(Received October 22, 2018)

We propose a general theory for the critical and pseudogap temperatures $T_c$ and $T^*$ dependence on the doping concentration for high-$T_c$ oxides, taking into account the charge inhomogeneities in the $CuO_2$ planes. Several recent experiments have revealed that the charge density $\rho$ in a given compound (mostly underdoped) is intrinsic inhomogeneous with large spatial variations which leads to a local charge density $\rho(r)$. These differences in the local charge concentration yield insulator and metallic regions, either in an intrinsic granular or in a stripe morphology. In the metallic region, the inhomogeneous charge density produces also spatial or local distributions which form Cooper pairs at a local superconducting critical temperatures $T_c(r)$ and zero temperature gap $\Delta_0(r)$. For a given compound, the measured onset of vanishing gap temperature is identified as the pseudogap temperature, that is, $T^*$, which is the maximum of all $T_c(r)$. Below $T^*$, due to the distribution of $T_c(r)$’s, there are some superconducting regions surrounded by insulator or metallic medium. The transition to a coherent superconducting state corresponds to the percolation threshold among the superconducting regions with different $T_c(r)$’s. The charge inhomogeneities have been studied by recent STM/S experiments which provided a model for our phenomenological distribution. To make definite calculations and compare with the experimental results, we derive phase diagrams for the BSCO, LSCO and YBCO families, with a mean field theory for superconductivity using an extended Hubbard Hamiltonian. We show also that this novel approach provides new insights on several experimental features of high-$T_c$ oxides.

I. INTRODUCTION

It is well known that the properties of high-temperature superconductors (HTSC) vary in an unusual way when a moderate density of holes are introduced into the $CuO_2$ planes by chemical doping. This is one of the reasons why, despite of a large experimental and theoretical effort, the nature of the superconductivity in these materials remains to be explained\(^1\). Correlations make the parent undoped compound to be a Mott insulator and, upon doping, the underdoped compounds display unusual metallic properties with increasing $T_c$. Doping beyond the optimal level yields normal metals with Fermi liquid behavior and with decreasing $T_c$.

The non usual properties of underdoped samples have motivated several experiments and two features have been discovered which distinguish them from the overdoped compounds: firstly, the appearance of a pseudogap at a temperature $T^*$, that is, a discrete structure of the energy spectrum above $T_c$, identified by several different probes\(^2\). $T^*$ is found to be present also in overdoped samples\(^2,3\), but at temperatures near $T_c$. Second, there are increasing evidences that the electrical charges are highly inhomogeneous up to (and even further) the optimally doped region\(^4-9\). These charge inhomogeneities are neither due to impurities nor to crystal defects, but are intrinsic to the type of cuprate, producing local lattice distortions in the $CuO_2$ bond length\(^10\). In fact, such intrinsic inhomogeneities are also consistent with the presence of charge domains either in a granular\(^7-9\) or in a stripe\(^11-13\) form.

Therefore, in our view, it is very likely that the pseudogap and the intrinsic charge inhomogeneities are closely related and understanding their interplay is of great importance to understand the general phenomenology and the phase diagrams of the HTSC families. Currently there are two main different proposals to explain the existence of the pseudogap: In the first one, the pseudogap is regarded as a normal state precursor of the superconducting gap due to local dynamic pairing correlations in a state without long range phase coherence, and $T_c$ is much smaller than $T^*$ because of strong phase fluctuations\(^14,15\). In the second proposal, the pseudogap is a normal state gap, which is necessarily independent of the superconducting gap and which competes with the superconductivity, existing even below $T_c$ for compounds around the optimum doping, ending in a quantum critical point\(^16-18\) at zero temperature.

Recently we have described a simple new scenario\(^19\), when the temperature of a given sample is decreasing and reaches $T^*$, it activates the formation of pairs at some selected low doping metallic regions. Initially these superconducting or pair-rich regions are not connected and there is no phase coherence over the whole system. The coherent superconducting transition occurs when the temperature reaches a value ($T_c$) at which the different superconducting regions percolate. This scenario relies heavily upon the fact that the cuprates have an intrinsic inhomogeneous charge distribution. Thus a given HTSC compound with an average hole per $Cu$
ion density \( \rho \) and with an inhomogeneous microscopic charge distribution \( \rho(r) \) has a distribution of small clusters or stripes with a given local \( T_c(r) \) \((0 < \rho \leq 1 \) and \( 0 < \rho(r) \leq 1 \)). Thus the model depends strongly on the intrinsic charge distribution \( \rho(r) \) although their exact form is not well known and since the discovery of the spin-charge stripes\(^{11} \), they are a matter of intense current research. As a consequence, several recent experiments have demonstrated that the charge distributions are more inhomogeneous for underdoped and more homogeneous for overdoped compounds and may resemble either a granular\(^{4}\) or a stripe structure.

In the spin-charge striped scenario, some regions of the plane are heavily doped (the stripes) and other regions are underdoped, filling the space between the charge-rich stripes. Stripe phases occur due to the antiferromagnetic interaction among magnetic ions and Coulomb interaction between the charges, both of which favor localization. On the other hand, the zero-point motion of the holes favors delocalization and tends to create phase-separated states rich either of spin or charge. Experimentally, the stripes are more easily detected in insulating materials, where they are static, but there are evidences of fluctuating stripe correlations in metallic and superconducting compounds\(^{12,11,13} \).

Based on the results of the above mentioned experiments, we have introduced a local charge distribution \( \rho(r) \) to model the real charge distributions inside a HTSC compound. Since doping produces an intrinsic inhomogeneous charge distribution and metallic and insulator regions seem to coexist, we assume that it contains two parts: one for a hole-rich and other for a hole-poor partition. This mimics the striped phases. The hole-poor regions are, in most cases, antiferromagnetic Mott insulators. The hole-rich regions form an inhomogeneous metal with spatially varying charge density. The existence of the intrinsic charge inhomogeneities have several consequences, and one of them is the non-Fermi liquid behavior of the underdoped compounds. As concerns the superconductivity, they produce spatially dependent superconducting gaps \( \Delta_{sc}(r) \) due to short coherence length and also spatially dependent superconducting domains with critical temperatures \( T_c(r) \). Recently, very fine scanning tunneling microscopy/spectroscopy (STM/S) data\(^{7,8} \) has revealed the spatial variation through the differential conductance which provides a strong evidence for such distribution of zero temperature superconducting gap \( \Delta_{sc}(r) \). More recently, new STM data on Bi2212 using scattering resonances at Ni impurities atoms, has revealed a large nanoscale spatial dependence of the superconducting gap\(^{9} \).

All together, these experiments show variations on local density of states (LDOS) of just a few angstroms. This is consistent with the very short coherence length in HTSC. Since \( T_c(r) \) is proportional to \( \Delta_{sc}(r) \), the opening of the largest gap occurs at the highest of all the \( T_c(r) \)’s, which is exactly \( T^* \). Above \( T^* \) there is no gap and below it, there is the development of some superconducting clusters inside the material. Depending on the distribution of the values of \( T_c(r) \) in the compound, some regions become superconducting. Decreasing the temperature, the number of superconducting clusters increases, bringing about the superconducting domains to grow. When the temperature reaches a value which is the \( T_c \) of the compound, the superconducting regions percolate through the sample and therefore it can hold a dissipationless current.

On Fig.1 we show a schematic local charge density distribution \( \rho(r) \) which is based on the above experimental data, as mentioned, and could give rise to a gap distribution of \( \Delta_{sc}(r) \). This is a pictorial sketch of what should be the real charge distribution for a optimal doped HTSC, based on the above information. It reflects the nano-scale variations of the superconducting energy gap or the nano-scale variations on the density of charges in the material.

![FIG. 1. Sketch of the possible charge distribution in a HTSC compound. The white part represents the insulator or hole-poor regions. The colored region mimics the hole-rich metallic part of the compound. The lighter colors are for metals with higher values of the superconducting gap and the darker regions is for lower gap regions.](image-url)
obtained through the same method, namely, resistivity, the variation of the measured pseudogap magnitude with temperature, mostly measured for the optimally doped and underdoped compounds, the downturn of the linear specific heat coefficient, these properties will be discussed in more detail in section IV.

This paper is divided as follows: in section II, we introduce the charge distributions appropriate to mimic the real charge distribution inside the material and reproduce the $T^*$ and $T_c$ phase diagram. In section III, we derive the phase diagram for Bi2212, LSCO and YBCO and make comparison with the experimental data. We use a mean field BCS like method with an extended Hubbard Hamiltonian to derive the onset of vanishing gap at $T^*$, but it should be emphasized that the percolating approach introduced here is independent of any method of calculating the superconducting pair formation. In section IV, we comment on the applications and implications of the percolation theory to several physical properties of the HTSC and we finish with the conclusions in section V.

II. THE CHARGE DISTRIBUTION

The consequence of the microscopic charge inhomogeneities distribution in the CuO$_2$ planes, either in a striped or in a granular configuration, is the existence of domain walls between the two phases which are spontaneously created in the planes, regions which are heavily doped or hole-rich may form the stripes and others regions which are hole-poor are created between these charge-rich stripes. The exactly form of these charge distributions is not well known but we can get some insights from a number of recent experiments. The neutron powder diffraction data of Pan et al. and recent STM measurements reveal an interesting map of the superconducting gap spatial variation for underdoped Bi2212. Their data is compatible, as they pointed out, with a granular superconducting grains separated by non-superconducting regions. Based on their measured gap histogram (see Fig.4b of Lang et al.) and on similar data of Pan et al., we can draw some insights on the real charge distribution inside a HTSC.

Thus, in order to model the above experimental ob-
servations and to be capable of performing calculations which may reproduce the measured phase diagrams, namely $T^*$ and $T_c$ for a given family of compounds, we used a combination of a Poisson and a Gaussian distribution for the charge distribution $P(r)$. In fact, each type of distribution has a convenient property which we used below: The width of a Gaussian distribution is easy to be controlled and expresses the degree of disorder but since it is symmetric, it would imply in a rather small width to the low density compounds. On the other hand, a Poisson distribution starts sharply and has a long tail which is convenient to deal with these low densities compounds with their experimental measured large degree of inhomogeneities. Thus, for a given compound with an average charge density $\langle \rho \rangle$, the hole distribution $P(\rho; \langle \rho \rangle)$ or simply $P(\rho)$ is a histogram of the probability of the local hole density $\rho$ inside the sample, separated in two branches or domains. The low density branch represents the hole-poor or non-conducting regions and the high density one represents the hole-rich or metallic regions. As concerns the superconductivity, only the properties of the hole rich branch are important since the current flows only through the metallic region.

Such normalized charge probability distribution may be given by:

$$P(\rho) = (\rho_c - \rho) \exp[-(\rho - \rho_c)^2/2(\sigma_-^2)]/[(\sigma_-)^2(2-\exp(-\rho_c^2/2(\sigma_-^2)))] \quad \text{for} \quad 0 < \rho < \rho_c \quad (1)$$

$$P(\rho) = 0 \quad \text{for} \quad \rho_c < \rho < \rho_m \quad (2)$$

$$P(\rho) = (\rho - \rho_m) \exp[-(\rho - \rho_m)^2/2(\sigma_+^2)]/[(\sigma_+)^2(2-\exp(-\rho_m^2/2(\sigma_-^2)))] \quad \text{for} \quad \rho_m < \rho \quad (3)$$

The values of $\sigma_-$ ($\sigma_+$) controls the width of the low (high) density branch. Here, $\rho_c$ is the end local density of the hole-poor branch. $\rho_m$ is the starting local density of the hole-rich or metallic branch. Both $\rho_c$ and $\rho_m$ are shown in Fig.2 for a particular case. Each compound will have a its value of $\rho_m$. Thus, a compound having regions with different hole concentrations which are distributed according to the above probability density function $P(\rho)$, has an average value which depends on the parameters of the distribution. We can show that the average value of the charge density is

$$\langle \rho \rangle = \frac{\left[\sigma_+ \sqrt{\pi}/2 + \rho_m + \rho_c - \sigma_- \sqrt{\pi}/2 \right] \times \text{erf}([\rho_c/\sqrt{\pi}/2])]}{[(\sigma_+)^2(2-\exp(-(\rho_c)^2/2(\sigma_-^2)))]}. \quad (4)$$

here erf is the error function. For most compounds, due to the small values of $\sigma_+$, $\langle \rho \rangle \approx \rho_m$, see Table I below. Indeed, for a compound with average density $\langle \rho \rangle$, the values of $\sigma_{\pm}$ are chosen in order that percolation in the hole-rich branch occurs at a given density called $\rho_p$.

As the doping level $\langle \rho \rangle$ increases, the compounds become more homogeneous and therefore, we take larger values of $\sigma_-$ and smaller values of the metallic branch width $\sigma_+$. We take $\rho_c \approx 0.05$ as the end of the low branch because it corresponds to the onset of superconductivity to mostly cuprates. However, $\rho_c \approx 0.1$ for the Bi2212 family. During the preparation of this work, we discovered that the charge probability distribution for the metallic branch, introduced as an ansatz in the beginning of our calculations, but based on the results of Pan et al., was confirmed by the very fine STM measurements of Lang et al. They measured the gap probability distribution which has a Gaussian form but with a long tail which is more characteristic of a Poisson type distribution. Since there is not any experimental measurements for the hole-poor branch, $\sigma_-$ is just a free parameter.

| $\rho_m$  | $\sigma_-$ | $\sigma_+$ | $\langle \rho \rangle$ | $\rho_p$ |
|---------|-----------|-----------|-----------------|--------|

* marks the distributions plotted in Fig.2. The value of $\sigma_+ = 0.04$ for $\langle \rho \rangle = 0.16$ is taken from the experimental data of Pan et al.
We can get a reliable estimation of the $\sigma_+$ values from the experimental STM/S Gaussian histogram distribution for the local gap in an optimally doped $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_{8+x}$ ($\rho_m \approx 0.32$). From Fig. 2d of Ref. 7, one sees that the half-width for the metallic branch is about half of the mean doping value, that is, $2\sigma_+ = 0.16$, since the local gap is proportional to the local hole density. As mentioned, the metallic branch distribution has exactly the same form of the STM histogram data of Lang et al. which express the inhomogeneous superconducting regions in Bi2212. For the LSCO system, assuming that it has the same STM/S Gaussian histogram distribution, the optimally doped compound ($\langle \rho \rangle \approx 0.16$) must have $2\sigma_+ = 0.08$. Since the $\sigma_+$ values are related with the degree of inhomogeneities, we estimate the $\sigma_+$ values for the other compounds using the fact that it decreases with the hole density. Below we show some selected distributions for an underdoped, optimally doped and overdoped compounds.

![Poisson-Gaussian Distribution](image)

**FIG. 2.** Model charge distribution for the inhomogeneities or stripe two phase regions. The low density insulating (antiferromagnetic) branch is near $\rho = 0$. The high density hole-rich region starts at the compound average density $\rho_m$ which are indicated by long arrows for some selected compounds. $\rho_p$, indicated by the short arrows, is the density where percolation can occur.

The density distribution is normalized to unity. For compounds like LSCO with average densities of $\rho \gg 0.25$, that is, in the far overdoped region, we use a single Gaussian distribution which reflects the more homogeneous character of these compounds. For Bi2212, since the optimally doped compound is about twice that of the other families, the single Gaussian distribution is appropriate for compounds with $\rho \gg 0.5$. In the next section we show how to estimate $T_c$ as function of the local density $\rho(r)$. As already discussed, HTSC compounds are intrinsic inhomogeneous, and each region in the material may have a different superconducting critical temperature $T_c(r)$. The maximum of these temperatures $T_c(r)$ is the pseudogap temperature since it is connected with the opening of the largest gap, that is, the $T^*$ of a given sample with $\langle \rho \rangle$, i.e., $T^*(\langle \rho \rangle)$. Eventually for temperatures below $T^*(\langle \rho \rangle)$ the regions with local density between $\rho_m$ and $\rho_p$ becomes superconducting and the supercurrent may percolate through the sample. Therefore, the local $T_c(\rho_p)$ is the maximum temperature at which a dissipationless current can flow through the system and which is identified as $T_c(\langle \rho \rangle)$, the experimental superconducting critical temperature.

According to the percolation theory, the site percolation threshold occurs in a square lattice when 59% of the sites are filled. Thus, we find the density where the hole-rich branch percolates integrating $\int P(\rho)d\rho$ from $\rho_m$ till the integral reaches the value of 0.59, where we define $\rho_p$. Below $T_c(\langle \rho \rangle)$ the system percolates and, consequently, it is able to hold a dissipationless supercurrent. We should point out that 0.59 is an appropriate value for a single layer cuprate. The site percolation threshold is 0.16 for a simple cubic lattice. Therefore, for a two layers system like Bi2212, the site percolation threshold may be less than 0.59, but since the true value is not known, we will use 0.59 as a first approximation. In the Table I, we show some of the parameters used for certain sample and we plot the distribution, as discussed above, in Fig. 2. Notice that the Table I and Fig. 2 are for a HTSC system with optimum doping ($\rho \approx 0.16$ like LSCO or YBCO). For Bi2212, the optimum hole doping is about twice this value and in this case new parameters must be used. Some charge distributions used for the calculations with the Bi2212 family, similar to the ones shown in Fig. 2 above, were also derived.

### III. THE PHASE DIAGRAM

The experimental based phenomenological charge distribution probability introduced in the last section enable us to estimate the appearance of pre-formed pair at different regions in the crystal provided that we know the onset of superconductivity $T^*(\rho(r))$. There are several different approaches which can be used to obtain $T^*(\rho(r))$. We can simply use the experimental measured pseudogap temperature $T^* = T^*(\langle \rho \rangle)$ for several different compounds through the identification $T^*(\rho(r)) = T^*(\langle \rho \rangle)$ which is probably the best estimation. Another possibility is perform a theoretical calculation as we have done in the past for the $T_c$ of a given compound with density $\langle \rho \rangle$ and take $T^*(\rho(r)) = T_c(\langle \rho \rangle)$.

Strictly speaking, due to the non-uniform charge distribution, we do not have translational symmetry and we should use a method which takes the disorder into account. However, such theories require the introduction of a phenomenological random potential to simulate the disorder. Since our purpose here is to demonstrate that phase coherence is attained by perco-
luation and it is independent of the pairing mechanism, we will take the simplest theoretical approach: we use a BCS-type mean-field approximation in $k$-space on a two-dimensional square lattice with uniform carrier density $\rho$ to estimate the onset temperature of the superconducting d-wave gap, i.e. $T^*(\rho)$. Then we take $T^*(\rho(\epsilon)) = T^*(\rho)$ in order to make a map of the superconducting region. We have to bear in mind that this is an approximation but which is worthwhile since it capable to reproduce the experimental $T^*$ values and is reasonable if the size of the grain or stripes domains are larger than the typical pair coherent length. In fact, the latest STM/S results yields grain boundaries of the order of 100-10 nanometers while the typical coherent lengths are of the order of angstroms. Thus, this approach, with appropriate choice of experimental or calculated parameters, was used before to derive the $T_c(\rho)$ curves for some HTSC families, since $T_c$ was, as in normal superconductors, taken as the onset temperature of vanishing gap. It is more appropriate to call the pseudogap temperature of the compound is $\rho(\mu, T)$ where $0 < \rho < 1$.

Eq. (10) together with the gap equation (6) must be solved together self-consistently. They may be used to derive the onset of vanishing gap temperature as function of a given value of the density of carriers $\rho$. This procedure was used in the past to derive, with appropriate set of parameters, the $T_c(\rho)$ phase diagram for different HTSC systems for a single type of order parameter symmetries.

In the present work, we assume a different view: $\rho$ here is not the compound average hole density but the local hole density $\rho(\epsilon)$. For a given value of $\rho(\epsilon)$, we use Eq. (10) and Eq. (6) to calculate the local onset temperature of vanishing gap. It is more appropriate to call this temperature as $T^*(\rho)$; therefore, $T^*(\rho) = T_c(\rho)$ and hereafter we will deal only with $T^*(\rho)$. On the other hand, the pseudogap temperature of the compound is $T^*_{\text{p.g.}}(\rho) = \max\{T_c(\rho)\}$, or simply $T^*$. Below, in Fig. 3, we present the results for the $La_{2-x}Sr_xCuO_4$ family. We have used a dispersion relation derived from the Schabel et al.

- The theoretical curves in Fig. 3 are derived in the following way: For each local density $\rho > \rho_m$, that is, inside the metallic branch, $T^*(\rho)$, calculated with the mean field equations, is a decreasing function. Thus the maximum value of $T^*(\rho)$ is equal $T^*(\rho_m)$. This is the onset temperature of the superconducting gap (in the metallic
we draw an arrow in Fig.3 showing how $T^*(\rho)$ is obtained. The $T^*(\rho)$ curve calculated with the above parameter is in good qualitative agreement with the displayed experimental data$^{28,48}$. The value of superconducting critical temperature $T_c(\rho)$ is estimated in the following manner: we calculate the maximum temperature at which the superconducting region percolates in the metallic branch. This percolation occurs when all the clusters with local density between $\rho_m$ and $\rho_p$ are superconducting. Fig.3a shows how this happens for $\langle \rho \rangle = 0.16$ which yields $\rho_p = 0.23$. This value of $\rho_p$ can be seen in the panel following the arrow which shows that $T^*(0.23)$ is equal the superconducting critical temperature of the compound, $T_c(0.16)$. In general $T_c(\rho) = T^*(\rho_p)$ and the system will be superconducting when submitted to any temperature below $T^*(\rho_p)$ (see Fig.3b). Below we show the results for the LSCO family. A similar curve was also studied which the $T^*$ is in reasonable agreement with the $T^{MF}_c$ extracted from the high-resolution dilatometry data$^{49}$ for $YBa_2Cu_3O_x$.

![FIG. 3. Phase diagram for the LSCO family. To explain how $T^*(\rho)$ and $T_c(\rho)$ are obtained, we plot in (a) the probability distribution for the optimal compound with $\langle \rho \rangle = 0.16$, $P(\rho,0.16)$. The arrows shows $T^*(0.16)$ and the percolation threshold at $\rho_p = 0.23$ with $T_c(\rho) = 0.16 = T_c(0.23)$. The experimental data are taken from Ref.$^{48}$ and $T_{onset}$ is taken from the flux flow experiment of Ref.$^{28}$ (open squares). Notice that values of $T^*(\rho)$ are the same of $T_c(\rho)$ but $T^*$ refers to the compound density $\langle \rho \rangle$ and $T_c$ refers to the local density $\rho$.

![FIG. 4. a) The probability distribution for the optimal compound with $\langle \rho \rangle = 0.32$. b) The calculated local onset of vanishing gap $T^*(\rho)$ and the compound pseudogap temperature $T^*(\rho)$].

IV. DISCUSSION

It is worthwhile to mention that the percolating approach is independent of the above mean field calculations for $T^*(\rho)$. It can be used in connection with any method which yields a $T^*(\rho)$ curve. The only requirement is that it would not cross the $T_c(\langle \rho \rangle)$ curve as some have proposed$^{16}$. Thus the percolating approach could be used with some experimental measurements or other theoretical methods to calculate $T^*(\langle \rho \rangle)$, like, for instance, the calculations made with the Hubbard-Holstein Hamiltonian$^{50}$.

We have also used this procedure to calculate the phase diagram for the Bi2212 family which is in agreement with the experimental data as one can see in Fig.4. The details of the calculations are similar to the ones described above and can be found in ref.19.

There are several HTSC phenomena which are not well understood and can be explained with the percolating ideas, and with our model and calculations:

1-ARPES measurements$^{3,29}$ have revealed the anomalous behavior of the zero temperature gap $\Delta_0(\langle \rho \rangle)$ which decreases steadily with the doping $\langle \rho \rangle$ although $T_c$ increases by a factor of 2 for their underdoped samples. This overall relation between $\Delta_0(\langle \rho \rangle)$ and $T_c$ is totally unexpected since it is well known that normal superconductors have a constant value for the ratio $2\Delta_0/k_BT_c$, being 3.75 for usual isotropic order parameter and 4.18 for $d_{x^2-y^2}$ wave solution$^{51}$. 

branch) and therefore $T^*(\rho_m) = T^*(\rho)$.
La

nario: The magnetotransport measurements in magnetic field seem to agree with the percolating sc

approaches in order to obtain the correct temperature dependence. Several measurements made in the presence of a magnetic field penetrates partially in the superconducting regions and destroys some of the superconducting clusters in the film. We have already mentioned the recent measurements of magnetic domains above \( T_c \) which has been interpreted as a diamagnetic precursor to the Meissner state, produced by performed pairs in underdoped \( La_{2−x}Sr_xCuO_4 \) thin films\(^{29}\). The existence of superconducting clusters between \( T^* \) and \( T_c \) easily explains the appearance of local diamagnetic or Meissner domains and, if there is a temperature gradient in the sample, the local flux flows and produces the dynamic flux flow state\(^{28}\).

4-Another important consequence which follows is that the superconducting pairing mechanism should be more easily investigated by experiments performed mainly at \( T^* \). A such experiment was accomplished by Rubio Temprano et al\(^{54}\), which measured a large isotope effect associated with \( T^* \) and an almost negligible isotopic effect associated with \( T_c \) in the slightly underdoped \( HoBa_2Cu_4O_8 \) compound. The results strongly support the fact that electron-phonon induced effects are present in the superconducting mechanism associated with \( T^* \). Bussmann-Holder et al have also calculated \( T^* \) as function of a phonon induced gap\(^{55}\).

In order to gain further insight on the nature of the pair potential, we have measured the resistivity under hydrostatic pressure on an optimally doped \( Hg_{0.80}Re_{0.18}Ba_2Ca_2Cu_3O_{7+\delta} \) sample. The data indicate a linear increase of \( T^* \) with the pressure at the same rate as \( T_c \). In the context of our theory, this result might be in agreement with the phonon induced mechanism: the inhomogeneity local charge densities in a given compound yield varying values for the Fermi level, broadening \( N(E_F) \)\(^{24}\). The applied pressure on a cuprate with an inhomogeneous charge distribution is also expected to broaden the density of states\(^{36}\) \( N(E_F) \), and the main effect of an applied pressure on \( T_c \) is an increase of the phonon or Debye frequency. This is seen through the linear increase of \( T^* \)\(^{56}\) which also provides a very interesting physical explanation on the origin of the linear pressure induced \( \Delta \)\(^{36,57,58}\). This anomalous behavior can be explained by the existence of superconducting islands above \( T_c \) which gradually turn into metallic phase as the temperature is raised. Such superconducting regions can be regarded as empty spaces in a disordered hole-rich (metallic) and hole-poor (insulator) background. Therefore, as the metallic region increases, it increases also the number of carrier. However, we have to point out that

2-Transport experiments have also been used to study the pseudogap\(^7\). The underdoped and optimum doped high-\( T_c \) oxides have a linear behavior for the resistivity below the linear behavior between \( T_c \) and \( T^* \). This behavior can be understood by the increasing of superconducting cluster numbers and size, as the temperatures decreases below \( T^* \). Each superconducting cluster produces a short circuit which decreases the resistivity below the linear behavior between \( T^* \) and \( T_c \). To obtain a quantitative fitting of this effect, we are presently working on a simulation for the resistivity of a linear metallic medium with short circuited regions which varies with the temperature. The linear behavior of the resistivity above \( T^* \) may be also be explained by a percolation procedure. The conductivity of inhomogeneous systems has been considered from different percolative approches in order to obtain the correct temperature dependence\(^{32,52}\). The temperature functional form depends on how the percolation is achieved in the system.

3-Several measurements made in the presence of a magnetic field seem to agree with the percolating scenario: The magnetotransport measurements\(^{53}\) in a \( La_{2−x}Sr_xCuO_4 \) film just above the irreversibility line is in agreement with the notion that the magnetic field penetrates partially in the superconducting regions and destroys some of the superconducting clusters in the film. We have already mentioned the recent measurements of magnetic domains above \( T_c \) which has been interpreted as a diamagnetic precursor to the Meissner state, produced by performed pairs in underdoped \( La_{2−x}Sr_xCuO_4 \) thin films\(^{29}\). The existence of superconducting clusters between \( T^* \) and \( T_c \) easily explains the appearance of local diamagnetic or Meissner domains and, if there is a temperature gradient in the sample, the local flux flows and produces the dynamic flux flow state\(^{28}\).

FIG. 5. The zero temperature gap for 9 samples as measured by Harris et al\(^{29}\) and our calculations.

At low temperatures, since the superconducting phase percolates through different regions, each one has a given \( \Delta_0(\rho) \). Thus, tunneling and ARPES experiments detect the largest gap present in the compound. Consequently, \( \Delta(\rho) \) must be correlated with the onset of vanishing gap \( T^*(\rho) \) which is the largest superconducting temperature in the sample, and should not be correlated with \( T_c(\rho) \). As we show in Fig.5, correlating the values plotted in Fig.3b for \( T^*(\rho) \) with \( \Delta_0(\rho) \), we are able to give a reasonable fit for the data\(^3,29\) on \( Dy−BSCCO \) and explains the different energy scales pointed out by several others authors.

2-Transport experiments have also been used to study the pseudogap\(^7\). The underdoped and optimum doped high-\( T_c \) oxides have a linear behavior for the resistivity in the normal phase up to very high temperatures. However, at \( T^* \) there is a deviation from the linear behavior and the resistivity falls faster with decreasing temperature\(^3,48\). This behavior can be understood by the increasing of superconducting cluster numbers and size, as the temperatures decreases below \( T^* \). Each superconducting cluster produces a short circuit which decreases the resistivity below the linear behavior between \( T^* \) and \( T_c \). To obtain a quantitative fitting of this effect, we are presently working on a simulation for the resistivity of a linear metallic medium with short circuited regions which varies with the temperature. The linear behavior of the resistivity above \( T^* \) may be also be explained by a percolation procedure. The conductivity of inhomogeneous systems has been considered from different percolative approches in order to obtain the correct temperature dependence\(^{32,52}\). The temperature functional form depends on how the percolation is achieved in the system.

3-Several measurements made in the presence of a magnetic field seem to agree with the percolating scenario: The magnetotransport measurements\(^{53}\) in a \( La_{2−x}Sr_xCuO_4 \) film just above the irreversibility line is in agreement with the notion that the magnetic field penetrates partially in the superconducting regions and destroys some of the superconducting clusters in the film. We have already mentioned the recent measurements of magnetic domains above \( T_c \) which has been interpreted as a diamagnetic precursor to the Meissner state, produced by performed pairs in underdoped \( La_{2−x}Sr_xCuO_4 \) thin films\(^{29}\). The existence of superconducting clusters between \( T^* \) and \( T_c \) easily explains the appearance of local diamagnetic or Meissner domains and, if there is a temperature gradient in the sample, the local flux flows and produces the dynamic flux flow state\(^{28}\).

4-Another important consequence which follows is that the superconducting pairing mechanism should be more easily investigated by experiments performed mainly at \( T^* \). A such experiment was accomplished by Rubio Temprano et al\(^{54}\), which measured a large isotope effect associated with \( T^* \) and an almost negligible isotopic effect associated with \( T_c \) in the slightly underdoped \( HoBa_2Cu_4O_8 \) compound. The results strongly support the fact that electron-phonon induced effects are present in the superconducting mechanism associated with \( T^* \). Bussmann-Holder et al have also calculated \( T^* \) as function of a phonon induced gap\(^{55}\).

In order to gain further insight on the nature of the pair potential, we have measured the resistivity under hydrostatic pressure on an optimally doped \( Hg_{0.80}Re_{0.18}Ba_2Ca_2Cu_3O_{7+\delta} \) sample. The data indicate a linear increase of \( T^* \) with the pressure at the same rate as \( T_c \). In the context of our theory, this result might be in agreement with the phonon induced mechanism: the inhomogeneities local charge densities in a given compound yield varying values for the Fermi level, broadening \( N(E_F) \)\(^{24}\). The applied pressure on a cuprate with an inhomogeneous charge distribution is also expected to broaden the density of states\(^{36}\) \( N(E_F) \), and the main effect of an applied pressure on \( T_c \) is an increase of the phonon or Debye frequency. This is seen through the linear increase of \( T^* \)\(^{56}\) which also provides a very interesting physical explanation on the origin of the linear pressure induced \( \Delta \)\(^{36,57,58}\). This anomalous behavior can be explained by the existence of superconducting islands above \( T_c \) which gradually turn into metallic phase as the temperature is raised. Such superconducting regions can be regarded as empty spaces in a disordered hole-rich (metallic) and hole-poor (insulator) background. Therefore, as the metallic region increases, it increases also the number of carrier. However, we have to point out that
the saturation seems to occur near the room temperature, which is much higher than some of the measured values for $T^*$.  

6- The pseudogap has also been detected through the specific heat coefficient which undergoes changes below $T^*$. It is well known that the electronic specific heat $\gamma$ term of the normal phase is a material dependent and temperature independent constant. However, several measurements have detected\textsuperscript{5,16,17} the suppression in the $\gamma$ term in mostly underdoped compounds of different families. In the percolating approach, with the existence of superconducting clusters below $T^*$, we can qualitatively explain such depression. While the metallic region specific heat behaves as $\gamma T$, the superconducting region contributes with terms proportional to $\exp(-\Delta(r)/T)$, which decreases much faster with $T$. As the temperature falls below $T^*$ and the superconducting region increases, its contribution to the specific heat becomes more important and produces the overall downturn in the $\gamma$ coefficient. For overdoped samples, since $T^*$ is very close $T_c$, this effect may be difficult to be detected and this is the suppression of the $\gamma$ term was not seen for overdoped compounds\textsuperscript{16,17}.

7- Magnetization measurements above $T_c$ in oriented powder of $Y_{1-x}Ca_xBa_2Cu_3O_y$ has revealed a pattern\textsuperscript{60} which cannot be explained by the usual fluctuation of the magnetization order parameter\textsuperscript{61}. Such pattern were interpreted by the formation of superconducting regions above the percolating model above. We are presenting using the Ginsburg-Landau formalism\textsuperscript{61} in connection of the hole charge distribution introduced in Section II in order to provide a quantitavive calculation for such anomalous induced diamagnetism. The results will be published elsewhere together with a new analysis on the behavior of $H_{c2}$ for high-$T_c$ superconductors.

V. CONCLUSIONS

We have demonstrated that the percolating approach for local pre-formed pairs due to an inhomogeneous charge distribution on the $CuO_2$ planes provides a novel and general approach to the phase diagram of the high-$T_c$ cuprates superconductors. The pseudogap is regarded as the largest superconducting gap among the superconducting regions in an inhomogeneous compound. The critical temperature $T_c$ is the maximum temperature at which these superconducting regions percolate. We have shown, through the calculations presented in this paper, that this approach is suitable to reproduce the measured $T_c$ and $T^*$ phase diagrams for several cuprates using a phenomenological real charge distribution drawn from the STM/S data.

One of the advantages of our approach is that the pair formation and the phase coherent superconducting state are studied independently. The phase coherence is attained by percolation. On the other hand, the pair formation was studied by a mean field BCS like method in order to estimate the onset of superconducting gap $T^*$ for any doping level. This was the simplest method and the calculations could have been done with other theoretical approaches. However, notice that the pair formation mechanism is independent of how the coherent percolative phase is reached. This general approach is in agreement with new trends and ideas\textsuperscript{26,27}, which are based on new data and new experimental facts that mostly HTSC are inhomogeneous materials.

The method developed provides also new insights and introduces a new interpretation on several typical anomalous properties of HTSC: like the dependence of the zero temperature gap $\Delta_0(T)$ with the hole concentration, the downturn of the linear dependence to the resistivity with the temperature, the linear dependence of the hole concentration with the temperature, the suppression of the specific heat coefficient $\gamma$, the dependence of $T^*$ with the pressure, and others new implications which are presently being studied and which will be discussed in the future.
