³(Dated: March 4, 2010)

We present an effective contour model for electrical discharges deduced as the asymptotic limit of the minimal streamer model for the propagation of electric discharges, in the limit of small electron diffusion. The incorporation of curvature effects to the velocity propagation and not to the boundary conditions is a new feature and makes it different from the classical Laplacian growth models. For the first time, the dispersion relation for a non planar 2-D discharge is calculated. The development and propagation of finger-like patterns are studied and their main features quantified.

PACS numbers: 51.50.+v, 52.80.-s

The electrical breakdown of various media is usually caused by the appearance and propagation of ionization waves and, in particular, streamers. The difficulties for the understanding of this important and interesting phenomena are both experimental and theoretical. From experimental point of view, the historical lack of quantitative data, from small to large scales discharges, are mainly due to the fast time scales of the processes involved. Recently this situation is starting to change with the development of new experimental techniques. On the other hand, the theory is still far from being complete. Even in the simplest hydrodynamic approximation for describing the phenomena, it is necessary to solve a non-linear system of balance equations, together with Poisson equation, which poses a challenging problem both numerical and analytical. Among the recent progress in the understanding of the propagation mechanism we can mention: the study of stationary plane ionization waves [2, 3], first self-similar solutions for ionization waves in cylindrical and spherical geometries [4, 5], and the formation of streamers as the result of the instability of planar ionization fronts [6–8]. In the simplest hydrodynamic approximation, the fronts are subject to both stabilizing forces due to diffusion which tend to dampen out any disturbances, and destabilizing forces due to electric field which promote them.

In this letter we introduce and justify theoretically a contour dynamical model which allows us to make some progress in 2-D and 3-D more general situations. Here we will use ideas coming from the context of electrolyte solutions [9], but suitably adapted to the context of electric (plasma) discharges. We will obtain the dispersion relation for 2-D discharges like those described in some experiments [1].

For our contour model, in the asymptotic limit of small diffusion $D \ll 1$ (electron diffusions are typically of order $0.1$ m$^2$/s and, since typical velocities and streamer size [1] are $10^5$ m/2 and $10^{-2}$ m we get $D$ of order $10^{-5}$), the interface will move according to

$$v_N = -E^e_\nu + 2\sqrt{D\alpha(E^e_\nu) - D\kappa}$$

being $v_N$ the normal velocity and $\kappa$ twice the mean curvature and $\alpha(E^e_\nu)$ to be defined below. The free charge density on the boundary will be concentrated in a diffuse layer, and for the limit considered, its behavior will be characterized by a negative charge surface density $\sigma$ given by

$$\frac{\partial \sigma}{\partial t} + \kappa v_N \sigma = -\frac{E^e_\nu}{\varrho} - j^e_\nu,$$

where $j^e_\nu$ is the current density coming from the ionized region ($\Omega$) to its boundary ($\partial\Omega$) in the normal direction and $\varrho$ is related to the resistivity of the plasma. $E^e_\nu$ is the normal component of the electric field at the interface when approaching it from the region without/with plasma, i.e

$$E^e_\nu^+ = \lim_{x \to (\partial\Omega)^+} \left( \frac{\partial V}{\partial \nu} \right), \quad E^e_\nu^- = \lim_{x \to (\partial\Omega)^-} \left( -\frac{\partial V}{\partial \nu} \right),$$

with $V$ found by solving

$$\Delta V = \sigma \delta(r - r_{\partial\Omega}).$$

Notice that in the case $\varrho^{-1} \gg 1$, we arrive to Lozansky-Firsov model [10] with a correction due to electron diffusion, meanwhile in the limit $D = 0$ we arrive at the classical Hele-Shaw model. Such a model is known to possess solutions that develop singularities in the form of cusps in finite time [11] but, when regularized by surface tension corrections, the interface may develop various patterns including some of fractal-type (see [12] for a recent development and references therein).

Let’s derive the equations (1) and (2). We start from a minimal model of the discharge that in dimensionless units reads [6]

$$\frac{\partial n_c}{\partial t} - \nabla \cdot (n_c \vec{E} + D \nabla n_c) = n_c \alpha(|\vec{E}|),$$

$$\frac{\partial n_p}{\partial t} = n_p \alpha(|\vec{E}|),$$

$$\nabla \cdot \vec{E} = n_p - n_c.$$
with $\alpha(|E|) = |E| \exp(-1/|E|)$. Next we derive a contour dynamics equation for the evolution of the interface between the region occupied by the plasma and the region free (or with a very small density) of plasma. Note that this interface does not exist as such but, as in the case of planar fronts, the region where $n_e$ jumps from values close to 1 to values close to 0 has a thickness $O(D^{-1})$ [4]. Hence from (5) and (7) we will give an equation, valid in the asymptotic limit $D \ll 1$.

We take a level surface of $n_e$ representing the interface, and introduce local coordinates $\tau$ (along the level surface of $n_e$) and $\nu$ (orthogonal to the level surface of $n_e$). Since the front thickness is $O(D^{-1})$ it is natural to introduce $\nu = D^{-1} \chi$, so we can write approximately

$$D \Delta = \frac{\partial^2}{\partial \nu^2} + \sqrt{D\kappa} \frac{\partial}{\partial \chi} + D \left( \Delta_\perp - \kappa^2 \chi \frac{\partial}{\partial \chi} \right) + O(D^2)$$

where $\Delta_\perp$ is the transverse laplacian and $\kappa$ is twice the mean curvature in 3-D or just the curvature in 2-D (see e.g. [12]). Hence from (5) and (7)

$$\frac{\partial n_e}{\partial t} - \nu \frac{\partial n_e}{\partial \tau} - \left( \frac{E_\nu}{\sqrt{D}} + \sqrt{D\kappa} \right) \frac{\partial n_e}{\partial \chi} - \frac{\partial^2 n_e}{\partial \chi^2} = n_e (\alpha(|E|) + n_p - n_e) + O(D).$$

We expand now $|E|$ and $n_p$ at the diffusive boundary layer as explained in [4] and [8], so it is straightforward to end with

$$\frac{\partial n_e}{\partial t} - \nu \frac{\partial n_e}{\partial \tau} - \left( \frac{E_\nu}{\sqrt{D}} - 2\alpha(E_\nu) + \sqrt{D\kappa} \right) \frac{\partial n_e}{\partial \chi} = O(D^{-1}),$$

where a curvature term appears and is relevant provided $1 \ll \kappa \ll D^{-1}$. Eq. (8) is a transport equation for the electron density so that the level line of $n_e$ that we have chosen to describe the evolution of the interface moves with a normal velocity given by (11). Notice that the tangential velocity does not change the geometry of the curve during its evolution. Nevertheless, tangential exchanges of charge affect the evolution through the dependence of $\nu_N$ on $E_\nu$.

Next we describe the charge transport along the interface. We trace a “pillbox” $D$ around a surface element. The region $D$ will be such that $\Delta \tau \gg \Delta \nu$ and will contain both the diffusive layer for $n_e$ and the region where $n_e - n_p$ (the net negative charge) has significant values. If we subtract (9) from (11) and integrate over $D$ we find

$$\frac{\partial}{\partial t} \int_D (n_e - n_p) \, dV = \int_{\partial D} (n_e E + D \nabla n_e) \cdot \nu dS =$$

$$= n_e E_\nu \Delta \tau |_{\chi = -\infty} + O(D^{-1}),$$

where we have used that $n_e \rightarrow 0$ for $\chi = \nu/\sqrt{D} \gg 1$, $|\nabla n_e| \rightarrow 0$ for $|\chi| \gg 1$ and we have neglected the contributions of the lateral transport of charge by $E_\nu$ in comparison with exchange of charge with the bulk by $E_\nu$.

This assumption is also common in the Taylor-Melcher model and we will follow it. Notice that

$$\frac{\partial}{\partial t} \int_D (n_e - n_p) \, dV = \frac{\partial}{\partial t} \int_{-\infty}^{\infty} (n_e - n_p) \Delta \tau d\nu = \frac{\partial}{\partial t} (\sigma \Delta \tau),$$

and the length (or area) element of the surface will suffer a change during interface deformation given by

$$\frac{\partial \Delta \tau}{\partial t} = \kappa v_N \Delta \tau.$$

We can also include a source (an insulated wire inside the plasma, for instance at $x_0$, carrying a electric current $I(t)$). This source will create a current density inside the plasma and as quasineutrality is fulfilled, we will have for the interior of $\Omega$

$$\nabla \cdot j = I(t) \delta(x - x_0).$$

By putting (9)-(12) together we can finally write the equation (2), where $\varrho$ is the effective resistivity of the medium, given in this case as $\varrho^{-1} = \lim_{\chi \to -\infty} n_e$ and $E_\nu^+$ is the normal component of the electric field when approaching the interface from inside the plasma region. $j_\nu^+$ is normal component of the current density given by (12) arriving at the interface. There is a jump in the normal component of the electric field across the interface given by

$$E_\nu^+ - E_\nu^- = -\sigma.$$

Eq. (2) will provide the surface charge density $\sigma$ as a function of time. From it, we can compute the electric field and move the interface with (1). Two limits can be easily identified in the case of $j \approx 0$: a) the limit of large conductivity

$$\varrho^{-1} \gg 1, \quad E_\nu^- = 0 \Rightarrow V = C(t).$$

so that the interface is equipotential and b) the limit of small conductivity

$$\varrho^{-1} \ll 1, \quad \frac{\partial}{\partial t} (\sigma \Delta \tau) = 0 \Rightarrow \sigma \Delta \tau = Cst.$$

where the charge contained by a surface element is constant and the density only changes through deformation (with change of area) of the interface.

Next we study as an application a 2-D case. The 2-D case is not at all academic as there have been experiments where a 2 dimensional streamer discharge is created on a surface and branched pattern are observed. In Fig. (1) we can see a numerical simulation intended to mimic the experiment of [1] using (11) and (2). This set of equations also allow us to calculate the dispersion relation for the front stability and give some analytical insight.

Let’s write the position and the charge “surface” density of the interface as

$$r(\theta, t) = r(t) + \delta S(\theta, t)$$

$$\sigma(\theta, t) = -\frac{Q(t)}{2\pi r^2(\theta, t)} + \delta \Sigma(\theta, t)$$

(14)
where \( r(t) \) is the solution of the equations for the radial symmetrical front, \( Q(t) = \int_0^t I(t) \, dt \) and \( \delta \) is our bookkeeping small parameter for the expansions that follow.

We will start calculating the correction to the electric field due to the geometrical perturbation of the surface and the extra charge deposited on it. The electric potential will be up to delta order \( \Phi(x) = V(x) + \delta V_p(x) \) being \( V \) the solution for the symmetrical problem. The term \( V_p(x) \) will satisfy the equation \( \Delta V_p = 0(\delta) \) and further on, we will change coordinates to \( x \rightarrow \tilde{x} = x r(t)/r(\theta, t) \) so the perturbed surface becomes a disk of radius \( r(t) \). Now at zero order \( V_p \) satisfies the Laplace equation with the boundary being a disk. Hence we have in the new polar coordinates

\[
V_p(\tilde{r}, \theta) = \begin{cases} 
\sum_{n=1}^{\infty} \psi_n \cos(n\theta) \left( \frac{\tilde{r}}{r} \right)^n, & \tilde{r} > r \\
\sum_{n=1}^{\infty} \varphi_n \cos(n\theta) \left( \frac{\tilde{r}}{r} \right)^n, & \tilde{r} \leq r
\end{cases}
\]  

(16)

where we have imposed the conditions of \( V_p \) remains finite at the origin and becomes zero at very large distances. The potential at the surface position coming from the exterior is \( \Phi(x^+_{\text{ext}}) = -Q(t) \log(r(\theta, t))/2\pi + \delta V_p(x^+_{\text{ext}}) \) and from the interior is \( \Phi(x^-_{\text{int}}) = C(r(t), t) + \delta V_p(x^-_{\text{int}}) \) where \( C(r(t), t) \) is a function independent of \( \theta \). So if we write the surface perturbation as

\[
S = \sum_{n=1}^{\infty} s_n(t) \cos(n\theta),
\]  

(17)

imposing the condition of continuity for the potential, we find that the coefficients of the potential in \[16\] are related by

\[
\psi_n = \varphi_n + \frac{Q(t)}{2\pi r} s_n.
\]  

(18)

Now we can calculate the electric field to \( \delta \) order. Changing back coordinates, from \( \tilde{x} \) to \( x \), the normal compon-ents of the electric field at both sides of the surface are

\[
E^+_\nu = \frac{Q(t)}{2\pi(r + \delta S)} + \delta \sum_{n=1}^{\infty} \left( \varphi_n + \frac{Q(t)}{2\pi r} s_n \right) \frac{n}{r} \cos(n\theta),
\]

\[
E^-_\nu = -\delta \sum_{n=1}^{\infty} \varphi_n \frac{n}{r} \cos(n\theta).
\]

Then, the jump condition \[14\] together with \[13\] give the following expression for the charge perturbation

\[
\Sigma = -\sum_{n=1}^{\infty} \left( 2\varphi_n + \frac{Q(t)}{2\pi r} s_n \right) \frac{n}{r} \cos(n\theta),
\]

(19)

where \( r = r(t) \) is the evolving radius of the unperturbed circle, i.e. the radially symmetric solution to \[11, 12\].

We still need the expression of the curvature at \( \delta \) order to find the dynamics of the front. In polar coordinates, after introducing the perturbation \[14\], the curvature turns out to be

\[
\kappa = \frac{r^2 + 2rS\delta - rS\theta \delta + O(\delta^2)}{(r^2 + 2rS\delta + O(\delta^2))^2} = \frac{1}{r} \frac{S + S\theta \delta + O(\delta^2)}{r^2} = \frac{1}{r} \frac{S}{r^2} + \frac{\delta}{r^3} + O(\delta^2),
\]

and the normal component of the velocity

\[
v_N = \mathbf{v} \cdot \mathbf{n} = \frac{dv_n}{dt} + \delta \frac{dS}{dt} \Theta(\theta, t).
\]

Now Eqs. \[11\] and \[12\] after introducing the perturbations to first order, defining \( \epsilon = D \), and doing some algebraic manipulations yield

\[
\frac{ds_n}{dt} = -\left[ \frac{Q(t)}{2\pi r^2} (n - 1) - \frac{\epsilon}{r^2} (n^2 - 1) \right] s_n - \frac{n}{r} \varphi_n,
\]

(20)

\[
\frac{d\varphi_n}{dt} = \left[ \frac{Q(t)}{2\pi r^2} + \frac{n(n + 2)\epsilon}{2r} - \frac{n}{r} \right] s_n + \frac{1}{2} \left[ \frac{Q(t)}{2\pi r^2} - \frac{1}{\theta} \right] \varphi_n.
\]

(21)

Thus the time evolution of each particular mode has been obtained and it is governed by \[20\] and \[21\]. First let’s study the limit of ideal conductivity. It makes \( \varrho \to 0 \), so we can see from \[21\] that \( \varphi_n \to 0 \). Physically it means that in the limit of very high conductivity, the electric field inside goes to zero \( (E^-_n \to 0) \), as we approach to the behaviour of a perfect conductor. If we consider that \( Q(t) = Q_0 \) is constant or its variation in time is small compared with the evolution of the modes (which also implies \( I(t) \to 0 \)) and the same for the radius of the front \( r(t) = r_0 \), we can try a solution \( s_n = \exp(\omega_n t), \varphi_n = 0 \), to our system, and we get a discrete dispersion relation of the form

\[
\omega_n = -\frac{Q_0}{2\pi r_0^2} (n - 1) - \frac{\epsilon}{r_0^2} (n^2 - 1).
\]

(22)

Next we consider the limit of finite resistivity, but such that the total charge is constant at the surface, or varies very slowly. Writing \[21\] as

\[
\frac{d\varphi_n}{dt} = -\frac{d}{dt} \left( \frac{Q(t)}{4\pi r} s_n \right) - \frac{Q(t) dr}{4\pi r^2 dt} n s_n - \frac{1}{2\theta} \varphi_n,
\]
we have now
\[ \frac{d\varphi_n}{dt} = -\frac{Q_0}{4\pi r_0} \frac{ds_n}{dt} - \frac{1}{2} \frac{\omega_n}{\omega_n}. \]

For a small enough conductivity, so no extra charge reaches the surface, we find \( \varphi_n = -\frac{Q_0}{4\pi r_0} s_n \), and with \( s_n = \exp(\omega_n t) \), (20) yields
\[ \omega_n = -\frac{Q_0}{2\pi r_0^2} \left( \frac{n^2}{2} - 1 \right) - \frac{\varepsilon}{r_0} (n^2 - 1). \] (23)

In a curved geometry we can see that the modes are discrete. If we compare (22) and (23), for \( n = 1 \) corresponds the same \( \omega_1 = 0 \) which reveals the translation invariance of the front. However, for small \( n \), there is a 1/2 factor discrepancy in the dispersion curve between the two limits. In (14), the origin of this prefactor was discussed for planar fronts (the dispersion relation for planar fronts was obtained in the case of constant charge in [8]). So imposing constant charge at the surface, this factor is independent of the planar or curve geometry. On the other hand, imposing constant potential at the surface gives a factor of 1. The intermediate situations can be studied by solving the system (20) and (21). Another consequence is that in both cases the maximum growth correspond to a perturbation with
\[ n \propto |Q_0|/D, \] (24)

implying that the number of fingers increases with the net charge and decreases with electron diffusion.

To test the analytical predictions, we have calculated numerically the dispersion relation curves for these two cases. In Fig. 2 for different charges \( \omega_1 = 0 \), the slope increases with the amount of charge, the maxima moves to higher modes, and for larger \( n \)'s the dispersion curves become negative as predicted by (23). In the inset of Fig. 2 the dispersion relation curve is calculated for the case of constant charge and constant potential. The slope around the origin \( n = 1 \) is bigger for the case of ideal conductivity, when the interface is equipotential. The ratio of the slopes can be estimated as \( \approx 0.49 \) which is in agreement with our prediction of 1/2 (see [14]).

To conclude, we have introduced a contour dynamics model a la Taylor-Melcher [9] for the streamers discharges. Our model contains as a particular limit the Lozansky-Firsov model [10] with a correction due to electron diffusion which effectively acts as a surface tension. In the limit \( D = 0 \) the classical Hele-Shaw model [11] is recovered. In this framework we have studied the stability of 2-D discharges. It is our hope that this model can open the door for the study of 3-D problems of streamer discharges in realistic geometries. An extra advantage of this model is its relatively low computational cost and the high analytical insight which provides.
