ABSTRACT

A new simple dynamo model for stellar activity cycle is proposed. By considering an inhomogeneous flow effect on turbulence, it is shown that turbulent cross helicity (velocity–magnetic-field correlation) enters the expression of turbulent electromotive force as the coupling coefficient for the mean absolute vorticity. This makes the present model different from the current \(\alpha\)-\(\Omega\) models in two main ways. First, in addition to the usual helicity (\(\alpha\)) and turbulent magnetic diffusivity (\(\beta\)) effects, we consider the cross-helicity effect as a key ingredient of the dynamo process. Second, the spatiotemporal evolution of cross helicity is solved simultaneously with the mean magnetic fields. The basic scenario is as follows. In the presence of turbulent cross helicity, the toroidal field is induced by the toroidal rotation. Then, as in usual models, the \(\alpha\) effect generates the poloidal field from the toroidal one. This induced poloidal field produces a turbulent cross helicity whose sign is opposite to the original one (negative production). With this cross helicity of the reversed sign, a reversal in field configuration starts. Eigenvalue analyses of the simplest possible model give a butterfly diagram, which confirms the above scenario and the equatorward migrations, the phase relationship between the cross helicity and magnetic fields. These results suggest that the oscillation of the turbulent cross helicity is a key for the activity cycle. The reversal of the cross helicity is not the result of the magnetic-field reversal, but the cause of the latter. This new model is expected to open up the possibility of the mean-field or turbulence closure dynamo approaches.

Key words: dynamo – magnetohydrodynamics (MHD) – stars: general – Sun: magnetic fields – turbulence

1. INTRODUCTION

Stellar magnetic activity cycles, in particular the solar cycles, has been investigated in an elaborate manner with several types of dynamo model (Brandenburg & Subramanian 2005; Charbonneau 2010, 2014). Depending on the ingredients of the models, such as the field-generation mechanism, location for the dynamo action to work, role of the large-scale flows, etc., the dynamo model may be classified into several categories or classes. The mean-field \(\alpha\)-\(\Omega\) dynamos (Parker 1955, 1979; Moffatt 1978; Krause & Rädler 1980), the interface dynamos (Parker 1993; Tobias 1996), the flux-transport dynamos (Wang et al. 1991; Choudhuri et al. 1995; Durney 1995; Choudhuri 2011), and the nonlinear dynamic dynamos (Brandenburg et al. 1989; Tobias 1997; Arlt & Rüdiger 1999; Pipin 1999, 2004; Kleeroin et al. 2000, 2006; Pipin & Kosovichev 2011; Weiss & Tobias 2016) are representative ones.

Among others, the migrating mean-field dynamo mechanism (Parker 1955, 1979) has been paid considerable attention because of the novelty of its physical insights and the simplicity of the model structure. In the presence of helical properties of fluid motions, magnetic fields moving in the fluid can be twisted, leading to the possibility of a magnetic-field configuration that is perpendicular to the original magnetic-field one (Parker 1955). This effect is usually called the \(\alpha\) effect. Under this effect, the poloidal field can be generated from the twisted toroidal magnetic field. In addition to the \(\alpha\) effect, if fluid motions perpendicular to the magnetic field are nonuniform with respect to the magnetic-field direction, the magnetic field advected by the inhomogeneous flow leads to a magnetic-field configuration that is perpendicular to the original one. This differential-rotation effect is often called the \(\Omega\) effect. If the toroidal field in the solar convection zone is nonuniform along the latitudinal direction, a toroidal magnetic field can be produced from a poloidal one. Combination of the \(\alpha\) and \(\Omega\) effects may lead to an oscillational behavior of the toroidal and poloidal magnetic-field components. On the basis of this notion, Parker (1955) constructed a system of equations for the poloidal and toroidal magnetic-field components represented by the toroidal component of the vector potential, \(A^\phi(=A)\), and the toroidal component of the magnetic field, \(B^\phi(=B)\). In this system of equations (Parker equations), the statistical properties of small-scale or turbulent motions are represented by two transport coefficients, \(\alpha\) and \(\beta\).

The expressions for \(\alpha\) and \(\beta\) are obtained with the aid of a magnetohydrodynamic (MHD) turbulence closure theory. The expressions of \(\alpha\) and \(\beta\) depend on the closure theory adopted, ranging from simplest parameter expressions with no closure to elaborated ones based on a sophisticated MHD theory and modeling. The coefficient \(\alpha\) represents the helical properties of turbulence. On the other hand, \(\beta\) represents the enhanced or effective magnetic diffusivity due to turbulence. This effect is often called the turbulent magnetic diffusivity or anomalous resistivity. Under the assumption that the magnetic Reynolds number is low \((Rm \ll 1)\) where \(Rm = UL/\eta\) with \(U\) the characteristic velocity, \(L\) the characteristic length, and \(\eta\) the magnetic diffusivity, \(\alpha\) can be expressed in terms of the turbulent kinetic helicity \(\langle u' \cdot \omega \rangle\) \(u'\); velocity fluctuation; \(\omega'\) \((=\nabla \times u')\); vorticity fluctuation; \(\langle \cdots \rangle\); ensemble average). However, it is well known that in the high-\(Rm\) case, which is much more relevant to astrophysical phenomena, \(\alpha\) is expressed not only by the kinetic helicity but also with the correction due to the turbulent current helicity \(\langle b' \cdot j \rangle\) \(b'\);...
magnetic-field fluctuation; \(j' (= \nabla \times b')\); electric-current density fluctuation) (Pouquet et al. 1976). Since \(\alpha\) and \(\beta\) represent how much magnetic field is generated and destroyed by turbulence, respectively, the evaluations of \(\alpha\) and \(\beta\), as well as the spatiotemporal distribution and evolution of the differential rotation, are essential information for the evolution of the Parker equations. For a review of MHD closure theories in dynamos and more elaborated analysis of the inhomogeneous MHD turbulence, see Brandenburg & Subramanian (2005), Yoshizawa (1990), and Yokoi (2013).

More than a few studies have been done in this framework of the Parker equations. By assuming some flow configurations compatible with the observations, Steenbeck & Krause (1969) and Yoshimura (1975a, 1975b) succeeded in numerically reproducing the latitudinal evolution of the toroidal magnetic field (butterfly diagram). In order to obtain the equatorward migration of the toroidal magnetic field, it is required that the angular velocity should decrease as the radius increases in the solar convection zone (\(\partial \omega_r / \partial r < 0\) for the positive \(\alpha\) in the northern hemisphere; \(\omega_r\): angular velocity). However, the developments of helioseismology revealed that the real radial distribution of the angular velocity in the solar convective zone does not satisfy this requirement. In addition to this, Parker himself discussed the limitation of the \(\alpha\) dynamo in the solar convection zone from the viewpoint of magnetic-field buoyancy (Parker 1975). Once the magnitude of a magnetic field has been amplified to some level, the magnetic flux tube starts moving upward from deeper to shallower regions. Since this buoyancy convection timescale, even for a very weak magnetic field, is estimated to be very short as compared with the \(\alpha\)-dynamo amplification timescale, it reaches the solar surface without being sufficiently amplified by the dynamo. This is called the magnetic buoyancy dilemma intrinsic to the magnetic flux tube.

These difficulties have been considered to be obviated by assuming that the dynamo action is operated in a convectively stable thin layer between the radiative and convection zones (Parker 1975). This region is associated with a large differential rotation and is called the tachocline. In the tachocline dynamo picture, the solar magnetic field is generated by a strong differential rotation there and may have enough time to be amplified by the \(\alpha\) dynamo before it is raised by the magnetic buoyancy (Spiegel & Weiss 1980; van Ballegooijen 1982).

As mentioned above, depending on the location of the field generation, the dynamo models are divided into two types: (i) the flux-transport dynamo, which operates in the overshoot layer below the bottom of the convection zone; and (ii) the mean-field distributed dynamo, which works in the bulk of the convection zone, in particular at the subsurface shear layer.

On the surface of the Sun, large-scale meridional circulations with a speed of \(\sim 15\) m s\(^{-1}\) in the poleward direction have been observed. The combination of the meridional circulation and the \(\alpha-\Omega\) mean-field model demonstrated its ability to reproduce the basic features of the solar magnetic activity cycle such as the equatorward migration of the sunspots, the cycle period, and the phase difference between the poloidal and toroidal magnetic fields. In the combination with meridional circulations or convective-diffusive motions such as the Babcock–Leighton-type convection, which produces the east–west tilt of the sunspot pairs under the action of the Coriolis force on the magnetic flux tube during its rise through the convection zone, it is expected that the tachocline dynamo can reproduce several properties of the solar-activity cycle (Choudhuri et al. 1995; Dikpati & Gilman 2006). This approach is called the flux-transport dynamo. In practical numerical simulations of the model, the large-scale fluid motion is fixed according to the helioseismology observation data. It should be noted that the thin flux tube simulations by D’silva & Choudhuri (1993), Fan et al. (1993), and Caligari et al. (1995) showed that, with their initial and boundary conditions, the magnetic-field energy is greater than the turbulent-equipartition energy inside the convection zone, so it is hard for the toroidal field lines represented by the flux tube to be twisted by the helical turbulence. This suggests that the \(\alpha-\Omega\) dynamo is unlikely to operate on the flux tube inside the solar convection zone. At the same time, there are some unresolved problems on the flux-transport model results from the active-region observations, which include that (i) emerging bipolar active regions have no tilt, which is developed later (Stenflo & Kosovichev 2012; Stenflo 2012); (ii) the evolution of tilt depends on the size of the active regions (Tlatov et al. 2013; Mcclintock & Norton 2016); (iii) the active regions rotate more slowly than surrounding plasma with angular velocity that corresponds to the near-surface shear layer (Benevolenskaya et al. 1999); (iv) the greatest effect to the relative sunspot number comes from small active regions (Stenflo 2012); and (v) the long-term evolution of tilt in the solar cycle is still open (Dasi-Espuga et al. 2010; Tlatov et al. 2013).

As for the meridional circulation, however, its spatial pattern is still observationally open. It has been reported that the behavior of the dynamo magnetic field highly depends on the flow pattern of the meridional circulation adopted in the numerical simulation (Bonanno et al. 2006; Jouve & Brun 2007). The current observational status is seen in Zhao et al. (2013), Schad et al. (2013), and Rajaguru & Antia (2015). The flux-transport dynamo with very complicated meridional flow patterns was investigated, and it was shown that if an equatorward flow in low latitudes at the bottom of the convective zone is present, the flux-transport dynamo works even in the case of a meridional circulation with very complicated flow structures (Hazra et al. 2014). Similar works are seen for dynamos with double and multiple cells (Pipin & Kosovichev 2013, 2014) and dynamos in the global 3D simulations (Racine et al. 2011; Warnecke et al. 2014).

Apart from the practical predictability of the solar-activity cycle, there are still open issues in the flux-transport dynamo models. Some of them are related to the evaluation of spatiotemporal distributions of turbulence, its effects, and boundary conditions in the solar convection zone. For example, one of the essential ingredients of the flux-transport dynamo in general is the requirement for the spatial distribution of the effective or turbulent magnetic diffusivity: the turbulent magnetic diffusivity should decrease as the radial position becomes deeper. Because of this requirement, the magnetic field moves in the equatorward direction, reflecting the large-scale circulation motion in the deeper region. Otherwise, the magnetic field may move in the poleward direction, reflecting the circulation motion in the shallow region.

As has been seen in the above descriptions of the radial dependence of the turbulent magnetic diffusivity \(\beta\), basic behaviors of the large-scale magnetic field highly depend on the turbulent transport coefficients \(\alpha\) and \(\beta\), whose spatiotemporal evolutions are still not fully understood. In the current flux-transport dynamo model, the spatial distribution of the turbulent magnetic diffusivity \(\beta\) is prescribed, and the turbulent helicity-related transport coefficient \(\alpha\) is often treated as an adjustable parameter. An interesting point is the role of the magnetic fluctuations in magnetic-field reversal (Choudhuri et al. 2007; Choudhuri 2011). By comparing the observation of the photospheric magnetic-field
data with the predictions from a simple dynamo model with magnetic fluctuations, it was shown that the magnetic fluctuation level is highly connected with the behavior of the solar dipole during the polarity reversal (Pipin et al. 2014).

One possible alternative approach is to consider the spatiotemporal distributions of $\alpha$ and/or $\beta$ by solving the transport equations of them. Since the evolutions of $\alpha$, $\beta$, etc., depend on the mean fields, $\mathbf{B}$, $\nabla \times \mathbf{B}$, etc., the inclusion of the transport equations of them enables the incorporation of the nonlinear dynamics of dynamo into the model. In this line of thought, Schlichenmaier & Stix (1995) introduced the dynamic part of the $\alpha$ coefficient, $\alpha^\ast$, in addition to the given kinetic part $\alpha_m$, and constructed a simple transport equation of $\alpha^\ast$. By solving the equation of $\alpha^\ast$, as well as the equations for the toroidal components of the vector potential and magnetic field, $A$ and $B$, the phase difference between the poloidal and toroidal magnetic fields was reproduced in the numerical simulation. Related to the inviscid invariance of the total magnetic helicity $\int_V \mathbf{a} \cdot d\mathbf{b} dV$, it has some meaning to construct a transport equation of the current helicity density $\langle \mathbf{b} \cdot \mathbf{j} \rangle$ part of $\alpha$, $\alpha_m$. Kleeorin et al. (1995) adopted a simple model equation for $\alpha_m$ and estimated the magnitude of the dynamo-generated magnetic field in the solar-type convection zones.

In this paper, we suggest a new dynamo mechanism without showing any preference to the flux-transport dynamo scenario itself. We shall focus our attention on the inhomogeneous large-scale flow effect on the turbulent electromotive force (EMF). As we see in the following section, such an effect in the turbulent EMF is represented by the turbulent cross helicity (cross-correlation between the velocity and magnetic fluctuations) coupled with the mean or large-scale vorticity. Unlike the helicity and energy-related transport coefficients, $\alpha$ and $\beta$, the cross-helicity-related transport coefficient, $\gamma$, does change its sign during the magnetic-field reversal. In this sense, the spatiotemporal behavior of the turbulent cross helicity is directly connected to the evolution of magnetic fields, including the polarity reversal.

The cross helicity itself has been investigated in several contexts in space and astrophysical turbulence (Yokoi 2013). Plasma relaxation with a cross-helicity constraint (Biskamp 1993), the large-scale behavior of cross helicity in the solar-wind turbulence (Yokoi et al. 2008; Yokoi 2011), and the transport enhancement and suppression in the turbulent magnetic reconnection (Yokoi & Hoshino 2011; Higashimori et al. 2013; Yokoi et al. 2013; Widmer et al. 2016) are representative subjects of such investigations. In the context of the solar dynamo and activity cycle, some studies have been done related to the cross helicity. On the basis of an expression for the turbulent cross-helicity and/or the evolution equation of the turbulent cross helicity, the dynamic evolution of the turbulent cross helicity under the effects of the density stratification, large-scale magnetic fields, differential rotation, etc., was examined in the frameworks of a mean-field dynamo and of a flux-transport dynamo (Kleeorin et al. 2003; Kuzanyan et al. 2007; Pipin et al. 2011). An attempt to measure the cross helicity on the surface of the Sun by observation has also been reported (Zhao et al. 2011).

A dynamo model, where the poloidal and toroidal magnetic fields are induced by the helicity and cross-helicity effects, respectively, had been applied to the solar magnetic-field reversal problem (Yoshizawa et al. 2000). Although the dynamics of the toroidal-field evolution was not solved there, an oscillational behavior of the magnetic field was predicted with the aid of a very simple toy model. With this point in mind, in addition to the mean magnetic-field equations, in this work we shall include the transport equation of the turbulent cross helicity rather than the counterparts of the turbulent energy and/or helicity.

The organization of this paper is as follows. In Section 2, we point out the importance of the mean-flow inhomogeneity in treating turbulence, and how this inhomogeneity leads to the cross-helicity effect. In Section 3, the dynamo equations with the cross-helicity effect are presented and reduced to the simplest form, with several assumptions and boundary conditions. In Section 4, an eigenvalue analysis is carried out and the critical condition for the oscillation of the magnetic field and the turbulent cross helicity is discussed. In Section 5, the butterfly diagram of the magnetic field is discussed, with special reference to the cross-helicity effect. The concluding remarks are given in Section 6.

2. FLOW INHOMOGENEITY AND CROSS-HELiCITY EFFECT

The inhomogeneities of the mean or large-scale fields are important ingredients providing a free-energy source for turbulence. For example, the mean-velocity shear, or strictly speaking the mean-velocity strain, is considered to be one of the key ingredients producing turbulent energy. In the absence of the large-scale flow shear, we need some external source or forcing to generate and sustain turbulence. Here we focus on the mean-flow inhomogeneity in dynamo and turbulence and examine the resultant effect on the turbulent EMF in the global magnetic-field equation.

2.1. Mean Flow Inhomogeneity in Dynamos

The equation of the mean magnetic field $\mathbf{B}$ is written as

$$\frac{\partial \mathbf{B}}{\partial t} = \nabla \times \left( \mathbf{U} \times \mathbf{B} \right) + \nabla \times \mathbf{E}_M + \eta \nabla^2 \mathbf{B},$$

(1)

where $\mathbf{U}$ is the mean velocity, $\eta$ is the molecular magnetic diffusivity, and $\mathbf{E}_M$ is the turbulent EMF defined by

$$\mathbf{E}_M \equiv \left\langle \mathbf{u}' \times \mathbf{b}' \right\rangle$$

(2)

($\mathbf{u}'$: velocity fluctuation; $\mathbf{b}'$: magnetic fluctuation; $\langle \cdots \rangle$: ensemble average), which represents the turbulence effect in the mean magnetic-field induction. In the first term of Equation (1), the motions parallel to the mean magnetic field have no contributions, so we rewrite the first term on the right-hand side as

$$\nabla \times \left( \mathbf{U} \times \mathbf{B} \right) = \nabla \times \left( \mathbf{U}_\perp \times \mathbf{B} \right) = -\left( \mathbf{U}_\perp \cdot \nabla \right) \mathbf{B} - \mathbf{B} \left( \nabla \cdot \mathbf{U}_\perp \right) + \left( \mathbf{B} \cdot \nabla \right) \mathbf{U}_\perp,$$

(3)

where $\mathbf{U}_\perp$ is the mean velocity perpendicular to the mean magnetic field. The first term in Equation (3) represents the advective derivative of the mean magnetic field due to the mean velocity. The second term represents the mean magnetic-field reduction (or induction) due to the divergence ($\mathbf{U}_\perp \cdot \nabla > 0$) (or convergence ($\mathbf{U}_\perp \cdot \nabla < 0$)) of the mean velocity. The third term indicates that the mean magnetic field is induced by a mean flow in the direction of the mean velocity if the velocity is inhomogeneous along the mean magnetic field (the differential-rotation effect). In the dynamo studies, this differential-rotation effect, often called the $\Omega$ effect, has been considered to play an essential role in producing the toroidal component of the mean magnetic field from the poloidal one.
Next, we consider the evolution of the fluctuation fields. The equations of the velocity and magnetic fluctuations, \( \mathbf{u}' \) and \( \mathbf{b}' \), are given as

\[
\frac{D\mathbf{u}'}{Dt} = (\mathbf{B} \cdot \nabla)\mathbf{b}' + (\mathbf{b}' \cdot \nabla)\mathbf{B} - (\mathbf{u}' \cdot \nabla)\mathbf{U} + \cdots, \tag{4}
\]

\[
\frac{D\mathbf{b}'}{Dt} = (\mathbf{B} \cdot \nabla)\mathbf{u}' - (\mathbf{u}' \cdot \nabla)\mathbf{B} + (\mathbf{b}' \cdot \nabla)\mathbf{U} + \cdots. \tag{5}
\]

In the case that the mean velocity \( \mathbf{U} \) is assumed to be uniform \( \mathbf{U} = \mathbf{U}_0 (\mathbf{U}_b; \text{uniform mean velocity}) \) and the inhomogeneity of the mean velocity is entirely neglected, Equations (4) and (5) are reduced to

\[
\frac{D\mathbf{u}'}{Dt} = (\mathbf{B} \cdot \nabla)\mathbf{b}' + (\mathbf{b}' \cdot \nabla)\mathbf{B} + \cdots, \tag{6}
\]

\[
\frac{D\mathbf{b}'}{Dt} = (\mathbf{B} \cdot \nabla)\mathbf{u}' - (\mathbf{u}' \cdot \nabla)\mathbf{B} + \cdots. \tag{7}
\]

The temporal evolution of the turbulent EMF \( E_M \) (Equation (2)), in general, is given by the equations for the velocity and magnetic-field fluctuations as

\[
\frac{D}{Dt} \langle \mathbf{u}' \times \mathbf{b}' \rangle = \left( \frac{D\mathbf{u}'}{Dt} \times \mathbf{b}' + \mathbf{u}' \times \frac{D\mathbf{b}'}{Dt} \right). \tag{8}
\]

If we adopt Equations (6) and (7) for the fluctuation equations, \( E_M \) has no direct dependence on the mean-velocity inhomogeneities. The often-adopted ansatz “the turbulent electromagnetic force should be expressed in terms of the expansion of linear functions of the mean magnetic field” as

\[
\langle \mathbf{u}' \times \mathbf{b}' \rangle^a = \alpha^{ab} B^b + \beta^{abc} \frac{\partial B^a}{\partial x^b} + \cdots, \tag{9}
\]

should be understood in this context of neglecting the mean-velocity inhomogeneities in turbulence equations.

If we compare the fluctuation equations (Equations (6) and (7)) with the mean-field equation (Equation (1)), it is obvious that the treatments of the mean-velocity inhomogeneities in fluctuation and mean equations are remarkably different. In the mean magnetic-field evolution, an inhomogeneous mean flow is considered to play an essential role in magnetic field generation. On the other hand, in the fluctuation evolution, the effects of inhomogeneous mean flow are completely neglected.

### 2.2. Cross-helicity Effect

#### 2.2.1. Mean Flow Inhomogeneity and Cross Helicity

The turbulent cross helicity is the cross-correlation between the velocity and magnetic-field fluctuations defined by

\[
W \equiv \langle \mathbf{u}' \cdot \mathbf{b}' \rangle. \tag{10}
\]

If we retain the mean-velocity inhomogeneities in the fluctuation equations (Equations (4) and (5)), from Equation (8), we naturally have contributions of the cross helicity to the turbulent EMF as

\[
\tau \langle \mathbf{u}' \times [(\mathbf{b}' \cdot \nabla)\mathbf{U}] + [(\mathbf{u}' \cdot \nabla)\mathbf{U}] \times \mathbf{b}' \rangle^a = e^{ab}_{\text{mean}} \langle \mathbf{u}'^a \mathbf{b}'^b \rangle \frac{\partial U^b}{\partial x^c} - e^{ab}_{\text{mean}} \langle \mathbf{b}'^a \mathbf{u}'^b \rangle \frac{\partial U^b}{\partial x^c} \tag{11}
\]

\[
\tau \langle \mathbf{u}'^a \mathbf{b}'^b \rangle \frac{\partial U^b}{\partial x^c} = \tau \langle \mathbf{u}'^a \mathbf{b}'^b \rangle e^{cd}_{\text{mean}} \frac{\partial U^b}{\partial x^c}, \tag{12}
\]

where \( \tau \) is the characteristic timescale of turbulence. If we adopt the isotropic representation of the cross-correlation tensor,

\[
\langle \mathbf{u}'^a \mathbf{b}'^b \rangle = \frac{2}{3} \delta^{ab} \langle \mathbf{u}' \cdot \mathbf{b}' \rangle \tag{13}
\]

For simplicity, Equation (11) is reduced to

\[
\tau \langle \mathbf{u}' \cdot [(\mathbf{b}' \cdot \nabla)\mathbf{U}] + [(\mathbf{u}' \cdot \nabla)\mathbf{U}] \times \mathbf{b}' \rangle^a
\]

\[
= \frac{2}{3} \tau \langle \mathbf{u}' \cdot \mathbf{b}' \rangle \langle \nabla \times \mathbf{U} \rangle^a. \tag{13}
\]

Of course, depending on the statistical properties of turbulence, the cross-correlation should have been expressed in a more elaborated form. In this sense, the isotropic representation (Equation (12)) is too simplified. However, we still see that the primary quantity that is coupled with the mean-flow inhomogeneity is the cross helicity or the cross-correlation between the velocity and magnetic-field fluctuations. For the elaborated expression for the mean vorticity-related term in the turbulent EMF, see Yoshizawa (1990) and Yokoi (2013).

The above argument clearly shows that, if we retain the mean-flow inhomogeneity in the turbulence equations, we should include the cross-helicity effect into the expression for the turbulent EMF, in addition to the usual effects such as the turbulent magnetic diffusivity \( \beta \) and the helicity or \( \alpha \) effect. Then turbulent EMF should be expressed as

\[
E_M = -\beta \mathbf{J} + \alpha \mathbf{B} + \gamma \mathbf{\Omega}. \tag{14}
\]

Here \( \beta \) is the turbulent magnetic diffusivity, which is related to the turbulent MHD energy, \( \alpha \) is the helicity or \( \alpha \) effect, which is related to the turbulent residual helicity (the difference of the kinetic and current helicity), and \( \gamma \) is the cross-helicity effect, which is related to the turbulent cross helicity. Simplified relationships are written as

\[
\beta = C_\beta \tau \langle \mathbf{u}'^2 + \mathbf{b}'^2 \rangle / 2 \equiv C_\beta \tau K, \tag{15a}
\]

\[
\alpha = C_\alpha \tau \langle -\mathbf{u}' \cdot \mathbf{\omega}' + \mathbf{b}' \times \mathbf{j}' \rangle \equiv C_\alpha \tau H, \tag{15b}
\]

\[
\gamma = C_\gamma \tau \langle \mathbf{u}' \times \mathbf{b}' \rangle \equiv C_\gamma \tau W, \tag{15c}
\]

where \( \tau \) is the characteristic timescale of turbulence and \( C_\beta, C_\alpha, \) and \( C_\gamma \) are the model constants. More elaborated expressions for these transport coefficients and their relationship to Equation (15) are given in the Appendix.

#### 2.2.2. Physical Origins

Equation (8) with Equation (11) or (13) shows that the cross-correlations between the velocity and magnetic fluctuations coupled with the mean-flow inhomogeneities lead to the cross-helicity effect in the turbulent EMF. In order to get a clear understanding of the cross-helicity effect, here we shall feature the physical processes and conditions that cause this effect.

As we saw in the expressions of Equation (15) (and its generalized ones in Equation (74)), the transport property of
turbulence is mainly determined by the largest-scale fluctuations or the energy-containing eddies. Since our main interests lie in the turbulent transport represented by the turbulent EMF, we shall here suppose that the random fluctuations are characterized by the length scale $\ell_c$ of the largest-scale fluctuations, which is roughly equal to the energy-containing eddies. The mean fields can be inhomogeneous within the dimension of $\ell_c$, as schematically depicted in Figure 1.

In hydromagnetic turbulence, it has been established that a nonuniform mean flow will greatly affect the turbulent transport. For instance, it is well known that the inhomogeneous mean flow gives an essential contribution to the momentum transport through the Reynolds stress, which is often expressed in terms of the eddy-viscosity representation after Boussinesq as

$$
\langle u^\alpha u^\beta \rangle_D = -\nu_T \left( \frac{\partial U^\alpha}{\partial x^\beta} + \frac{\partial U^\beta}{\partial x^\alpha} \right),
$$

(16)

where $\nu_T$ is the eddy or turbulent viscosity and $A_D$ denotes the traceless or deviatoric part of the tensor defined by $A_D^{\alpha\beta} = A^{\alpha\beta} - A^{\mu\nu} \delta_{\mu\beta}/3$. Note that Equation (16) is one of the simplest heuristic models for the Reynolds stress. As for the theoretical derivation of the Reynolds-stress expression (Equation (16) and further) with the analytical expressions of the transport coefficients, the reader is referred to Yoshizawa (1984) (for the mirror-symmetric case) and Yokoi & Yoshizawa (1993) and Yokoi & Brandenburg (2016) (for the non-mirror-symmetric case).

In what follows, we focus our attention on the mean-flow inhomogeneity effect on the magnetic-field transport.

**Magnetic fluctuation in mean-flow shear.** Let us consider a magnetic fluctuation $b'$ located in a large-scale vortical or rotational motion (Figure 2). Induction of the magnetic fluctuation arising from the mean fluid motion is subject to

$$
\frac{\partial b'}{\partial t} = \nabla \times (U \times b') + \cdots
$$

(17)

or equivalently

$$
\frac{D b'}{D t} = -b' \nabla \cdot U + (b' \cdot \nabla) U + \cdots
$$

(18)

(see also Equation (5)). The first term in Equation (18) is the mean-flow dilatation effect, which vanishes in the incompressible or solenoidal velocity case. The second term is associated with the rate of change that is observed in the mean velocity $U$ as we move along $b'$. The $b'$ induction due to this effect is written as

$$
\delta b' = \tau (b' \cdot \nabla) U.
$$

(19)

The direction of $\delta b'$ is in the direction of the mean flow $U$ as in Figure 2. This effect may be regarded as the turbulent counterpart of the differential-rotation effect (Equation (3)). If we assume that the turbulent cross helicity is positive ($\langle u' \cdot b' \rangle > 0$), the velocity fluctuation $u'$ is statistically aligned with the magnetic fluctuation $b'$, although the relationship between the turbulent velocity and magnetic-field vectors is much more random in each realization. It follows from Equation (19) that we have a contribution to the turbulent EMF as $\langle u' \times \delta b' \rangle$, which is parallel to the mean vorticity $\Omega$ for a positive turbulent cross helicity (Figure 2). For a negative turbulent cross helicity ($\langle u' \cdot b' \rangle < 0$), the contribution is antiparallel to $\Omega$. In Figure 2, only a case with increasing $U$ along $b'$ is depicted. In the opposite case with decreasing $U$ along $b'$, the direction of $\delta b'$ is antiparallel to the mean velocity $U$. Even in this case, the final contribution to the turbulent EMF, $\langle u' \times \delta b' \rangle$, is parallel to the mean vorticity $\Omega$ as long as the turbulent cross helicity is positive.

The above argument shows that the combination of the modulation of the magnetic fluctuation through the inhomogeneous mean flow and the cross-correlation between the velocity and magnetic fluctuations leads to the cross-helicity effect in the turbulent EMF.

**Velocity fluctuation in mean-flow shear.** We consider a fluid element fluctuating ($u'$) in the mean vortical or rotational motion $\Omega$ shown in Figure 3. The motion is subject to the mean vortical motion, which is locally equivalent to the rotation with an angular velocity of $\omega = \Omega/2$. A modulation of the velocity fluctuation, $\delta u'$, is induced by the Coliories-like force as

$$
\delta u' = \tau u' \times \Omega.
$$

(20)

As in the previous case, we assume a positive cross helicity in turbulence ($\langle u' \cdot b' \rangle > 0$). Due to this assumption, the magnetic fluctuation $b'$ is statistically aligned with the velocity fluctuation $u'$. It follows from Equation (20) that we have a contribution to the turbulent EMF as $\langle \delta u' \times b' \rangle$, which is parallel to the mean vorticity $\Omega$ for a positive turbulent cross helicity (Figure 3).
The Astrophysical Journal, 824:67 (12pp), 2016 June 20

Yokoi et al.

Figure 3. Velocity fluctuation in the mean-flow inhomogeneity. Contribution to the turbulent EMF is parallel to the mean vorticity if the cross helicity is positive in turbulence.

The above argument shows that it is the combination of the local angular-momentum conservation and the cross helicity in turbulence that induces the cross-helicity effect in the turbulent EMF.

2.2.3. Field Configurations

In the usual dynamo model, the turbulent EMF is expressed by Equation (14) with the cross-helicity-related term $\gamma \Omega$ dropped. There the turbulent EMF is composed of the turbulent magnetic diffusivity $\beta$ and the helicity or $\alpha$ effects. The turbulent magnetic diffusivity $\beta$ always arises as far as turbulence is present. In this sense, $\beta$ is the primary effect of turbulence in the mean magnetic-field evolution. If the mirror symmetry of turbulence is broken typically by a rotation, some other turbulence effects such as the $\alpha$ effect enter into the turbulent EMF. In case the $\beta$ effect is mainly balanced by the $\alpha$ effect, a mean-field configuration with the alignment between the mean electric-current density and magnetic field, $J$ and $B$, is expected. In an extreme situation, the so-called force-free field configuration ($B \parallel J$, $J \times B = 0$) arises. The direction of $B$ relative to $J$ (parallel or antiparallel) depends on the sign of $\alpha$. In the other extreme case where the $\beta$ effect is mainly balanced by the cross-helicity or $\gamma$ effect, a mean-field configuration with the alignment between the mean electric-current density and vorticity, $J$ and $\Omega$, is expected. One possible configuration that leads to this alignment of $J$ and $\Omega$ is the alignment of $B$ with the mean flow $U$. This suggests that a typical mean-field configuration in the cross-helicity dynamo is the mean magnetic field aligned to the mean velocity.

These situations may be schematically expressed as

\[
\begin{align*}
E_M &= \alpha B - \beta J + \gamma \Omega, \\
\text{cross-helicity dynamo}
\end{align*}
\]

(21)

Which of the $\alpha$ and $\gamma$ effects plays a more relevant role in turbulent dynamo depends on how much $\alpha$ and $\gamma$ we have in turbulence, in addition to how much strong mean magnetic field and vorticity, $B$ and $\Omega$, we have. We already saw in Equation (15) that the transport coefficients are directly related to the statistical property of turbulence. From the turbulent dynamo viewpoint, the mean-field configurations realized in astrophysical phenomena are determined by how many residual and cross helicities we have in turbulence and how they are spatiotemporally distributed in relation to the turbulent energy, which determines the dynamics of the turbulent magnetic diffusivity $\beta$.

It is worthwhile to note that the turbulent EMF expression (Equation (14)) was validated with the aid of a direct numerical simulation (DNS) of the Kolmogorov flow with an imposed magnetic field in the inhomogeneous direction (Yokoi & Balarac 2011). In the numerical experiment, it was shown that the cross-helicity effect coupled with the mean vorticity is the main balancer to the turbulent magnetic diffusivity, and the role of the helicity effect in this particular flow is almost negligible. For detailed explanations of the cross helicity and related dynamo, the reader is referred to Yokoi (2013).

2.2.4. Cross-helicity Evolution

Thus far, we have seen that the turbulent EMF has a contribution from the mean-flow inhomogeneity in the presence of the turbulent cross helicity. How much cross helicity we have in turbulence is another problem. In this subsection, we address this problem by considering the transport equation of the turbulent cross helicity.

From Equations (4) and (5), the evolution equation of the turbulent cross helicity $W$ is written as

\[
\frac{DW}{Dt} = -\mathcal{R}^{ab} \frac{\partial B^b}{\partial x^a} - E_M \cdot \Omega - \varepsilon_W + T_W, 
\]

(22)

where $\mathcal{R} = \{ \mathcal{R}^{\alpha \beta} \}$ is the Reynolds stress defined by

\[
\mathcal{R}^{\alpha \beta} = \langle u^\alpha u^\beta - B^\alpha B^\beta \rangle. 
\]

(23)

Strictly speaking, this should be called the Reynolds stress subtracted by the turbulent Maxwell stress, but we denote Equation (23) as the Reynolds stress of MHD turbulence in this work.

In Equation (22), the first and second terms are called the production terms since they express how much cross helicity is generated in turbulence through the cascade from the mean-field cross helicity $U \cdot B$. This point is clearer if we write the evolution equation of $U \cdot B$ as

\[
\frac{D}{Dt} U \cdot B = +\mathcal{R}^{ab} \frac{\partial B^b}{\partial x^a} + E_M \cdot \Omega + \cdots, 
\]

(24)

which contains exactly the same terms but with the opposite signs as Equation (22).

The third and fourth terms in Equation (22), $\varepsilon_W$ and $T_W$, are the dissipation and transport terms, respectively, whose definitions and detailed expressions are suppressed here. In turbulence modeling, the transport terms are expressed as

\[
T_W = B \cdot \nabla K + \nabla \cdot \left( \frac{\nu_K}{\sigma_W} \nabla W \right),
\]

(25)

where $\nu_K$ is the turbulent viscosity and $\sigma_W$ is the Prandtl number for the cross-helicity diffusion.

For detailed arguments on the turbulent cross-helicity evolution, including the modeling of the turbulent cross-helicity dissipation rate $\varepsilon_W$, the reader is referred to Yokoi (2011).

3. DYNAMO EQUATIONS WITH THE CROSS-HELICITY EFFECT

3.1. Basic Dynamo Equations with the Cross-helicity Effect

If we adopt Equation (14) for $E_M$, the mean magnetic induction equation is written as

\[
\frac{\partial B}{\partial t} = \nabla \times (U \times B) + \nabla \times (-\beta \nabla \times B + \alpha B + \gamma \Omega). 
\]

(26)
In usual simple dynamo models such as the Parker model, only the transport equations for the magnetic field are taken into account, with the transport coefficients being treated as parameters. In contrast, in the present work, in addition to the $B$ equation, we consider the spatiotemporal evolution of the transport coefficient $\gamma$, which is related to the cross-helicity effect. On the basis of Equation (22), the $\gamma$ equation is modeled as
\[
\frac{\partial \gamma}{\partial t} = \beta \gamma^2 - \alpha \tau B \cdot \Omega + \beta \tau (\nabla \times B) \cdot \Omega - \gamma \tau \Omega^2. 
\] (27)
Here the first term arises from the second term in Equation (25), and the second to fourth terms come from the second term in Equation (22) with $E_M$ (Equation (14)).

Equations (26) and (27) constitute the basic dynamo equations with the cross-helicity effect.

### 3.2. Assumptions on the Rotation and Magnetic Field

Let us consider the local Cartesian coordinate $(x, y, z)$, where $x$, $y$, and $z$ axes are directed in the colatitudinal ($\theta$), azimuthal ($\phi$), and radial ($r$) directions, respectively:
\[
(x, y, z) = (r, \phi, \theta). 
\] (28)
We assume the azimuthal symmetry:
\[
\frac{\partial}{\partial \phi} = 0. 
\] (29)
As for the solar rotation in the convection zone, we assume the mean velocity is only in the azimuthal direction and omit the meridional circulations as
\[
U = (U_x, U_y, U_z) = (0, 0, U_z), 
\] (30)
with the mean-velocity shear in the lateral and radial direction, $\partial U_x/\partial y$ and $\partial U_y/\partial y$. As usual, the mean magnetic field is decomposed into the toroidal and poloidal components, $B_{tor}$ and $B_{pol}$, respectively, as
\[
B = (B_x, B_y, B_z) = B_{tor} + B_{pol} \\
= (0, B_y, 0) + \nabla \times (0, A_x, 0) \\
= (0, B_y, 0) + \left( \frac{\partial A_x}{\partial z} - \frac{\partial A_y}{\partial x}, 0, \frac{\partial A_y}{\partial x} \right). 
\] (31)
Hereafter we drop index $y$ on $B_y$, $A_x$, and $U_y$ for brevity of notation.

### 3.3. Basic Dynamo Equations

We further omit the $\alpha$-related term in the equation for $B$. This is because we assume that the toroidal magnetic field is dominantly generated by the mean-velocity inhomogeneities. Under these assumptions, Equations (26) and (27) are reduced to the following equations.

**Vector potential for poloidal field:**
\[
\frac{\partial A}{\partial t} = \beta \left( \frac{\partial^2 A}{\partial x^2} + \frac{\partial^2 A}{\partial z^2} \right) + \alpha B. 
\] (32)

**Toloidal field:**
\[
\frac{\partial B}{\partial t} = \beta \left( \frac{\partial^2 B}{\partial x^2} + \frac{\partial^2 B}{\partial z^2} \right) - \frac{\partial^2 U}{\partial z^2} \gamma - \frac{\partial^2 U}{\partial x^2} \gamma \\
- \frac{\partial U}{\partial z} \frac{\partial A}{\partial x} - \frac{\partial U}{\partial x} \frac{\partial A}{\partial z} - \frac{\partial U}{\partial x} \frac{\partial A}{\partial z} - \frac{\partial U}{\partial z} \frac{\partial A}{\partial x}. 
\] (33)

Cross helicity:
\[
\frac{\partial \gamma}{\partial t} = \beta \left( \frac{\partial^2 \gamma}{\partial x^2} + \frac{\partial^2 \gamma}{\partial z^2} \right) - \alpha \tau \left( \frac{\partial U}{\partial x} \frac{\partial A}{\partial x} + \frac{\partial U}{\partial z} \frac{\partial A}{\partial z} \right) \\
+ \beta \tau \left( \frac{\partial U}{\partial x} \frac{\partial B}{\partial x} - \frac{\partial U}{\partial z} \frac{\partial B}{\partial z} \right) \\
- \gamma \tau \left( \frac{\partial U}{\partial x} + \frac{\partial U}{\partial z} \right)^2. 
\] (34)

### 3.4. Nondimensionalization

We introduce nondimensional variables as
\[
B = B_0 \bar{B}, \quad A = B_0 \bar{A}, \quad \gamma = \gamma_0 \bar{\gamma}, \quad x = L_x, \\
t = (L^2/\beta_0) \bar{t}, \quad U = U_0 \bar{U}, \quad \alpha = \alpha_0 \bar{\alpha}, \quad \beta = \beta_0 \bar{\beta}, 
\] (35)
with characteristic magnetic-field strength $B_0$, length scale $L$, cross-helicity effect $\gamma_0$, turbulent magnetic diffusivity $\beta_0$, mean-flow speed $U_0$, and helicity effect $\alpha_0$.

We assume some symmetries with respect to the equator ($x = \pi/2$) for the mean-flow speed $U$, helicity effect $\alpha$, turbulent magnetic diffusivity $\beta$, and timescale $t$ as
\[
\bar{U} = \sin x, \quad \bar{\alpha} = \cos x, \quad \bar{\beta} = 1, \quad \bar{t} = 1. 
\] (36)
Namely, at the equator, the mean flow is symmetric and maximum, while the helicity is antisymmetric and vanishes. The turbulent magnetic diffusivity and characteristic timescale are uniform.

We omit all the tildes ($\sim$) of the nondimensional variables in the following. As for the radial or $z$ dependence of $A$, $B$, and $\gamma$, we assume $\exp(ikz)$ dependence and assume $\partial U/\partial z = k_a U$. Then Equations (32)–(34) are rewritten as
\[
\frac{\partial A}{\partial t} = \frac{\partial^2 A}{\partial x^2} - k^2 A + R_a \cos x B, 
\] (37)
\[
\frac{\partial B}{\partial t} = \frac{\partial^2 B}{\partial x^2} - k^2 B \\
- R_a \left( k^2 \sin x \gamma + i k k_a \sin x \gamma - \sin x \gamma + \cos x \frac{\partial \gamma}{\partial x} \right) \\
+ R_a \left( k_a \sin x \frac{\partial A}{\partial x} - i k \cos x A \right), 
\] (38)
\[
\frac{\partial \gamma}{\partial t} = \frac{\partial^2 \gamma}{\partial x^2} + \frac{\partial^2 \gamma}{\partial z^2} \\
- R_a R_a \left( \cos^2 x \frac{\partial A}{\partial x} - i k k_a \sin x \cos x A \right) \\
+ R_a \left( \cos x \frac{\partial B}{\partial x} - i k k_a \sin x B \right) \\
- R_a \left( \cos^2 x + k^2 \sin^2 x \gamma \right), 
\] (39)
where
\[
R_a = U_0 L/\beta_0, 
\] (40)
\[
R_a = \alpha_0 L/\beta_0. 
\] (41)

The first one, $R_a$, is the turbulent Reynolds number based on the turbulent magnetic diffusivity $\beta$. The second one, $R_a$, represents the relative amplitude of the helicity or $\alpha$ effect to...
the turbulent magnetic diffusivity $\beta$. These two nondimensional numbers determine the basic behavior of the magnetic field and the cross helicity in this system of equations.

For the sake of simplicity, we assume $k = 0$, i.e., neglect the radial or $z$ derivatives of $A$, $B$, and $\gamma$. It implies from Equation (31) that the colatitudinal component of the magnetic field vanishes ($B^r \approx B^0 = 0$).

Here we introduce $f_i = \{0, 1\}$ to switch individual terms on and off. With $f_i$ Equations (37)–(39) are written as

$$\frac{\partial A}{\partial t} = \frac{\partial^2 A}{\partial x^2} + R_o \cos x B,$$  

$$\frac{\partial B}{\partial t} = \frac{\partial^2 B}{\partial x^2} + R_u \left( -f_1 k^2 \sin x \gamma + f_2 \sin x \gamma \right) - f_3 \cos x \frac{\partial \gamma}{\partial x} + R_u \left( f_4 k_u \sin x \frac{\partial A}{\partial x} \right),$$

$$\frac{\partial \gamma}{\partial t} = \frac{\partial^2 \gamma}{\partial x^2} - R_o R_u f_5 \left( \cos^2 x \frac{\partial A}{\partial x} \right) + R_u f_6 \cos x \frac{\partial B}{\partial x} - R^2 f_7 \left( \cos^2 x + k^2 \sin^2 x \right) \gamma.$$  

If we put $f_1 = f_2 = f_3 = f_4 = f_5 = f_6 = 1$ in Equations (42)–(44) and omit the equation of $\gamma$ itself, we get the usual $\alpha$–$\Omega$ dynamo model:

$$\frac{\partial A}{\partial t} = \frac{\partial^2 A}{\partial x^2} + R_o \cos x B,$$  

$$\frac{\partial B}{\partial t} = \frac{\partial^2 B}{\partial x^2} + R_u \left( k_u \sin x \frac{\partial A}{\partial x} \right).$$

If we put $f_1 = f_2 = f_4 = f_5 = 0, f_3 = f_6 = 1$, we reproduce the original cross-helicity dynamo model:

$$\frac{\partial A}{\partial t} = \frac{\partial^2 A}{\partial x^2} + R_o \cos x B,$$  

$$\frac{\partial B}{\partial t} = \frac{\partial^2 B}{\partial x^2} + R_u \sin x \gamma,$$  

$$\frac{\partial \gamma}{\partial t} = \frac{\partial^2 \gamma}{\partial x^2} - R_o R_u \left( \cos^2 x \frac{\partial A}{\partial x} \right).$$

We further introduce new variables

$$\tilde{A} = R_o R_u A, \quad \tilde{B} = R^2 R_u B,$$  

and omit the tilde ($\tilde{}$) again, and then we have

$$\frac{\partial A}{\partial t} = \frac{\partial^2 A}{\partial x^2} + \cos x B,$$  

$$\frac{\partial B}{\partial t} = \frac{\partial^2 B}{\partial x^2} + P^2 \sin x \gamma,$$  

$$\frac{\partial \gamma}{\partial t} = \frac{\partial^2 \gamma}{\partial x^2} - \cos^2 x \frac{\partial A}{\partial x},$$

where

$$P = R_o R_u.$$  

Equations (51)–(53) show that the solution depends only on the square of dynamo number $P = R_o R_u$.

Figure 4. Colatitudinal coordinate or $x, x = 0$ corresponds to the Northpole, $x = \pi/2$ the Equator, $x = \pi$ the Southpole.

### 3.5. Boundary Conditions and Free-decay Modes

We define the characteristic length scale $L = \pi/2$. For the $x$ or colatitudinal coordinate, $x = 0, x = \pi/2, x = \pi$ correspond to the “Northpole,” “Equator,” “Southpole,” respectively (Figure 4).

The boundary conditions for the solutions of $A, B$, and $\gamma$ for the poles should be

$$x = 0, \pi: \quad A = B = \frac{\partial \gamma}{\partial x} = 0.$$  

As for the equator, the boundary conditions for the antisymmetric solution (“dipole”) are

$$x = \pi/2: \quad \frac{\partial A}{\partial x} = B = \gamma = 0,$$  

and the ones for the symmetric solution (“quadrupole”) are

$$x = \pi/2: \quad A = \frac{\partial B}{\partial x} = \frac{\partial \gamma}{\partial x} = 0.$$  

In what follows, we adopt only the boundary conditions for the antisymmetric (“dipole”) solution.

The boundary conditions for $\gamma$ or equivalently the turbulent cross helicity are not so clear as compared with those for $A$ and $B$ or the mean magnetic fields. In the dipole field configuration, from the antisymmetric property of the turbulent cross helicity, $\gamma$ should vanish at the equator as Equation (55b). However, the spatio-temporal distributions of the turbulent cross helicity near the poles are still open. Since we adopted a slab geometry with the local Cartesian coordinate, Equation (28), there are several differences between the boundary regions ($x = 0, \pi$) and the real pole regions. With this point in mind, we adopt Equation (55a) as the simplest boundary conditions for $\gamma$ or the turbulent cross helicity.

We consider the case of “free-decay” of $A, B$, and $\gamma$, which obey

$$\frac{\partial A}{\partial t} = \frac{\partial^2 A}{\partial x^2}, \quad \frac{\partial B}{\partial t} = \frac{\partial^2 B}{\partial x^2}, \quad \frac{\partial \gamma}{\partial t} = \frac{\partial^2 \gamma}{\partial x^2}.$$  

In this situation, all of $A, B$, and $\gamma$ just decay due to the turbulent magnetic diffusion represented by the first terms of Equations (32)–(34). The solutions of these equations, satisfying the boundary conditions Equations (55a) and (55b), can be written as

$$A_n = e^{i \omega t} \sin nx \quad \text{with} \quad \omega_n = -n^2, \quad n = 1, 3, 5, \ldots,$$  

$$B_n = e^{i \omega t} \sin nx \quad \text{with} \quad \omega_n = -n^2, \quad n = 2, 4, 6, \ldots,$$  

$$\gamma_n = e^{i \omega t} \cos nx \quad \text{with} \quad \omega_n = -n^2, \quad n = 1, 3, 5, \ldots.$$  

Note that these solutions constitute a complete and orthogonal system of functions that already satisfies the boundary conditions (Equations (55a) and (55b)).
4. EIGENVALUE ANALYSIS

Now we consider the solution of the present dynamo equations (Equations (51)–(53)) as an eigenvalue problem. We may expand the dynamo solution in any complete orthogonal system of functions that satisfies the boundary conditions. For the sake of simplicity, here we expand the dynamo solution in the free-decay modes (Equation (57)):

\[
A(x, t) = e^{\omega t} \sum_{n=1,3,5,\ldots}^{N-1} a_n \sin nx, \quad (58a)
\]

\[
B(x, t) = e^{\omega t} \sum_{n=2,4,6,\ldots}^{N} b_n \sin nx, \quad (58b)
\]

\[
\gamma(x, t) = e^{\omega t} \sum_{n=1,3,5,\ldots}^{N-1} c_n \cos nx. \quad (58c)
\]

Substituting Equation (58) into Equations (51)–(53), we obtain

\[
\omega \sum_{n=1,3,\ldots} a_n \sin nx = - \sum_{n=1,3,\ldots} a_n n^2 \sin nx + \cos x \sum_{n=2,4,\ldots} b_n \sin nx, \quad (59)
\]

\[
\omega \sum_{n=2,4,\ldots} b_n \sin nx = - \sum_{n=2,4,\ldots} b_n n^2 \sin nx + P^2 \sin x \sum_{n=1,3,\ldots} c_n \cos nx, \quad (60)
\]

\[
\omega \sum_{n=1,3,\ldots} c_n \cos nx = - \sum_{n=1,3,\ldots} c_n n^2 \cos nx - \cos^2 x \sum_{n=1,3,\ldots} a_n n \cos nx. \quad (61)
\]

After simplifying Equations (59)–(61) with trigonometric relations, we multiply equations for \(a_n\) and \(b_n\) by \(m \sin x\) and the equation for \(c_n\) by \(m \cos x\), and we integrate \((\pi/4) \int_0^{\pi/2} dx\). Using orthogonality relations such as

\[
\int_0^{\pi/2} \sin nx \sin mxdx = \int_0^{\pi/2} \cos nx \cos mxdx = \frac{\pi}{4} \delta_{nm}, \quad (62a)
\]

\[
\int_0^{\pi/2} \sin nx \cos mxdx = 0, \quad (62b)
\]

we obtain

\[
\omega a_m = -m^2 a_m + \frac{1}{2} (b_{m-1} + b_{m+1})
\]

\[(m = 1, 3, 5, \ldots, N), \quad (63)\]

\[
\omega b_m = -m^2 b_m + \frac{p^2}{2} (c_{m-1} - c_{m+1})
\]

\[(m = 2, 4, 6, \ldots, N + 1), \quad (64)\]

\[
\omega c_m = -m^2 c_m - \frac{1}{4} [(m - 2)a_{m-2} + 2ma_m + (m + 2)a_{m+2}]
\]

\[(m = 1, 3, 5, \ldots, N). \quad (65)\]

We then have a matrix eigenvalue problem

\[
\omega u = \mathcal{M} u, \quad (66)
\]

with the vector constituted by the expansion coefficients

\[
u = (a_1, b_2, c_1, a_3, b_4, c_3, a_5, b_6, c_5, \ldots, a_N, b_{N+1}, c_N)^T, \quad (67)
\]

and the matrix

\[
\mathcal{M} = \begin{pmatrix}
-1 & 1/2 & -p^2/2 & -p^2/22 \\
-2/4 & -1 & -3/4 & -p^2/22 \\
1/2 & -9 & 1/2 & -p^2/2 \\
-1/4 & -6/4 & -9 & -5/4 \end{pmatrix}
\]

\[
= \begin{pmatrix}
1/2 & -N^2 & 1/2 & 1 \ldots \\
-2N/4 & -2(N + 1)^2 & P^2/2 & \ldots \\
\end{pmatrix} \quad (68)
\]

The eigenvalue \(\omega\) is expressed in terms of \(P\) (Equation (54)). We display \(\omega(P)\) diagrams for \(P > 0\) and \(P < 0\). The diagram is schematically depicted in Figure 5.
The Astrophyisical Journal, 824:67 (12pp), 2016 June 20

YOKAI ET AL.

Once the poloidal magnetic field has been induced, the turbulent cross helicity with the opposite sign (negative [positive] in the northern [southern] hemisphere) starts being generated. This process starts in the higher-latitude regions and moves to the lower-latitude regions.

6. CONCLUDING REMARKS

We proposed a new simple dynamo model for the stellar activity cycle, in which the effect of the mean-flow inhomogeneity on turbulence is incorporated through the turbulent cross helicity (velocity–magnetic-field correlation). In addition to the mean magnetic-field equations, the transport equation of the turbulent cross helicity is simultaneously solved in the model. The basic scenario of this dynamos model is as follows.

1. The positive or negative turbulent cross helicity, whose total amount through the full volume or sphere is zero, is locally generated by the inhomogeneous configurations of the mean velocity and magnetic fields.
2. A large-scale toroidal magnetic field is generated by the turbulent cross-helicity effect coupled with the large-scale vortical or rotational motions.
3. A large-scale poloidal magnetic field is generated from the toroidal magnetic field through the helical property of turbulence coupled with the large-scale magnetic field.
4. The poloidal magnetic field generated by the helicity effect is coupled with the large-scale vortical or rotational motions and then contributes to generating the turbulent cross helicity, whose sign is opposite to the original turbulent cross helicity.
5. Starting with the turbulent cross helicity of a reversed sign, a toroidal magnetic field whose polarity is reversed as compared to the original one is induced. Then the second half of a cycle of the oscillatory behavior of the magnetic field follows.

In this scenario, the oscillation of the turbulent cross helicity is considered to play an essential role in the magnetic polarity reversal. It is clear that the sign of the cross helicity changes as the magnetic field changes its polarity:

\[
\langle \mathbf{u} \cdot \mathbf{b} \rangle \rightarrow \langle \mathbf{u} \cdot - \mathbf{b} \rangle = - \langle \mathbf{u} \cdot \mathbf{b} \rangle,
\]

with \( \mathbf{b} \rightarrow - \mathbf{b} \). The important point to examine is the phase relationship between the turbulent cross helicity and the mean magnetic field: which of the turbulent cross helicity and the mean magnetic field changes its sign in advance of the other. As for this phase relationship, the present results of the eigenvalue analysis show that the sign change of the turbulent cross helicity should proceed to the counterpart of the mean magnetic field. In this sense, the cross-helicity oscillation is not the result of the magnetic polarity reversal, but the cause of the latter.

In the present model we adopt the cross-helicity effect coupled with the mean vorticity (the \( \Omega^2 \)-related terms in Equation (52) that originated from the \( f_1 \) and \( f_2 \)-related terms in Equation (43)) but neglect the differential-rotation or \( \Omega \) effect (the \( f_2 \)-related term in Equation (43)) as the toroidal magnetic-field generation mechanism. This treatment does not deny the importance of the \( \Omega \) effect. What we showed here is that some basic features of the
solar-activity cycle can be reproduced by the cross-helicity effect even without resorting to the $\Omega$ effect.

On the other hand, the cross-helicity effect presented in this work seems to be similar to the $\Omega$ effect since both arise from the mean-velocity inhomogeneity (compare the second terms of Equations (46) and (48)). The cross-helicity effect depends on the presence of the turbulence and of the cross-correlation between the velocity and magnetic-field fluctuations, whereas the $\Omega$ effect does not need turbulence itself. Examination of the relative importance of the cross-helicity effect to the $\Omega$ one in a realistic stellar situation, including the solar case, would provide a very interesting subject of study.

The relative importance of the cross-helicity effect to the differential rotation effect is estimated by

$$
\Gamma = \frac{|\nabla \times (\gamma \Omega)|}{|\nabla \times (U \times B)|}.
$$

(71)

From the second terms of Equations (48) and (46), $\Gamma$ can be expressed as

$$
\Gamma = \frac{\gamma}{k_u} \frac{\partial A}{\partial x} \sim \frac{\langle u' \cdot b' \rangle}{D \delta U} \tau_{\text{turb}} \sim \frac{\langle u' \cdot b' \rangle}{\delta U B^2} \text{Ro}^{-1},
$$

(72)

where $D$ is the radial length scale (dimension of convection zone), $\delta U$ is the toroidal velocity difference with respect to the radial direction, and $\text{Ro}$ is the Rossby number based on differential velocity (ratio of the mean and turbulence timescales, $\tau_{\text{mean}}$ and $\tau_{\text{turb}}$), defined by

$$
\text{Ro} = \frac{\tau_{\text{mean}}}{\tau_{\text{turb}}} = \frac{D}{\delta U K/\varepsilon}.
$$

(73)

($K$: turbulent energy defined in Equation (15a); $\varepsilon$: its dissipation rate). We see from Equation (72) that the $\Gamma$ ratio cannot be negligible if the turbulent cross helicity associated with the mean toroidal fields is comparable with the poloidal magnetic field $B'$ multiplied by the differential velocity $\delta U$. Of course, in a nearly solid rotation case ($\delta U \approx 0$), $\Gamma$ becomes very large.

An estimate of $\Gamma$ using a DNS of the solar-like convective shell suggests that $\Gamma \lesssim 0.2$ at the bottom of the convection zone ($r/r_0 \leq 0.75$). The $\Gamma$ value monotonically increases as the radial position increases, and it reaches $\Gamma \gtrsim 2$ near the surface ($r/r_0 \geq 0.96$). This increase is mainly caused by the increase of the mean vorticity near the surface region. This suggests that the cross-helicity effect is important near the surface of the solar convection zone (M. Miesch 2016, private communication).

As we saw in Section 2.2.2, the physical origin of the cross-helicity effect consists of the vortical and/or rotational motion and the cross-correlation between the velocity and magnetic-field fluctuations. This suggests that the cross-helicity effect arises even in a solid-rotation case while the $\Omega$ effect requires a preferred differential rotation. This is a substantial difference between the two effects. It would be very interesting to apply the present cross-helicity dynamo to an astrophysical body that rigidly rotates in a highly turbulent state, such as a red dwarf (a small and relatively cool star on the main sequence).

On 2013 December 4, one of the authors, Dieter Schmitt, tragically died after his heart surgery. This was a terrible shock, and we and many others have felt an overwhelming loss. May his soul rest in peace at Eddigehausen beloved of him. The rest of the authors would like to cordially dedicate this paper to the memory of Dieter. The authors are indebted to Manfred Schüssler, Arnab Rai Choudhuri, and Kirill Kuzanyan for basic references in this topic. Parts of this work were performed during the periods one of the authors (N.Y.) stayed at the Institut für Astrophysik (IAF), Georg-August-Universität Göttingen in 2013, the Kiepenheuer-Institut für Sonnenphysik (KIS) and Max-Planck Institut für Sonnensystemforschung (MPS) in 2014, and the Nordic Institute for Theoretical Physics (NORDITA) program on Magnetic Reconnection in Plasmas in 2015. This work was also supported by the Japan Society for the Promotion of Science (JSPS) Grants-in-Aid for Scientific Research (No. 24540228).

APPENDIX

DETAILED EXPRESSIONS FOR THE TRANSPORT COEFFICIENTS

It is worthwhile to note that Equation (13) is based on the most simplified assumption on the statistical property of turbulence, Equation (12). In realistic turbulence, we should adopt more elaborated closure applicable to the inhomogeneous anisotropic MHD turbulence. Results obtained from one of such elaborated closure schemes are seen in Yoshizawa (1990) and Yokoi (2013). These results were obtained without resorting to the quasi-linear or so-called first-order smoothing approximation. On the contrary, these results are based on a theory that is appropriate for the fully nonlinear turbulence with very high kinetic and magnetic Reynolds numbers (Kraichnan 1959; Yoshizawa 1984, 1990; Yokoi 2013). According to the results of such analyses, the primary part of the EMF is expressed by Equation (14), but with much more elaborated expressions for the turbulent transport coefficients such as

$$
\beta = \int dk \int_{-\infty}^{t} d\tau' G(k, x; \tau, \tau', t) \times [Q_{uu}(k, x; \tau, \tau', t) + Q_{bb}(k, x; \tau, \tau', t)],
$$

(74a)

$$
\alpha = \int dk \int_{-\infty}^{\tau} d\tau' G(k, x; \tau, \tau', t) \times [-H_{uu}(k, x; \tau, \tau', t) + H_{bb}(k, x; \tau, \tau', t)],
$$

(74b)

$$
\gamma = \int dk \int_{-\infty}^{\tau} d\tau' G(k, x; \tau, \tau', t) \times [Q_{ab}(k, x; \tau, \tau', t) + Q_{ba}(k, x; \tau, \tau', t)],
$$

(74c)

where $G, Q_{uu}, Q_{bb}, H_{uu}, H_{bb}, Q_{ab}, \text{etc.}$, denote the propagators (response or Green’s functions and spectral functions) of lowest-order turbulent fields in the wavenumber space. The Green’s function $G$ tells the weight of the past: how much the past affects the present state of turbulence. For example, if we can treat the time and spectral integrals independently, the time integral of the Green’s function just gives a timescale of turbulence:

$$
\tau = \int_{-\infty}^{t} d\tau' G(x; \tau, \tau'),
$$

(75)
with the spectral integral of the spectral function leading to the turbulent energy density,

$$K = \int dk \{ Q_{\text{uu}}(k, x; t) + Q_{\text{bb}}(k, x; t) \}. \tag{76}$$

In this specific case, we obtain the simplest expression corresponding to Equation (15a). In this sense, expressions (Equation (74)) are the natural generalization of the simplest model expressions of Equation (15).
