1. Introduction. In many statistical problems, especially those associated with change points, we often have to derive the distributions of functionals of a compound Poisson process (CPP). Examples include the estimation of the location of a discontinuity in density (e.g., Chernoff and Rubin (1956)), and the estimation of thresholds in threshold regression, also called two-phase regression or segmentation (e.g., Koul and Qian (2002), Seijo and Sen (2011) and Yu (2012, 2015)), threshold autoregressive (TAR) models (e.g., Chan (1993), Tsay (1989, 1998), Gonzalo and Pitarakis (2002) and Li and Ling (2012)), threshold double autoregressive (TDAR) models (e.g., Li, Ling and Zakoian (2015) and Li, Ling and Zhang (2016)), conditionally heteroscedastic AR models with thresholds (T-CHARM) (e.g., Chan, et al. (2014)), threshold moving-average (TMA) models (e.g., Li, Ling and Li (2013)), threshold autoregressive moving-average (TARMA) models (e.g., Li, Li and Ling (2011)), and others. However, it is typically difficult to derive their distributions in closed-form.

To circumvent the difficulty, an important approach is to approximate the CPP by a Brownian
motion (BM) in some sense because the situation is much more tractable in the latter. See, e.g., Stryhn (1996). The primary objective of this paper is to introduce a new approximation of

\[
P(z) = I(z < 0) \sum_{k=1}^{N_1(-z)} \xi_{k}^{(1)} + I(z \geq 0) \sum_{k=1}^{N_2(z)} \xi_{k}^{(2)}, \quad z \in \mathbb{R},
\]

where \(\{N_1(z), z \geq 0\}\) and \(\{N_2(z), z \geq 0\}\) are independent Poisson processes with rates \(\lambda_1\) and \(\lambda_2\), respectively, \(\{\xi_{k}^{(1)} : k \geq 1\}\) and \(\{\xi_{k}^{(2)} : k \geq 1\}\) are independent and identically distributed (i.i.d.) sequences with \(E\xi_{k}^{(i)} > 0\) for \(i = 1, 2\), respectively, and mutually independent. \(\{N_i(z)\}\) and \(\{\xi_{k}^{(j)}\}\) are also mutually independent. Throughout the paper, these assumptions are always supposed to hold.

This paper is organized as follows. We state the main results in Section 2. In Section 3, we describe some important applications in threshold models. In Section 4, we assess the efficacy of the theoretical results of approximation by numerical simulations. A real data set is also included. All proofs of Theorems are in the online supplementary material.

2. Main results. Using the parameterizing technique (e.g. Kushner (1984) and Skorokhod, Hoppensteadt and Salehi (2002)), we introduce a new parameter \(\gamma > 0\) to re-parameterize (1.1) to \(\{P_{\gamma}(z) : z \in \mathbb{R}\}\) to

\[
P_{\gamma}(z) = I(z < 0) \sum_{k=1}^{N_1(|z|/\gamma)} \xi_{k}^{(1)} + I(z \geq 0) \sum_{k=1}^{N_2(z/\gamma)} \xi_{k}^{(2)}, \quad z \in \mathbb{R}.
\]

Denote

\[m_{\gamma} = s- \arg \min_{z \in \mathbb{R}} P_{\gamma}(z),\]

where ‘s-argmin’ stands for the smallest argmin.

Thus, we embed (1.1) into a sequence of \(\{P_{\gamma}(z) : z \in \mathbb{R}\}\). Our interests are \(m_{\gamma}\) and the limits of \(\{P_{\gamma}(z) : z \in \mathbb{R}\}\) as \(\gamma\) shrinks to zero under some suitable conditions. To this end, we first introduce two assumptions.

**Assumption 1.** \(E\xi_{1}^{(i)} = a_{i}\gamma + o(\gamma)\) and \(E\xi_{1}^{(i)^2} = b_{i}\gamma + o(\gamma)\) as \(\gamma \to 0\) for some positive constants \(a_{i}\) and \(b_{i}\), \(i = 1, 2\).

**Assumption 2.** The rate of \(N_i(\cdot)\) is \(\lambda_i > 0\), \(i = 1, 2\).

Note that the choice of \(\lambda_i\) is critical. For example, if the rate of the component Poisson process is chosen as a function such that it tends to a deterministic continuous one, the CPP converges weakly to
a CPP. See, e.g., Jacod and Shiryaev (2003). In our approach, \( \lambda_i \)'s are fixed constants. The following theorem states that the sequence of stochastic processes \( \{ \mathcal{P}_\gamma(z) : z \in \mathbb{R} \} \) can be approximated by a two-sided BM with drift.

**Theorem 1.** Let \( \Rightarrow \) stand for weak convergence. Let \( \mathbb{D}(\mathbb{R}) \) denote the space of functions defined on \( \mathbb{R} \), which are right continuous and have left limits. Let the space be endowed with the Skorokhod topology. If Assumptions 1-2 hold, then, as \( \gamma \to 0 \),

\[
\mathcal{P}_\gamma(z) \Rightarrow \mathcal{W}(z) \quad in \mathbb{D}(\mathbb{R}),
\]

where

\[
\mathcal{W}(z) = \begin{cases} 
\lambda_1 a_1 |z| - \sqrt{\lambda_1 b_1} \mathbb{B}_1(|z|), & \text{if } z \leq 0, \\
\lambda_2 a_2 z - \sqrt{\lambda_2 b_2} \mathbb{B}_2(z), & \text{if } z > 0,
\end{cases}
\]

with \( \mathbb{B}_1(z) \) and \( \mathbb{B}_2(z) \) being two independent standard Brownian motions on \( [0, \infty) \). Further, let \( T := \arg \min_{z \in \mathbb{R}} \mathcal{W}(z) \). Then \( m_\gamma \Rightarrow T \).

In the literature, the density of \( T \) is readily available and has a closed form, which is given in the following theorem; see Proposition 1 in Stryhn (1996).

**Theorem 2.** The probability density of \( T \) is given by

\[
f_T(x; a_i, b_i, \lambda_i) = \begin{cases} 
g(|x|; a_1 \sqrt{\lambda_1/b_1}, (a_2/b_2)\sqrt{\lambda_1 b_1}), & \text{for } x < 0, \\
g(x; a_2 \sqrt{\lambda_2/b_2}, (a_1/b_1)\sqrt{\lambda_2 b_2}), & \text{for } x \geq 0,
\end{cases}
\]

where

\[
g(x; \theta_1, \theta_2) = 2\theta_1(\theta_1 + 2\theta_2) \exp\{2\theta_2(\theta_1 + \theta_2)x\} \Phi(-\theta_1 + 2\theta_2) - 2\theta_1^2 \Phi(-\theta_1) \sqrt{x}, \quad x \geq 0,
\]

and \( \Phi(\cdot) \) is the standard normal distribution.

**Corollary 1.** Suppose that \( \gamma = E_\xi^{(1)} = E_\xi^{(2)} > 0, \lambda_1 = \lambda_2 := \lambda, \) and \( E\{\xi_i^{(i)}\}^2 = b_i \gamma + o(\gamma) \) as \( \gamma \to 0 \) for positive constants \( b_i, i = 1, 2 \). Then

\[
\lambda m_\gamma \Rightarrow T := \arg \min_{z \in \mathbb{R}} \mathcal{W}^*(z),
\]
where
\[ W^*(z) = \begin{cases} |z| - \sqrt{b_1} B_1(|z|), & \text{if } z \leq 0, \\ z - \sqrt{b_2} B_2(z), & \text{if } z > 0, \end{cases} \]
and the density of \( T_1 \) is
\[ f_{T_1}(x; b_1, b_2) = \begin{cases} g(|x|; 1/\sqrt{b_1}, \sqrt{b_1}/b_2), & \text{for } x < 0, \\ g(x; 1/\sqrt{b_2}, \sqrt{b_2}/b_1), & \text{for } x \geq 0, \end{cases} \]
where \( g(\cdot) \) is as in Theorem 2.

Corollary 2. Suppose that \( \gamma = E \xi_1^{(1)} = E \xi_1^{(2)} > 0, \lambda_1 = \lambda_2 := \lambda, \) and \( E \{ \xi_1^{(1)} \}^2 = E \{ \xi_1^{(2)} \}^2 = b\gamma + o(\gamma) \) as \( \gamma \to 0 \) for some positive constant \( b \). Then
\[ \frac{4\lambda m\gamma}{b} \Rightarrow T_2, \]
where \( T_2 \) has the density
\[ f_{T_2}(x) = \frac{3}{2} \Phi \left( -\frac{3}{2} \sqrt{|x|} \right) e^{x|x|} - \frac{1}{2} \Phi \left( -\frac{1}{2} \sqrt{|x|} \right). \]  

Thus, Theorem 2 includes the density (2.2) as a special case. Yao (1987) used this special case in his study of the approximation of the limiting distribution of the maximum likelihood estimate of a change-point problem. The distribution of \( T_2 \) has exponential tails; see Remark 1 in Yao (1987). Note that Theorem 1 includes Theorem 1 of Hansen (2000) as a special case. Figure 1 displays the density and the cumulative distribution function (CDF) of \( T_2 \). From Figure 1, we can see that \( T_2 \) is symmetric. Moreover, for our needs, it is easy to tabulate the quantiles of \( T_2 \). For any given level \( \alpha \in (0,1) \), denote by \( Q_{\alpha} \) the \( \alpha \)th quantile of \( T_2 \). Table 1 gives some commonly used quantiles.

| \( \alpha \) | 0.5 | 0.95 | 0.975 | 0.995 |
|---|---|---|---|---|
| \( Q_{\alpha} \) | 7.6873 | 11.0333 | 19.7665 |

3. Applications.
3.1. Threshold regression model. To the best of our knowledge, the threshold regression model, also called the two-phase regression model or the segmentation model, can be dated back to Quandt (1958). Since then it has been widely used in economics and other areas. Asymptotics on statistical inference for such models have been considered; see, e.g., Hinkley (1969, 1971), Hansen (2000), Koul and Qian (2002), Seijo and Sen (2011) and Yu (2012, 2015).

We say \((x', y, z)\) follows a threshold regression model if

\[
y = \begin{cases} 
  x'\beta_1 + \sigma_1 \varepsilon, & \text{if } z \leq r, \\
  x'\beta_2 + \sigma_2 \varepsilon, & \text{if } z > r,
\end{cases}
\]  

(3.1)

where \(y\) is a scalar dependent variable and \(x = (x_1, ..., x_p)'\) explanatory variables (or independent variables), \(z\) is called the threshold variable and \(r\) the threshold parameter, and \(\varepsilon\) is the error with zero mean and unit variance.

Suppose that \(\{(x_i', y_i, z_i)\}\) is a random sample of size \(n\) from model (3.1) with the true parameter \(\theta_0 = (\beta_{10}', \beta_{20}', r_0)'\) and \((\sigma_{10}, \sigma_{20})\). Denote by \(\hat{\theta}_n\) the least squares estimator (LSE) of \(\theta_0\). Under some conditions (e.g., Koul and Qian (2002)), we have

\[n(\hat{r}_n - r_0) \Rightarrow M_- := s\arg\min_{z \in \mathbb{R}} \mathcal{P}(z),\]

where

\[
\mathcal{P}(z) = I(z \leq 0) \sum_{i=1}^{N_1(z)} \zeta_i^{(1)} + I(z > 0) \sum_{i=1}^{N_2(z)} \zeta_i^{(2)}.
\]  

(3.2)
Here, $N_1(\cdot)$ and $N_2(\cdot)$ are independent Poisson processes with the same rate $\pi(r_0)$, which is the value of the density $\pi(\cdot)$ of $z$ at $r_0$, and where $\{\zeta_k^{(1)} : k \geq 1\}$ is a sequence of i.i.d. random variables with the same distribution as the one induced by

$$\zeta^{(1)} = \{x'(\beta_{10} - \beta_{20})\}^2 + 2\sigma_{10}^{\epsilon}\{x'(\beta_{10} - \beta_{20})\}$$

given $z = r_0^-$,

and the sequence $\{\zeta_k^{(2)} : k \geq 1\}$ by

$$\zeta^{(2)} = \{x'(\beta_{10} - \beta_{20})\}^2 - 2\sigma_{20}^{\epsilon}\{x'(\beta_{10} - \beta_{20})\}$$

given $z = r_0^+$. Here, $z = r_0^-$ and $z = r_0^+$ denote convergence to $r_0$ from below and from above respectively.

Clearly, $E\zeta^{(i)}$ is a function of $\beta_{10} - \beta_{20}$. To obtain an approximation of $M_-$ by Theorem 1 when $||\beta_{10} - \beta_{20}||$ is small, we can introduce a new parameter $\gamma = E\zeta^{(1)}$ to re-parameterize the CPP (3.2). Note that unlike Hansen (1997), $||\beta_{10} - \beta_{20}||$ is fixed and not sample-size dependent.

By the definitions of $m_\gamma$ and $M_-$, we have $m_\gamma = \gamma M_-$. Note that $E\zeta^{(1)} = E\zeta^{(2)} = \gamma$, $E\{\zeta^{(1)}\}^2 = 4\sigma_{10}^2 \gamma + o(\gamma)$ and $E\{\zeta^{(2)}\}^2 = 4\sigma_{20}^2 \gamma + o(\gamma)$. Then, by Corollary 1, it follows that

$$\gamma \pi(r_0) n(\hat{r}_n - r_0) \rightsquigarrow T_1,$$

where $\rightsquigarrow$ means that $T_1$ is a usable approximation of $\gamma \pi(r_0) n(\hat{r}_n - r_0)$ in the distribution sense, and the density of $T_1$ is

$$f_{T_1}(x; \sigma_{10}, \sigma_{20}) = \begin{cases} 
   g(-x; 1/(2\sigma_{10}), \sigma_{10}/(2\sigma_{20}^2)), & \text{for } x < 0, \\
   g(x; 1/(2\sigma_{20}), \sigma_{20}/(2\sigma_{10}^2)), & \text{for } x \geq 0.
\end{cases}$$

In particular, if $\sigma_{10}^2 = \sigma_{20}^2 := \sigma^2$, then, by Corollary 2,

$$\frac{\gamma \pi(r_0)}{\sigma^2} n(\hat{r}_n - r_0) \rightsquigarrow T_2.$$

In practice, $\pi(\cdot)$ can be estimated by the nonparametric kernel method. Then, on using the plug-in method, an estimate $\hat{\pi}_n(\hat{r}_n)$ of $\pi(r_0)$ can be obtained. An estimate of $\sigma^2$ can be got from the residuals. However, the estimate of $\gamma$ is a little complicated since it is a conditional expectation, namely $\gamma = E(\{x'(\beta_{10} - \beta_{20})\}^2|z = r_0)$. Of course, if $x$ and $z$ are independent, then $\gamma$ is an unconditional expectation. In this case, it is easy to estimate $\gamma$ by $\hat{\gamma}_n = n^{-1}\sum_{i=1}^n\{x'_i(\beta_{1n} - \bar{\beta}_{2n})\}^2$. If they are not independent, a good choice is to use the best linear predictor of $\{x'(\beta_{10} - \beta_{20})\}^2$ based on $z$ with $\bar{\theta}_n$ in lieu of $\theta_0$ to approximate $\gamma$; see (3.7) in the following Subsection 3.3. Once the estimates of $\gamma$, $\pi(r_0)$ and $\sigma^2$ are obtained, we can construct confidence intervals of $r_0$ by using the quantiles of $T_2$. 
3.2. Threshold AR model. The TAR model is an important class of nonlinear time series models. The idea of threshold in the time series context was initially conceived around 1976, first appeared in Tong (1978) and was later formalized in Tong and Lim (1980). Fuller results can be found in the monograph of Tong (1990). For history and future outlook, see, e.g., Tong (2011, 2015). Chan (1993) is a significant contribution to the inference of TAR models. It is the first breakthrough in the asymptotic theory of the LSE of the threshold parameter in discontinuous two-regime TAR models. Other important contributions include Tsay (1989, 1998), Gonzalo and Pitarakis (2002), and others. Li and Ling (2012) first established the asymptotic theory of the LSE in multiple-regime TAR models.

A time series \{y_t\} is said to follow a two-regime TAR model of order \(p\) if it satisfies

\[
y_t = \begin{cases} 
  y_{t-1}'\beta_{10} + \sigma_{10}\varepsilon_t, & \text{if } y_{t-d} \leq r_0, \\
  y_{t-1}'\beta_{20} + \sigma_{20}\varepsilon_t, & \text{if } y_{t-d} > r_0,
\end{cases}
\]

where \(y_{t-1} = (1, y_{t-1}, ..., y_{t-p})'\), \(\{\varepsilon_t\}\) is a sequence of i.i.d. random variables with zero mean and unit variance and \(\varepsilon_t\) independent of \(\{y_{t-j} : j \geq 1\}\).

Suppose that \(\{y_1, ..., y_n\}\) is a sample from the TAR model (3.3). Denote by \(\hat{r}_n\) the LSE of \(r_0\). Under CONDITIONS 1-4 in Chan (1993) or Assumptions 3.1-3.4 in Li and Ling (2012), and by Theorem 3.3 in Li and Ling (2012), we have

\[
n(\hat{r}_n - r_0) \Rightarrow M_- := s- \arg\min_{z \in \mathbb{R}} \mathcal{P}(z),
\]

where the left and the right jump distributions in the two-sided CPP \(\mathcal{P}(\cdot)\) are induced by

\[
\zeta^{(1)}_t = \{y_{t-1}'(\beta_{10} - \beta_{20})\}^2 + 2\sigma_{10}\varepsilon_t\{y_{t-1}'(\beta_{10} - \beta_{20})\} \quad \text{given } y_{t-d} = r_0^{-}
\]

and

\[
\zeta^{(2)}_t = \{y_{t-1}'(\beta_{10} - \beta_{20})\}^2 - 2\sigma_{20}\varepsilon_t\{y_{t-1}'(\beta_{10} - \beta_{20})\} \quad \text{given } y_{t-d} = r_0^{+},
\]

respectively. Both rates are the same, i.e., \(\pi(r_0)\), which is the value of the density \(\pi(\cdot)\) of \(y_t\) at \(r_0\).

From the above expressions, we can set \(\gamma = E(\{y_{t-1}'(\beta_{10} - \beta_{20})\}^2 | y_{t-d} = r_0)\), which is a function of \(\beta_{10} - \beta_{20}\). Note that when \(\|\beta_{10} - \beta_{20}\|\) is small, the range of \(M_-\) is large. In this case, we can use Theorem 1 to approximate \(M_-\).

Note that \(E(\zeta^{(1)}_t | y_{t-d} = r_0) = E(\zeta^{(2)}_t | y_{t-d} = r_0) = \gamma\), and \(E(\{\zeta^{(1)}_t\}^2 | y_{t-d} = r_0) = 4\sigma_{10}^2\gamma + o(\gamma)\) and \(E(\{\zeta^{(2)}_t\}^2 | y_{t-d} = r_0) = 4\sigma_{20}^2\gamma + o(\gamma)\). Thus, by Corollary 1, we have

\[
\gamma\pi(r_0) n(\hat{r}_n - r_0) \rightarrow T_1
\]
with
\[
f_{T_1}(x; \sigma_{10}, \sigma_{20}) = \begin{cases} 
  g(|x|; \frac{1}{2\sigma_{10}}, \frac{\sigma_{10}}{2\sigma_{20}^2}), & \text{for } x < 0, \\
  g(x; \frac{1}{2\sigma_{20}}, \frac{\sigma_{20}}{2\sigma_{10}^2}), & \text{for } x \geq 0.
\end{cases}
\]

In applications, in order to construct confidence intervals of \( r_0 \) by (3.4), we must estimate \( \pi(r_0) \) and \( \gamma \). Clearly, estimating \( \pi(\cdot) \) is easy. For example, we can use the nonparametric kernel method and then use the plug-in method to get an estimate \( \hat{\pi}_n(\hat{r}_n) \) of \( \pi(r_0) \). However, it is rather difficult to estimate \( \gamma \) directly since it is a conditional expectation. An easy and good choice is to use the best linear predictor to replace it. Of course, the re-sampling method in Li and Ling (2012) is still helpful.

Now, by using Algorithms B and C in Li and Ling (2012), we can draw a new sample \( \{y^*_t\} \) with \( y^*_i - d = \hat{r}_n \) for each \( y^*_i \) and then use the new sample to estimate \( \gamma \) with \( \hat{\beta}_1 n - \hat{\beta}_2 n \) in lieu of \( \beta_{10} - \beta_{20} \).

In particular, we consider a simple discontinuous TAR(1) model:
\[
y_t = \left\{ \beta_{10} I(y_{t-1} \leq r_0) + \beta_{20} I(y_{t-1} > r_0) \right\} y_{t-1} + \varepsilon_t,
\]
where the notation is the same as in model (3.3), except for \( \text{var}(\varepsilon_t) = \sigma^2 \). In this case, the jumps are unconditional and simple:
\[
\zeta_t^{(1)} = \{r_0(\beta_{10} - \beta_{20})\}^2 + 2r_0(\beta_{10} - \beta_{20})\varepsilon_t
\]
and
\[
\zeta_t^{(2)} = \{r_0(\beta_{10} - \beta_{20})\}^2 - 2r_0(\beta_{10} - \beta_{20})\varepsilon_t.
\]
Let \( \gamma = \{r_0(\beta_{10} - \beta_{20})\}^2 \). Then, \( E\zeta_t^{(1)} = E\zeta_t^{(2)} = \gamma, \ E\{\zeta_t^{(1)}\}^2 = E\{\zeta_t^{(2)}\}^2 = 4\sigma^2\gamma + o(\gamma) \). By Corollary 2, it follows that
\[
\frac{\gamma \pi(r_0)}{\sigma^2} n(\hat{r}_n - r_0) \overset{\mathcal{D}}{\rightarrow} T_2.
\]
In this simple case, we can estimate \( \gamma \) by \( \hat{\gamma}_n = \{\hat{\beta}_n(\hat{\beta}_{1n} - \hat{\beta}_{2n})\}^2 \) and \( \pi(r_0) \) by \( \hat{\pi}_n(\hat{r}_n) \), a nonparametric kernel estimate, and \( \sigma^2 \) by \( \hat{\sigma}^2_n = n^{-1} \sum_{t=1}^n \hat{\varepsilon}_t^2 \), where \( \{\hat{\varepsilon}_t\} \) is the residual based on the LSE. Thus, (3.5)
\[
\text{NS}_n := \frac{\hat{\gamma}_n \hat{\pi}_n(\hat{r}_n)}{\hat{\sigma}^2_n} n(\hat{r}_n - r_0)
\]
can be approximated by \( T_2 \) when \( |r_0(\beta_{10} - \beta_{20})| \) is small.
3.3. **Threshold MA model.** The TMA model is an important class of threshold time series models. It is a natural generalization of linear MA models. The linear MA model was first introduced by Slutsky (1927) and since then it has been widely used in many areas such as business, economics, etc. It has played a prominent role in the development of time series analysis. However, nonlinear MA models have developed slowly and have been overshadowed by nonlinear AR models. The slow development was mostly due to difficulties in statistical inference for general nonlinear MA models; see Robinson (1977). To-date, studies on nonlinear MA models mainly focus on TMA ones; see, e.g., Ling and Tong (2005), Ling, Tong and Li (2007), Li and Li (2008), Li, Ling and Tong (2012) and Li (2012). Recently, Li, Ling and Li (2013) studied the asymptotic theory of the LSE in TMA models and succeeded in obtaining the limiting distribution of the estimated threshold for the first time in the literature.

A time series \( \{y_t\} \) is said to follow a TMA model of order 1 if it satisfies

\[
y_t = \varepsilon_t + [\phi_0 I(y_{t-1} \leq r_0) + \psi_0 I(y_{t-1} > r_0)]\varepsilon_{t-1},
\]

where \( \{\varepsilon_t\} \) is i.i.d. with mean zero and variance \( \sigma^2_\varepsilon \in (0, \infty) \), and \( \varepsilon_t \) is independent of \( \{y_j : j < t\} \). Let \( \theta = (\phi, \psi, r)' \) denote the parameter and \( \theta_0 \) its true value.

Let \( \hat{\theta}_n \) be the LSE of \( \theta_0 \). Li, Ling and Li (2013) showed that under their Assumptions 2.1-2.3

\[
n(\hat{r}_n - r_0) \Rightarrow M_- := s \arg \min_{z \in \mathbb{R}} \mathcal{P}(z),
\]

where

\[
\mathcal{P}(z) = I(z \leq 0) \sum_{i=1}^{N_1(-z)} \zeta_i^{(1)} + I(z > 0) \sum_{i=1}^{N_2(z)} \zeta_i^{(2)}.
\]

Here, \( N_1(\cdot) \) and \( N_2(\cdot) \) are independent Poisson processes with the same rate \( \pi(r_0) \), which is the value of the density \( \pi(\cdot) \) of \( y_t \) at \( r_0 \), and \( \{\zeta_k^{(1)} : k \geq 1\} \) is an i.i.d. random variable with the same distribution as the one induced by

\[
\zeta^{(1)} = (\phi_0 - \psi_0)^2 \varepsilon_t^2 \sum_{j=0}^{\infty} \prod_{i=0}^{j-1} \{\phi_0^2 I(y_{t+i} \leq r_0) + \psi_0^2 I(y_{t+i} > r_0)\}
\]

\[
+ 2(\phi_0 - \psi_0) \varepsilon_{t-1} \sum_{j=0}^{\infty} \varepsilon_{t+j} \prod_{i=0}^{j-1} \{-\phi_0 I(y_{t+i} \leq r_0) - \psi_0 I(y_{t+i} > r_0)\}
\]
given \( y_{t-1} = r_0^+ \). Similarly, for the sequence \( \{\zeta_k^{(2)} : k \geq 1\} \), we have

\[
\zeta^{(2)} = (\phi_0 - \psi_0)^2 \varepsilon_{t-1}^2 \sum_{j=0}^{\infty} \prod_{i=0}^{j-1} \{\phi_0^2 I(y_{t+i} \leq r_0) + \psi_0^2 I(y_{t+i} > r_0)\} - 2(\phi_0 - \psi_0)\varepsilon_{t-1} \sum_{j=0}^{\infty} \varepsilon_{t+j} \prod_{i=0}^{j-1} \{-\phi_0 I(y_{t+i} \leq r_0) - \psi_0 I(y_{t+i} > r_0)\}
\]

given \( y_{t-1} = r_0^- \). Here, the convention \( \prod_{i=0}^{-1} \equiv 1 \) is adopted.

When \( |\phi_0 - \psi_0| \) is small, that is when the threshold effect is small, we can approximate \( M_- \) or \( n(\hat{\tau}_n - r_0) \) by Theorem 1. Note that, if \( |\phi_0 - \psi_0| = 0 \), then \( \phi_0 = \psi_0 \). Thus,

\[
\gamma = E(\zeta^{(1)}|y_{t-1} = r_0) = E(\zeta^{(2)}|y_{t-1} = r_0) \\
= (\phi_0 - \psi_0)^2 \sum_{j=0}^{\infty} E\left\{\varepsilon_{t-1}^2 \prod_{i=0}^{j-1} \{\phi_0^2 I(y_{t+i} \leq r_0) + \psi_0^2 I(y_{t+i} > r_0)\}|y_{t-1} = r_0\right\} \\
= (\phi_0 - \psi_0)^2 E(\varepsilon_{t-1}^2|y_{t-1} = r_0) / 1 - \min(\phi_0^2, \psi_0^2)
\]

and

\[
E(\{\zeta^{(1)}\}^2|y_{t-1} = r_0) = E(\{\zeta^{(2)}\}^2|y_{t-1} = r_0) = 4\sigma_\varepsilon^2 \gamma + o(\gamma).
\]

Therefore, by Corollary 2, it follows that

\[
(3.6) \quad \frac{\gamma \pi(r_0)}{\sigma_\varepsilon^2} n(\hat{\tau}_n - r_0) \sim T_2.
\]

In applications, \( \pi(r_0) \) is readily estimated by the nonparametric kernel method, and \( \sigma_\varepsilon^2 \) by the residuals \( \{\varepsilon_t\} \) based on the LSE. The real hard work is in estimating or approximating \( \gamma \). The key point
is how to approximate \( E(\varepsilon_t^2|y_t = r_0) \). Here, we propose three ways to approximate this conditional expectation. One is the re-sampling method of Li, Ling and Li (2013). Similar to high-order TAR models in Subsection 3.2, we can draw a new sample satisfying the condition \( y_{t-1} = \hat{\tau}_n \) and then calculate the conditional expectation. This procedure is complicated and needs more computations. The second is to use nonparametric method to estimate it.

The third is to use the best linear predictor to replace \( E(\varepsilon_t^2|y_t = r_0) \) as it is simple relatively. Note that the best linear predictor of \( Y \) based on \( X \) is

\[
(3.7) \quad \mathcal{L}(Y|X) = EY + \frac{\text{cov}(X,Y)}{\text{var}(X)}(X - EX).
\]
For small $|\phi_0 - \psi_0|$, we can use $\varepsilon_t + ((\phi_0 + \psi_0)/2)\varepsilon_{t-1}$ to approximate $y_t$, i.e., $y_t \approx \varepsilon_t + ((\phi_0 + \psi_0)/2)\varepsilon_{t-1}$. Hence, we have the following approximation

$$E(\varepsilon_t^2 | y_t = r_0) \approx \sigma^2 + \frac{\kappa_3 r_0}{\sigma^2(1 + (\phi_0 + \psi_0)^2/4)}.$$

where $\kappa_3 = E\varepsilon^3_t$. Therefore,

$$\begin{align*}
\hat{\sigma}_t^2 + \frac{\hat{\kappa}_3 \hat{r}_n}{\sigma^2(1 + (\hat{\phi}_n + \hat{\psi}_n)^2/4)} & \left(\frac{\hat{\phi}_n - \hat{\psi}_n}{\sigma^2 \{1 - \min(\hat{\phi}_n^2, \hat{\psi}_n^2)\}}\right) n(\hat{r}_n - r_0) \\
\end{align*}$$

(3.8)

can be approximated by $T_2$ by Corollary 2, where $\hat{\sigma}_t^2 = n^{-1} \sum_{t=1}^n \varepsilon_t^2$, $\hat{\kappa}_3 = n^{-1} \sum_{t=1}^n \varepsilon_t^3$, and $\{\varepsilon_t\}$ is the residual.

In particular, if $\varepsilon_t$ is symmetric, then $\kappa_3 = 0$ and in turn (3.8) reduces to

$$\begin{align*}
\text{NS}_n := \left(\frac{\hat{\phi}_n - \hat{\psi}_n}{\sigma_n^2} \hat{\pi}_n(\hat{r}_n)\right) n(\hat{r}_n - r_0).
\end{align*}$$

(3.9)

3.4. Threshold ARMA model. The TARMA model is a natural extension of TAR and TMA models. Like linear ARMA models, TARMA model can provide a parsimonious form for high-order TAR or high-order TMA models. Recently, Chan and Goracci (2019) studied the ergodicity of one-order TARMA models. However, in the literature to-date, there are few results on the statistical inference of TARMA models. Exceptions are Li and Li (2011) and Li, Li and Ling (2011), who considered the LSE and established its asymptotic theory.

A time series $\{y_t\}$ is said to follow a TARMA model of order (1,1) if it satisfies

$$y_t = \begin{cases} 
\mu_1 + \phi_1 y_{t-1} + \varepsilon_t + \psi_1 \varepsilon_{t-1}, & \text{if } y_{t-1} \leq r, \\
\mu_2 + \phi_2 y_{t-1} + \varepsilon_t + \psi_2 \varepsilon_{t-1}, & \text{if } y_{t-1} > r,
\end{cases}$$

where $\{\varepsilon_t\}$ is i.i.d. with mean zero and variance $\sigma^2 \in (0, \infty)$, and $\varepsilon_t$ is independent of $\{y_j : j < t\}$. Let $\theta = (\mu_1, \phi_1, \psi_1, \mu_2, \phi_2, \psi_2, r)'$ be the parameter and its true value be $\theta_0$.

Li, Li and Ling (2011) showed that under their Assumptions 3.1-3.5

$$n(\hat{r}_n - r_0) \Rightarrow M_\ast := s - \text{arg min}_{z \in \mathbb{R}} \mathcal{P}(z),$$
where the left and right jump distributions are induced by

\[
\zeta^{(1)} = \delta_t^2 \sum_{j=0}^{\infty} \prod_{i=0}^{j-1} \{\psi_{10}^2 I(y_{t+i} \leq r_0) + \psi_{20}^2 I(y_{t+i} > r_0)\} + 2\delta_t \sum_{j=0}^{\infty} \varepsilon_{t+j} \prod_{i=0}^{j-1} \{(-\psi_{10} I(y_{t+i} \leq r_0) - \psi_{20} I(y_{t+i} > r_0)\}
\]

given \( y_{t-1} = r_0^- \), and

\[
\zeta^{(2)} = \delta_t^2 \sum_{j=0}^{\infty} \prod_{i=0}^{j-1} \{\psi_{10}^2 I(y_{t+i} \leq r_0) + \psi_{20}^2 I(y_{t+i} > r_0)\} - 2\delta_t \sum_{j=0}^{\infty} \varepsilon_{t+j} \prod_{i=0}^{j-1} \{(-\psi_{10} I(y_{t+i} \leq r_0) - \psi_{20} I(y_{t+i} > r_0)\}
\]

given \( y_{t-1} = r_0^+ \), where \( \delta_t = (\mu_1 - \mu_2) + (\phi_1 - \phi_2) r_0 + (\psi_1 - \psi_2) \varepsilon_{t-1} \).

When \(|(\mu_{10} - \mu_{20}) + (\phi_{10} - \phi_{20}) r_0| + |\psi_{10} - \psi_{20}| \) is small, we can approximate \( M^- \) or \( n(\hat{r}_n - r_0) \) by Theorem 1. Note that

\[
\gamma = E(\zeta^{(1)} | y_{t-1} = r_0^-) = E(\zeta^{(2)} | y_{t-1} = r_0^+)
\]

\[
= \sum_{j=0}^{\infty} E \left\{ \delta_t^2 \prod_{i=0}^{j-1} \{\psi_{10}^2 I(y_{t+i} \leq r_0) + \psi_{20}^2 I(y_{t+i} > r_0)\} | y_{t-1} = r_0 \right\}
\]

\[
\frac{E(\delta_t^2 | y_{t-1} = r_0)}{1 - \min(\psi_{10}^2, \psi_{20}^2)}
\]

and

\[
E(\{\zeta^{(1)}\}^2 | y_{t-1} = r_0) = E(\{\zeta^{(2)}\}^2 | y_{t-1} = r_0) = 4\sigma^2 \gamma + o(\gamma).
\]

Therefore, by Corollary 2, it follows that

\[
(3.10) \quad \frac{\gamma \pi(r_0)}{\sigma^2} n(\hat{r}_n - r_0) \sim T_2.
\]

Similar to the procedure described in Subsection 3.3, we can estimate \( \gamma \), \( \pi(r_0) \) and \( \sigma^2 \). We omit the detail.
3.5. **T-CHARM.** To characterize the martingale difference structure implied in log-returns of assets in financial time series, Chan, et al. (2014) proposed a simple yet versatile model, called the conditional heteroscedastic AR model with thresholds (T-CHARM), which is a special case of Rabemananjara and Zakoïan (1993), Zakoïan (1994), Li and Ling (2012), Li, Ling and Zakoïan (2015) and Li, Ling and Zhang (2016).

A simple T-CHARM is defined as

\[ y_t = \sigma_t \varepsilon_t, \quad \sigma_t^2 = \sigma_{10}^2 I(y_{t-1} \leq r_0) + \sigma_{20}^2 I(y_{t-1} > r_0), \]

where \( \{ \varepsilon_t \} \) is i.i.d. with zero mean and unit variance, \( \sigma_{10}^2 \neq \sigma_{20}^2 \).

Chan, et al. (2014) developed asymptotic theory on the quasi-maximum likelihood estimation (QMLE) of \( (\sigma_{10}^2, \sigma_{20}^2, r_0) \) under some assumptions, and proved that

\[ n(\hat{r}_n - r_0) \Rightarrow M_- := s - \arg\min_{z \in \mathbb{R}} P(z), \]

where the left and the right jumps in \( P(z) \) are respectively

\[ \zeta_k^{(1)} = \log \frac{\sigma_{20}^2}{\sigma_{10}^2} + \left( \frac{\sigma_{10}^2}{\sigma_{20}^2} - 1 \right) \varepsilon_k^2 \]

and

\[ \zeta_k^{(2)} = \log \frac{\sigma_{10}^2}{\sigma_{20}^2} + \left( \frac{\sigma_{20}^2}{\sigma_{10}^2} - 1 \right) \varepsilon_k^2. \]

Let \( \gamma = |\sigma_{10}^2 - \sigma_{20}^2|^2 / (\sigma_{10}^4 + \sigma_{20}^4) \). If \( \gamma \) is small, then we have

\[ E\{\zeta_k^{(1)}\} = E\{\zeta_k^{(2)}\} = \gamma + o(\gamma), \]

\[ E\{\zeta_k^{(1)}\}^2 = E\{\zeta_k^{(2)}\}^2 = 2(\kappa_4 - 1)\gamma + o(\gamma), \]

where \( \kappa_4 = E\varepsilon_1^4 \). Thus, by Corollary 2,

\[ (3.11) \quad \text{NS}_n := \frac{2\hat{\gamma}_n \hat{\pi}(\hat{r}_n)}{\hat{\kappa}_4 - 1} n(\hat{r}_n - r_0) \Rightarrow T_2, \]

where \( \hat{\gamma}_n = |\hat{\sigma}_{1n}^2 - \hat{\sigma}_{2n}^2|^2 / (\hat{\sigma}_{1n}^4 + \hat{\sigma}_{2n}^4) \), \( \hat{\kappa}_4 = n^{-1} \sum_{t=1}^n \hat{\varepsilon}_t^4 \), \( \{ \hat{\varepsilon}_t \} \) is the residuals based on the QMLE, \( \hat{\pi}(\cdot) \) is the nonparametric kernel estimator of \( \pi(\cdot) \).

For multiple-regime T-CHARM, approximations of the limiting distributions of the thresholds can be obtained similarly.
3.6. **Threshold DAR model.** The TDAR model is a significant extension of conditional heteroscedastic models, including the threshold ARCH model of Rabemananjara and Zakoian (1993) and Zakoian (1994). On TDAR models, recent work can be found in Li, Ling and Zakoian (2015) and Li, Ling and Zhang (2016).

A time series \( \{y_t\} \) is said to follow a TDAR model of order \((1, 1)\) if

\[
y_t = \begin{cases} 
\phi_0 + \phi_1 y_{t-1} + \varepsilon_t \sqrt{\alpha_0 + \alpha_1 y_{t-1}^2}, & \text{if } y_{t-1} \leq r, \\
\psi_0 + \psi_1 y_{t-1} + \varepsilon_t \sqrt{\beta_0 + \beta_1 y_{t-1}^2}, & \text{if } y_{t-1} > r,
\end{cases}
\]

where \( \{\varepsilon_t\} \) is i.i.d. with zero mean and unit variance.

Li, Ling and Zakoian (2015) and Li, Ling and Zhang (2016) studied the QMLE of TDAR model and discussed their asymptotics. Under Assumptions 3.1-3.5 in Li, Ling and Zhang (2016), we have

\[
n(\hat{r}_n - r_0) \Rightarrow M_- := s - \arg\min_{z \in \mathbb{R}} \mathcal{P}(z),
\]

where the left and the right jumps in \( \mathcal{P}(z) \) are respectively

\[
\zeta^{(1)}_k = \log \frac{\beta_0 + \beta_1 r^2}{\alpha_0 + \alpha_1 r^2} + \frac{\{(\phi_0 - \psi_0) + (\phi_1 - \psi_1)r + \varepsilon_k \sqrt{\alpha_0 + \alpha_1 r^2}\}^2}{\beta_0 + \beta_1 r^2} - \varepsilon_k^2,
\]

and

\[
\zeta^{(2)}_k = \log \frac{\alpha_0 + \alpha_1 r^2}{\beta_0 + \beta_1 r^2} + \frac{\{(\phi_0 - \psi_0) + (\phi_1 - \psi_1)r - \varepsilon_k \sqrt{\beta_0 + \beta_1 r^2}\}^2}{\alpha_0 + \alpha_1 r^2} - \varepsilon_k^2.
\]

For simplicity, we assume that \( \varepsilon_t \sim \mathcal{N}(0, 1) \) tentatively. Denote

\[
\gamma = \frac{\{(\beta_0 - \alpha_0) + (\beta_1 - \alpha_1)r^2\}^2}{(\alpha_0 + \alpha_1 r^2)^2 + (\beta_0 + \beta_1 r^2)^2} + \frac{2\{(\phi_0 - \psi_0) + (\phi_1 - \psi_1)r\}^2}{(\alpha_0 + \alpha_1 r^2) + (\beta_0 + \beta_1 r^2)}.
\]

By a simple calculation, we have

\[
E\{\zeta^{(1)}_1\} = E\{\zeta^{(2)}_1\} = \gamma + o(\gamma),
\]

\[
E\{\zeta^{(1)}_1\}^2 = E\{\zeta^{(2)}_1\}^2 = 4\gamma + o(\gamma).
\]

Thus, by Corollary 2,

\[
\gamma \pi(r) n(\hat{r}_n - r) \sim T_2.
\]

In applications, \( \gamma \) and \( \pi(r_0) \) can be estimated by their sample counterparts. For high-order cases, similar to high-order TAR models in Subsection 3.2, we can use the re-sampling method to estimate \( \gamma \).
4. Simulation studies. In this section, we use simulations to assess the performance of the approximation in Section 2. The TAR(1), TMA(1) models and T-CHARM are used as typical cases. The error \( \{\varepsilon_t\} \) is supposed to be i.i.d. \( \mathcal{N}(0, 1) \) for simplicity. For each model, the sample size is 500 and 2000 replications are used.

The TAR(1) model is defined as

\[
y_t = \{0.5I(y_{t-1} \leq 1.5) + 0.9I(y_{t-1} > 1.5)\}y_{t-1} + \varepsilon_t.
\]  

Figure 2 shows the histogram and the empirical CDF of \( NS_n \) in (3.5) as well as those of \( T^2 \) in (2.2), from which we can see that the approximation performs well, even when the threshold effect is not small with \( \gamma = |0.9 - 0.5| = 0.4 \).

Hansen (1997, 2000) was probably the first to adopt a BM approximation approach to handle statistical inference in TAR models. His approach is based on a different setting from ours: he has effectively replaced the TAR model by a sequence of TAR models indexed by the sample size \( n \), with \( n \)-dependent regression slopes, which coalesce (with a speed apparently not easily determined) as \( n \) goes to infinity. Let us call the difference between the regression slopes of the two regimes the threshold effect. On the other hand, for cases with fixed threshold effects, Li and Ling (2012) proposed a re-sampling method to simulate \( M_- \). This method works well when the range of \( M_- \) is not very large, e.g., when the expectation of the jump is sufficiently large, implying a large threshold effect. However, the range becomes very large when the expectation of the jump is small associated with a
small threshold effect. In this case the re-sampling method is not so accurate. We now take up the challenge of obtaining a BM approximation for the case with fixed (i.e. not $n$-dependent) but small threshold effects.

To compare the performance of likelihood ratio method in Hansen (1997) and ours, we compute the coverage probabilities of $r_0$ at 90% and 95% levels, respectively. The estimator of $\pi(\cdot)$ is obtained by two methods: one based on a nonparametric kernel method and the other the moving block bootstrapping (MBB) method. For this and other bootstrapping methods for dependent data, see Lahiri (2003). When the sample is small, the estimator $\hat{\pi}_n(\hat{r}_n)$ may have a larger bias and will affect the performance of the statistic $\text{NS}_n$. In this case, we recommend the MBB method. Table 2 reports the numerical results. Here, for each sample size, 1,000 replications are used. With each replication, 10 replicates are used for the MBB. From the table, we can see that Hansen’s method over-estimates the coverage probability and becomes quite conservative when the sample size $n$ is moderately large, like that in Hansen (1997, 2000). On the other hand, our method based on MBB performs well across all sample sizes; the method based on nonparametric kernels shows stable performance across all $n$, with good coverage probability for $n = 500$, but not as well as the MBB method for smaller $n$. Based on our experience, we recommend the nonparametric kernel method for large $n$, which will save computing costs, and the MBB for smaller $n$.

| Table 2 | The coverage probabilities of $r_0$ at 90% and 95% levels. |
|---------|----------------------------------------------------------|
|         | 90%  | 95%  | 90%  | 95%  | 90%  | 95%  |
| $n = 50$ | Hansen’s | 0.711 | 0.843 | 0.907 | Hansen’s | 0.739 | 0.900 | 0.962 |
| $n = 100$ | 0.912 | 0.818 | 0.899 | 0.934 | 0.871 | 0.952 |
| $n = 200$ | 0.934 | 0.853 | 0.901 | 0.967 | 0.889 | 0.949 |
| $n = 500$ | 0.935 | 0.895 | -     | 0.964 | 0.948 | -     |

For the TMA(1) model defined as

$y_t = \varepsilon_t + [0.6I(y_{t-1} \leq 0) + 0.9I(y_{t-1} > 0)]\varepsilon_{t-1}.$

Figure 3 shows the histogram and the empirical CDF of $\text{NS}_n$ in (3.9) as well as those of $T_2$ in (2.2), from which we can see that the approximation performs well.

For the T-CHARM defined as

$y_t = \sigma_t \varepsilon_t, \quad \sigma_t^2 = 1I(y_{t-1} \leq 0.5) + 2I(y_{t-1} > 0.5).$

Figure 4 shows that the performance of approximation is good. Here, the ratio $\kappa := \sigma_2^2/\sigma_1^2 = 2$. When
Fig 3. The histogram (a) and the empirical CDF (b) of $N_{S_n}$ in (3.9) for TMA(1) model in (4.2), as well as the density and CDF of $T_2$ in (2.2).

Fig 4. The histogram (a) and the empirical CDF (b) of $N_{S_n}$ in (3.11) for T-CHARM model in (4.3), as well as the density and CDF of $T_2$ in (2.2).
\( \kappa \) increases, the performance of approximation may deteriorate. For example, consider a T-CHARM model defined as

\[
y_t = \sigma_t \varepsilon_t, \quad \sigma_t^2 = 1 \mathbb{I}(y_{t-1} \leq 0.5) + 6 \mathbb{I}(y_{t-1} > 0.5). \tag{4.4}
\]

Here, the ratio \( \kappa = 6 \).

Figure 5 shows the approximation for (4.4). Compared with Figure 4, the approximation is poorer as expected. Of course, when \( \kappa > 5 \), simulating a CPP will generally result in a better approximation for \( n(\widehat{r}_n - r_0) \).

Unfortunately, there are no theoretical results to guide us on the choice between the resampling method in Li and Ling (2012) and our approximation method. However, our experience suggests the following procedure in practice. First, we use the resampling method in Li and Ling (2012) to simulate \( M_- \). If the simulated numerical range of \( M_- \) is large, e.g., bigger than 50, then we use our approximation method instead.

5. An empirical example. The unemployment rate is an important index in measuring economic activity. Hansen (1997) explored the presence of nonlinearities in the business cycle through the use of a TAR model for U.S. unemployment rate among males age 20 and over. The sample is monthly from January 1959 through July 1996. There are 451 observations in total over the period, which is plotted in Figure 6.
Let \( \{y_t\} \) be the rate. Hansen (1997) suggests the following fitted model

\[
\Delta y_t = \begin{cases} 
\phi_0 + \sum_{i=1}^{12} \phi_i \Delta y_{t-i} + \sigma_1 \varepsilon_t, & \text{if } y_{t-1} - y_{t-12} \leq 0.302, \\
\psi_0 + \sum_{i=1}^{12} \psi_i \Delta y_{t-i} + \sigma_2 \varepsilon_t, & \text{if } y_{t-1} - y_{t-12} > 0.302,
\end{cases}
\]

where \( \Delta y_t = y_t - y_{t-1} \), \( \sigma_1^2 = 0.154^2 \), \( \sigma_2^2 = 0.187^2 \), and the estimates of the coefficients are summarized in Table 3. For more details, including the standard errors and 95% confidence intervals of the estimated coefficients, see Table 5 in Hansen (1997).

### Table 3

| Variable | Intercept | \( \Delta y_{t-1} \)  | \( \Delta y_{t-2} \)  | \( \Delta y_{t-3} \)  | \( \Delta y_{t-4} \)  | \( \Delta y_{t-5} \)  | \( \Delta y_{t-6} \)  |
|----------|-----------|----------------|----------------|----------------|----------------|----------------|----------------|
| \( \phi \) | -0.18     | -0.16         | 0.084         | 0.132         | 0.165         | 0.070         | 0.027         |
| \( \psi \) | 0.062     | 0.044         | -0.031       | -0.057         | 0.091       | -1.36         |

| Variable | Intercept | \( \Delta y_{t-1} \)  | \( \Delta y_{t-2} \)  | \( \Delta y_{t-3} \)  | \( \Delta y_{t-4} \)  | \( \Delta y_{t-5} \)  | \( \Delta y_{t-6} \)  |
|----------|-----------|----------------|----------------|----------------|----------------|----------------|----------------|
| \( \phi \) | 0.086     | 0.241         | 0.241         | 0.124         | -0.026         | -0.020         | -0.084         |
| \( \psi \) | -0.151    | -0.035       | 0.092         | 0.103         | -0.114         | -0.412         |
From (3.4), using the estimated coefficients, we can obtain the density of $T_1$, which is displayed in Figure 7. The 2.5% and 97.5% quantiles of $T_1$ are $-0.2477$ and $0.3972$, respectively.

![The density of $T_1$](image.png)

**Figure 7.** The density of $T_1$ related to model (5.1).

Now, using these quantiles, we can construct confidence intervals of the threshold parameter $r_0$ by our nonparametric kernel method with the MBB. This method gives the 95% confidence interval as $[0.255, 0.332]$. Here, the length of the moving block is 15 and the number of replicates is 50. The corresponding result using Hansen’s method is $[0.213, 0.340]$, where the likelihood ratio is adjusted for residual heteroscedasticity by using a kernel estimator for the nuisance parameters. We note that Hansen’s method has given a much wider confidence interval.

6. **Conclusion and discussion.** In this paper, we have developed an alternative approach to approximate two-sided CPPs by two-sided BMs. Significantly, we address the issue with small but fixed threshold effects. The new approach provides a simple yet efficacious tool to derive distributions of some functionals of the sample paths of CPPs, thus rendering statistical inference of the key threshold parameter in a threshold model, such as the construction of its confidence intervals, a practical proposition. Further, our approach continues to apply to threshold regressive/autoregressive models with multiple regimes since the distributions of all estimated threshold parameters are asymptotically independent; see, e.g., Li and Ling (2012), Chan, et al. (2014), Li, Ling and Zakoïan (2015). Thus, we can use our approach to construct confidence intervals for the thresholds one by one.

Our theory can be applied for other applied-oriented problems. For example, Hansen (1997, 2000) proposed a likelihood ratio-based statistic $LR_n(r_0)$ to test the null hypothesis $H_0 : r = r_0$ in threshold
(auto)regression under his framework. However, under Tong’s framework, i.e., the threshold effect is fixed, the limiting distribution of the related likelihood ratio-based statistic $LR_n(r_0)$ is a functional of two-sided compound Poisson process, which is hard to use for the same purpose. Our new theory can provide a usable approximation on $LR_n(r_0)$ and statistical inference for threshold can be realised.

APPENDIX A: PROOF OF THEOREM 1

Write $P_\gamma(z)$ in (2.1) as

$$P_\gamma(z) = I(z \leq 0)P_{1,\gamma}(z) + I(z > 0)P_{2,\gamma}(z),$$

where

$$P_{j,\gamma}(z) = \sum_{k=1}^{N_j(z/\gamma)} \xi_k^{(j)}, \quad z \geq 0, \quad j = 1, 2.$$  

Since $P_{1,\gamma}(\cdot)$ and $P_{2,\gamma}(\cdot)$ are independent, it suffices to prove the weak convergence separately. Here, to avoid unnecessary repetition, we only prove the weak convergence of $P_{2,\gamma}(z)$ in $\mathbb{D}[0, \infty)$.

(i). Convergence of finite-dimensional distributions. For any $0 < z_1 < \ldots < z_m < \infty$, the character-
istic function of \((P_{2,\gamma}(z_1), ..., P_{2,\gamma}(z_m))\)

\[
\phi_{\gamma}(u_1, ..., u_m) = E\exp\{iu_1P_{2,\gamma}(z_1) + ... + iu_mP_{2,\gamma}(z_m)\}
\]

\[
= \prod_{k=1}^{m} E\exp\{iv_kP_{2,\gamma}(z_k - z_{k-1})\}
\]

\[
= \prod_{k=1}^{m} \exp\{-\lambda\gamma^{-1}(z_k - z_{k-1})[1 - \phi_{\xi_{(2)}(v_k)}]\}
\]

\[
= \prod_{k=1}^{m} \exp\{-\lambda\gamma^{-1}(z_k - z_{k-1})[-iv_ka^2 + v_k^2b\gamma/2]\} + o(\gamma)
\]

\[
\rightarrow \prod_{k=1}^{m} \exp\{\lambda(z_k - z_{k-1})[iv_ka^2 - v_k^2b^2/2]\}, \quad \gamma \to 0,
\]

where \(v_k = u_m + ... + u_k\) and the limit is the characteristic function of \((\lambda_2a_2z_1 - \sqrt{\lambda_2b_2B_2(z_1)}, ..., \lambda_2a_2z_m - \sqrt{\lambda_2b_2B_2(z_m)})\). Thus, the finite-dimensional distribution of \(P_{2,\gamma}(z)\) converges in distribution to that of \(\lambda_2a_2z - \sqrt{\lambda_2b_2B_2(z)}\) as \(\gamma \to 0\).

(ii). *Aldous's condition.* Since every CPP is a Lévy process, by the strong Markov property of Lévy process and stationary independent increment property of CPPs, we have

\[
P_{2,\gamma}(\rho_\gamma + \gamma^2) - P_{2,\gamma}(\rho_\gamma) \xrightarrow{d} P_{2,\gamma}(\gamma^2),
\]

where \(\{\rho_\gamma\}\) is a sequence of positive stopping times adapted to the process \(\{P_{2,\gamma}(z), z \in \mathbb{R}\}\) itself. Note that

\[
P_{2,\gamma}(\gamma^2) = \sum_{k=1}^{N_2(\gamma)} \xi_{(j)}^{(k)}
\]

and the Poisson process \(N_2(\cdot)\) is continuous in probability and \(N_2(0) = 0\) a.s. Then, as \(\gamma \to 0\), it follows that \(P_{2,\gamma}(\gamma^2) \to 0\) in probability. Thus, the *Aldous's condition* holds.

By Theorem 16 in Pollard (1984)(p.134), we claim that

\[
P_{2,\gamma}(z) \xrightarrow{} \lambda_2a_2z - \sqrt{\lambda_2b_2B_2(z)} \quad \text{as } \gamma \to 0.
\]

Similarly, we can show the weak convergence of \(P_{1,\gamma}(z)\). The proof of the first claim is complete.

We now prove the second claim. Note that \(P_{\gamma}(0) = 0\); by the definition of \(m_{\gamma}\), for any \(A > 0\), it
follows that

\[ P(|m_{\gamma}| > A) = P(P_{\gamma}(m_{\gamma}) \leq 0, |m_{\gamma}| > A) \]

\[ \leq P(\inf_{z>A} P_{\gamma}(z) \leq 0, m_{\gamma} > A) + P(\inf_{z<-A} P_{\gamma}(z) \leq 0, m_{\gamma} < -A) \]

\[ = P\left( \sum_{k=1}^{N_{2}(z/\gamma)} \xi_{k}^{(2)} \leq 0, m_{\gamma} > A \right) + P\left( \sum_{k=1}^{N_{1}(-z/\gamma)} \xi_{k}^{(1)} \leq 0, m_{\gamma} < -A \right) \]

:= I + II.

Since \( P_{\gamma}(z) \) has independent increments, we have

\[ I = P\left( \sum_{k=1}^{N_{2}(A/\gamma)} \xi_{k}^{(2)} + \inf_{z>A} \sum_{k=N_{2}(A/\gamma)+1}^{N_{2}(z/\gamma)} \xi_{k}^{(2)} \leq 0, m_{\gamma} > A \right) \]

\[ = P\left( \sum_{k=1}^{N_{2}(A/\gamma)} \xi_{k}^{(2)} + \inf_{z>0} P_{\gamma}(z) \leq 0, m_{\gamma} > A \right), \]
where $\bar{P}_\gamma(z) \overset{d}{=} P_\gamma(z)$ and $\tilde{P}_\gamma(z)$ is independent of $\sum_{k=1}^{N_2(A/\gamma)} \xi_k^{(2)}$ and $N_2(A/\gamma)$. Hence,

\[
I = P\left( \sup_{z > 0} \left\{ -\tilde{P}_\gamma(z) \right\} \geq \sum_{k=1}^{N_2(A/\gamma)} \xi_k^{(2)}, m_\gamma > A \right)
\]

\[
\leq P\left( \sup_{z > 0} \left\{ -\bar{P}_\gamma(z) \right\} \geq \sum_{k=1}^{N_2(A/\gamma)} \xi_k^{(2)}, N_2(A/\gamma) < A\lambda_2/(2\gamma) \right)
\]

\[
+ P\left( \sup_{z > 0} \left\{ -\bar{P}_\gamma(z) \right\} \geq \sum_{k=1}^{N_2(A/\gamma)} \xi_k^{(2)}, N_2(A/\gamma) \geq A\lambda_2/(2\gamma) \right)
\]

\[
\leq P\left( N_2(A/\gamma) < A\lambda_2/(2\gamma) \right)
\]

\[
+ P\left( \sup_{z > 0} \left\{ -\bar{P}_\gamma(z) \right\} \geq \sum_{k=1}^{N_2(A/\gamma)} \xi_k^{(2)}, N_2(A/\gamma) \geq A\lambda_2/(2\gamma), \sum_{k=1}^{N_2(A/\gamma)} \xi_k^{(2)} < \frac{1}{2} N_2(A/\gamma) E\xi_1^{(2)} \right)
\]

\[
+ P\left( \sum_{k=1}^{N_2(A/\gamma)} \xi_k^{(2)}, N_2(A/\gamma) \geq A\lambda_2/(2\gamma), \sum_{k=1}^{N_2(A/\gamma)} \xi_k^{(2)} \geq \frac{1}{2} N_2(A/\gamma) E\xi_1^{(2)} \right)
\]

\[
\leq P\left( N_2(A/\gamma) < A\lambda_2/(2\gamma) \right)
\]

\[
+ P\left( N_2(A/\gamma) \geq A\lambda_2/(2\gamma), \sum_{k=1}^{N_2(A/\gamma)} \xi_k^{(2)} < \frac{1}{2} N_2(A/\gamma) E\xi_1^{(2)} \right)
\]

\[
+ P\left( \sup_{z > 0} \left\{ -\bar{P}_\gamma(z) \right\} \geq \frac{1}{2} N_2(A/\gamma) E\xi_1^{(2)} \right).
\]

First, note that $N_2(A/\gamma) \sim \text{Poisson}(A\lambda_2/\gamma)$. Then, by Markov’s inequality, for large enough $A > 0$, as $\gamma \to 0$, we have

\[
P\left( N_2(A/\gamma) < A\lambda_2/(2\gamma) \right) \leq P\left( |N_2(A/\gamma) - A\lambda_2/\gamma| > A\lambda_2/(2\gamma) \right)
\]

\[
\leq \frac{A\lambda_2/\gamma}{(A\lambda_2/(2\gamma))^2} = \frac{4\gamma}{A\lambda_2} \to 0.
\]

Second, by the property of the conditional expectation and Assumption 1, for large enough $A > 0$,
as $\gamma \to 0$, 

$$\mathbb{P}\left(N_2(A/\gamma) \geq A\lambda_2/(2\gamma), \sum_{k=1}^{N_2(A/\gamma)} \xi_k^{(2)} < \frac{1}{2} N_2(A/\gamma) E\xi_1^{(2)}\right)$$

$$\leq \mathbb{P}\left(N_2(A/\gamma) \geq A\lambda_2/(2\gamma), \left| \sum_{k=1}^{N_2(A/\gamma)} [\xi_k^{(2)} - E\xi_k^{(2)}] \right| > \frac{1}{2} N_2(A/\gamma) E\xi_1^{(2)}\right)$$

$$= \sum_{m=A\lambda_2/(2\gamma)}^{\infty} \mathbb{P}(N_2(A/\gamma) = m) \mathbb{P}\left(\left| \sum_{k=1}^{m} [\xi_k^{(2)} - E\xi_k^{(2)}] \right| > \frac{m}{2} E\xi_1^{(2)}\right)$$

$$\leq \sum_{m=A\lambda_2/(2\gamma)}^{\infty} \mathbb{P}(N_2(A/\gamma) = m) \frac{m \text{var}(\xi_1^{(2)})}{(m E\xi_1^{(2)}/2)^2}$$

$$\leq \sum_{m=A\lambda_2/(2\gamma)}^{\infty} \frac{4m(b_2 \gamma + o(\gamma))}{a_2^2(m\gamma)^2 + o(m\gamma)^2} \mathbb{P}(N_2(A/\gamma) = m)$$

$$\leq \frac{8b_2}{a_2^2} \sum_{m=A\lambda_2/(2\gamma)}^{\infty} \frac{1}{m \gamma} \mathbb{P}(N_2(A/\gamma) = m)$$

$$= \frac{8b_2}{a_2^2} \sum_{m=A\lambda_2/(2\gamma)}^{\infty} \frac{m + 1}{m} \frac{1}{(m + 1)\gamma} \frac{1}{A\lambda_2} \frac{(A\lambda_2)^{m+1}}{a_2^2} \frac{1}{\gamma^m m!} \exp\left\{-A\lambda_2/\gamma\right\}$$

$$\leq \frac{16b_2}{A\lambda_2 a_2^2} \sum_{m=A\lambda_2/(2\gamma)}^{\infty} \frac{(A\lambda_2/\gamma)^{m+1}}{(m + 1)!} \exp\left\{-A\lambda_2/\gamma\right\}$$

$$= \frac{16b_2}{A\lambda_2 a_2^2} \sum_{m=A\lambda_2/(2\gamma)}^{\infty} \mathbb{P}(N_2(A/\gamma) = m + 1)$$

$$= \frac{16b_2}{A\lambda_2 a_2^2} \mathbb{P}(N_2(A/\gamma) \geq A\lambda_2/(2\gamma) + 1)$$

$$\leq \frac{16b_2}{A\lambda_2 a_2^2} \to 0.$$
Third, by Assumption 1, for large enough $A > 0$, as $\gamma \to 0$, we have

$$P \left( \sup_{z > 0} \left\{ -\tilde{P}_\gamma(z) \right\} \geq \frac{1}{2} N_2(A/\gamma)E\xi^{(2)}_1 \right)$$

= $P \left( \sup_{z > 0} \left\{ -\tilde{P}_\gamma(z) \right\} \geq \frac{1}{2} N_2(A/\gamma)E\xi^{(2)}_1, N_2(A/\gamma) < A\lambda_2/(2\gamma) \right)$

+ $P \left( \sup_{z > 0} \left\{ -\tilde{P}_\gamma(z) \right\} \geq \frac{1}{2} N_2(A/\gamma)E\xi^{(2)}_1, N_2(A/\gamma) \geq A\lambda_2/(2\gamma) \right)$

$\leq P(N_2(A/\gamma) < A\lambda_2/(2\gamma)) + P \left( \sup_{z > 0} \left\{ -\tilde{P}_\gamma(z) \right\} \geq \frac{1}{2} A\lambda_2/(2\gamma)E\xi^{(2)}_1 \right)$

$\leq P \left( \sup_{z > 0} \left\{ -\tilde{P}_\gamma(z) \right\} \geq \frac{A\lambda_2}{4\gamma} \left(a_2 \gamma + o(\gamma)\right) \right) + o(1)$

$\leq P \left( \sup_{z > 0} \left\{ -\tilde{P}_\gamma(z) \right\} \geq \frac{A\lambda_2 a_2}{8} \right) + o(1)$

= $P \left( \sup_{n \geq 0} \left\{ \sum_{k=1}^{n} (-\xi_k^{(2)}) \right\} \geq \frac{A\lambda_2 a_2}{8} \right) + o(1)$

$\leq \frac{8}{A\lambda_2 a_2} E \left\{ \sup_{n \geq 0} \sum_{k=1}^{n} (-\xi_k^{(2)}) \right\} + o(1)$

$\leq \frac{8}{A\lambda_2 a_2} \frac{E\{\xi^{(2)}_1\}^2}{2E\xi^{(2)}_1} + o(1)$

= $\frac{8}{A\lambda_2 a_2} \frac{b_2 + o(1)}{2a_2 + o(1)} + o(1) \to 0$

by Theorem 4 (iii) in Chow and Teicher (1997)(p.398). Thus, $I \to 0$. Similarly, we have $II \to 0$.

Therefore, for large enough $A > 0$, as $\gamma \to 0$, it follows that

$$P(|m_\gamma| > A) \to 0,$$

that is, $m_\gamma = O_p(1)$. By Theorem 3.2.2 in van der Vaart and Wellner (1996)(p.286), it follows that $m_\gamma \Rightarrow T$. The proof is concluded. □
