close to the classical turning point the logarithmic derivatives of the outward and inward integrated solutions are required to coincide by adjusting the eigenvalue \(E_b\). The parameters of the radial mesh, \(r_{\text{min}}, \Delta x,\) and \(N\) are varied until the numerical convergence of the eigenvalue is obtained.

C. Attractive electron-ion interaction

According to our numerical calculations, the attractive \(V_{TF}(r)\) of Eq.(4) gives \(E_b^{(TF)} = -0.2853\), while the \(V_H(r)\) of Eq.(5) results in \(E_b^{(H)} = -0.0296\) values for \(\alpha=4\), in Hartree units. There is an about order-of-magnitude reduction in binding due to an atomistic screening, beyond quasiclassics.

In order to study the so-called not everywhere nonpositive case (physically: the shielded positive charge) in more detail we will use, without loss of generality, \(\alpha = 4\) in Eq.(5) and modify it as

\[
V_{\text{eff}}^H(r) = -\Lambda \frac{1}{r} \left( 1 - 8\lambda r^2 [I_0(2r)K_1(2r) - I_1(2r)K_0(2r)] \right).
\] (10)

In Fig. 2 we have plotted the \(E_b^{(H)}(\lambda)\) energies obtained with \(\Lambda=1\) and \(\lambda \in [0.97,1.03]\). The \(\lambda\)-tuning refers to small under- and overscreening. The figure clearly shows the sensitivity of binding on the details of shielding. For \(\lambda > 1\) one has \(\int_0^\infty dr r V_{\text{eff}}(r) > 0\), with Eq.(10).

Additional information on the \(\Lambda\)-dependence of \(E_b^{(H)}(\Lambda)\) for Eq.(10) and \(\lambda=1\), are given in Fig. 3 with \(\Lambda \in [1.25,0.75]\). In this case \(\int_0^\infty dr r V_{\text{eff}}(r) = 0\) for any (finite) \(\Lambda\), as we pointed out earlier. In harmony with Simon’s theorem\(^11\), \(|E_b(\Lambda)| \leq \exp(-c\Lambda^{-2})\), we get for our case \([E_b^{(H)}(\Lambda)]\) an about \(c = 5.292\) value for the suitable constant in the investigated
FIG. 2: Binding energy, $E_b^{(H)}(\lambda)$, based on Eq.(7) with Eq.(10) for $\Lambda=1$ and $\lambda \in [0.97, 1.03]$. The macroscopic dielectric constant of a real medium can result in reduced, $\Lambda < 1$ values to effective interactions.

In this attractive impurity case we have shown a remarkable sensitivity of theoretical bound-state characteristics to shielding conditions. This is in accord with important spectroscopic information obtained by scanning tunneling spectroscopy for different adatoms in generated standing wave patterns. The observed peak-shift and amplitude-decrease in differential tunneling conductance, as adatoms are approached to a step on the surface, signal the experimental sensitivity.

We note that our detailed numerical analysis is based on an effective Schrödinger equation. Further attempts are needed therefore to consider the many-body aspects of the localization problem in more detail. For example, the proper description of the width of an adatom-induced weakly bound state and its influence on scattering characteristics are important questions to future studies.

D. Repulsive electron-electron interaction

The so-called not everywhere nonnegative case (physically: the shielded negative charge) will be treated similarly via Eq.(5) of positive sign, but with the constraint

$$\lambda \alpha^2 / 2\pi \equiv n_0 = 1/(\pi r_s^2)$$

in order to model bounded, complete depletion of the 2D electron gas density at $r = 0$. Here $r_s$ is the density-parameter of the 2D gas with density $n_0$. The same constraint is used to
FIG. 3: Binding energy, $E_b^{(H)}(\Lambda)$, based on Eq.(7) with Eq.(10) for $\lambda=1$ and $\Lambda \in [1.25, 0.75]$. The corresponding (positive sign) reparametrized Eq.(6) with

$$\lambda \beta^2/\pi \equiv n_0 = 1/(\pi r_s^2)$$

(12)
as

$$V_{eff}^G(r) = +\Lambda \frac{1}{r} \left( 1 - \lambda \sqrt{2\pi z} I_0(z) e^{-z} \right) ,$$

(13)
where, according to the above discussion, $z = (r/r_s)^2/(2\lambda)$ now. Remember, that at $\lambda = 1$ one has $\int_0^\infty dr r V_{eff}^G(r) = 0$, independently of the value of a finite $\Lambda$.

As we use the depletion-constraint-based densities to model effective electron-electron interactions, it is important to give an additional physical argument on their proper behaviour. The interaction energy ($\varepsilon$) of a repulsive point charge with the surrounding, normalized ($\lambda = 1$) shielding hole can be characterized by the classical equation

$$\varepsilon = -\frac{1}{2} 2\pi \int_0^\infty dr \frac{1}{r} \Delta n(r).$$

(14)
This equation results in the $\varepsilon_H = -1/(\sqrt{2}r_s)$, and $\varepsilon_G = -\sqrt{\pi}/(2r_s)$ expressions for the exponential and gaussian screening, respectively. These energies are between the values based on the exchange-only, $\varepsilon_x = -4\sqrt{2}/(3\pi r_s)$, and Wigner-monatom$^{13,14} \varepsilon_W = -1/r_s$, limiting approximations. The latter corresponds to the $\Delta n(r < r_s) = n_0$ extremum model for the hole-density, while the former to the Pauli-hole$^{15}$ of an ideal 2D system.

The two repulsive potentials, discussed above in details, are used in Eq.(7) with the reduced mass $\mu = 1/2$, and the following numerical results are obtained. The binding energies $E_b(r_s)$ are plotted in Fig. 4, as a function of the density parameter $r_s$. Computed
FIG. 4: (Color online) Binding energies, $E_b(r_s)$, in the shielded field of a negative charge. Data are based on Eq. (7) with $\mu = 1/2$, and $\Lambda = \lambda = 1$ in the applied two effective interactions. The solid blue and dashed red curves refer to hydrogenic [Eq. (5)] and gaussian [Eq. (6)] models, respectively. See the text for further details.

Remarkably, there are $r_s$ parameter values at which the binding energies are optimal, i.e., they have extremal values. By increasing or decreasing the density of the electron gas, the bindings become weaker. The extremal values are at about $r_s = 11.4$ for the hydrogen-like model, and at $r_s = 17.2$ for the gaussian model. The binding energies are in the $10^{-3}$ range in atomic units, for the dilute system. The low carrier density and thus a small Fermi energy, $\varepsilon_F = 1/r_s^2$, are important characteristics of cuprate superconductors. In these materials the ratio of the critical temperature ($T_c$) and the Fermi energy is in the range of $10^{-1}$. Furthermore, there is a saturation and supression of $T_c$ with increasing carrier density; for further detail we refer to Fig. 3 of Ref.[16].

The observed extremal character is related, physically, to our pseudononlineal construction of effective shielding of repulsive charges. Namely, the constraint via the bounded depletion hole at $r = 0$ fixes a reasonable scaling in the potentials. In standard linear-response theory the hole-density at $r = 0$ can become higher than the host density $n_0$. In such an attempt one can get a monotonic dependence of $E_b(r_s)$ on $r_s$ in the resulting shielded fields.

Further information is given in Figs. 5 and 6, which show the 2D radial densities,
FIG. 5: The radial density $2\pi r |\psi(r)|^2$ and the potential based on hydrogenic screening of a negative unit-charge. These are computed at the $r_s = 11.4$ value of the density parameter.

FIG. 6: The radial density $2\pi r |\psi(r)|^2$ and the potential based on gaussian screening of a negative unit-charge. These are computed at the $r_s = 17.2$ value of the density parameter.

$2\pi r |\psi(r)|^2$, computed with bound-state wave functions at the extremal Wigner-Seitz parameters. The corresponding potentials are also plotted. As expected, the square-integrable wave functions are localized at about the potential minima. In the investigated equal-mass case this extension can represent a certain coherence-length; somewhat surprisingly it is only twice of the extremal density parameter.

As we observed in Fig. 3 for the attractive case, the binding energy depends on the coupling, $\Lambda$. An illustration on this fact for the repulsive case is given in Fig. 7. The gaussian model of Eq. (13) is used with $\lambda = 1$, $\mu = 1/2$, and $r_s = 17.2$. Results for $\Lambda < 1$ are plotted. We can approximate our data by a quadratic expression, i.e., $|E_b^{(G)}(\Lambda)| \sim \Lambda^2$. Rescaling of $\Lambda = 1$ by a macroscopic dielectric constant could result in a notable reduction of the above-mentioned (see, Fig. 4, also) binding energies.

We finish our representation, by discussing the question of undershielding the repulsive
FIG. 7: The coupling-constant (Λ) dependence of the binding energy for the repulsive case. The results are based on the gaussian model of Eq.(13) with μ = 1/2 in Eq.(7). The Wigner-Seitz parameter is rs = 17.2 and Λ = 1.

FIG. 8: The shielding-constant (λ) dependence of the binding energy for the repulsive case. The results are based on the gaussian model of Eq.(13) with μ = 1/2 in Eq.(7). The Wigner-Seitz parameter is rs = 17.2 and Λ = 1.

charge. Fig. 8 is devoted to this problem. We have used Eq.(13) with Λ = 1 and λ < 1 in the Schrödinger equation, Eq.(7) with μ = 1/2, at rs = 17.2. One can observe (see, Fig. 2, for the attractive case) essential reductions of energies for the \( \int_0^\infty dr rV(r) > 0 \) unconventional condition.

The last results of Figs. 7 and 8, together with Figs. 4-6, signal a nontrivial sensitivity of the magnitude of the binding energy on the concrete physical situation. Fortunately, there is a physical limitation. It should be clear from the discussion at Eq.(14), and as our illus-
trative figures indeed show, that a more localized real-space character of the bounded (and normalized) depletion hole around a repulsive unit-charge, results in an effective potential with a repulsive part of a shorter range. Clearly, the limitation is given by the Wigner model, in which one has the $\Delta n(r \leq r_s) = n_0$ extremum for the hole.

III. SUMMARY

In this work we have investigated the problem of bound states in two-dimensional shielded potentials. Effective potentials, based on direct approximation for the screening charge densities around attractive and repulsive unit charges, are employed. Particularly, the effective electron-electron interaction is modelled via a properly constrained depletion hole. In the detailed numerical analysis performed, we found that in both of the basically attractive, and basically repulsive potentials bound states appear under the $\int_0^\infty drrV(r) = 0$ standard, and may appear under the $\int_0^\infty drrV(r) > 0$ unconventional conditions. In the repulsive case an extremal character of the binding energy, as a function of the density of the host 2D electron gas, is established with our physical models for effective electron-electron interactions.
