ABSTRACT
The statistical properties of cosmic structures are well known to be strong probes for cosmology. In particular, several studies tried to use the cosmic void counting number to obtain tight constrains on Dark Energy. In this paper we address this question by using the CoSphere model as introduced in de Fromont & Alimi (2017a). We derive their exact statistics in both primordial and non linearly evolved Universe for the standard \( \Lambda \)CDM model. We first compute the full joint Gaussian probability distribution for the various parameters describing these profiles in the Gaussian Random Field. We recover the results of Bardeen et al. (1986) only in the limit where the compensation radius becomes very large, i.e. when the central extremum decouples from its cosmic environment. We derive the probability distribution of the compensation size in this primordial field. We show that this distribution is redshift independent and can be used to model cosmic void size distribution. Interestingly, it can be used for central maximum such as DM haloes. We compute analytically the statistical distribution of the compensation density in both primordial and evolved Universe. We also derive the statistical distribution of the peak parameters already introduced by Bardeen et al. (1986) and discuss their correlation with the cosmic environment. We thus show that small central extrema with low density are associated with narrow compensation regions with a small \( R_1 \) and a deep compensation density \( \delta_1 \) while higher central extrema are located in larger but smoother over/under massive regions.

Key words: cosmology: theory; large-scale structure of Universe; N-body Simulations; Cosmic Voids; dark energy

INTRODUCTION
Statistical properties of high density regions (as dark matter (DM) haloes) or under dense regions (as cosmic voids) have been extensively used to address the main questions of modern cosmology such as the origin of dark energy (DE) or the nature of gravity. Numerous successes have been obtained from the mass function of DM haloes through the Press Schechter formalism (Press & Schechter 1974) or its powerful extensions like Excursion Set Theory (Bond et al. 1991). Predictions using these formalism are generally in very good agreement with numerical simulation results (Sheth & Tormen 1999; Jenkins et al. 2001; Tramonte et al. 2017) but these formalisms do not probe the large scale environment of DM haloes. Moreover a full understanding of such cosmological probes needs a full or at least a better understanding of the non linear evolution of gravitational collapse.

Concerning under dense regions as cosmic voids, it is even more challenging to describe precisely the statistics of such regions (Sheth & van de Weygaert 2004), mainly because we do not have an objective definition and a physically motivated dynamical model for voids. Both dynamical and statistical properties of cosmic voids depend on their algorithmic definition (Platen et al. 2007; Neyrinck 2008; Cautun et al. 2016), a full comparative analysis of algorithms for detecting voids in numerical simulations is for example necessary.

In de Fromont & Alimi (2017a), labelled thereafter paper I, we introduced the spherically compensated cosmic regions, named thereafter CoSpheres. Such regions describe the large scale cosmic environment around local extremum in the density field. CoSphere can be splitted in two distinct radial regions. An over (resp under) massive spherical core

around the central maximum (resp minimum) and an exterior under (resp over) massive surrounding belt. By over massive we mean that the total mass \( m(r) \) is higher than the homogeneous mass \( 4\pi/3\rho_m r^3 \). In the Newtonian limit, over massive regions collapse (i.e. \( \varphi < 0 \)) while under massive region expand toward larger radii. For each central extremum, the radius separating these two distinct regions is called the compensation radius \( R_1 \). By definition, it satisfies \( m(R_1) = 4\pi/3\rho_m R_1^3 \). The origin of CoSpheres within the primordial Gaussian Random Field (GRF) has been precisely described using the constrained GRF formalism with an appropriate compensation constraint (paper I). In this primordial Gaussian field, the expected spherically average profiles can be fully parametrized by four independent scalars. Besides the compensation radius \( R_1 \), they are described by three shape parameters: \( v \), \( x \) and \( v_1 \). The first parameters \( x \) and \( v \), already introduced by Bardeen et al. (1986), qualify the central extrema while \( v_1 \) defines the compensation density contrast \( \delta_1 = v_1 \sigma_0 \) as \( \delta(R_1) = \delta_1 \).

The non linear dynamical evolution of CoSpheres is described with high precision through the spherical collapse model. These cosmic regions can be detected in numerical simulations, in paper I we showed that they can be fully reconstructed from high redshift (within the Gaussian random field) until \( z = 0 \) in LCDM cosmology. Consequently, these regions can be used as powerful probes for cosmology and gravity itself as it will be investigated in Alimi & de Fromont (2017); de Fromont & Alimi (2017b).

While paper I focused on the construction of these cosmic regions and the derivation of their average density and mass profiles at any redshift, this paper is fully dedicated to the study of their statistical properties. We thus derive the full joint Gaussian probability distribution for the profile parameters \( R_1 \), \( v \), \( x \) and \( v_1 \) in GRF. This distribution measures the probability to obtain a CoSphere with the corresponding parameters in the primordial Gaussian Universe.

We then deduce the one-dimensional probability distribution \( dP(R_1) \) marginalized over the shape parameters \( v \), \( x \) and \( v_1 \). This distribution is proportional to the count number of compensation radii. It gives the probability to find a \( R_1 \) around any extremum. Despite being derived in the primordial Gaussian field, since compensation radii evolve comovingly (paper I), this distribution is expected to be redshift-independent. Using numerical simulations, we show that it is indeed well conserved during evolution. Interestingly, this size distribution provides a well defined analytical prediction for cosmic voids sizes once considered as compensated regions around minimum whose size is defined as \( R_1 \).

From the full joint Gaussian probability density distribution, we also compute the marginalized conditional distribution of the three shape parameters at a given compensation radius \( R_1 \). We then derive their constrained moments \( \langle a^m | R_1 \rangle \) with \( a = \{v, x, v_1\} \). For \( n = 1 \), the mean values \( \langle v | R_1 \rangle \), \( \langle x | R_1 \rangle \) and \( \langle v_1 | R_1 \rangle \) can be used to define the mean average profile at fixed compensation radius. These profiles are expected to reproduce the full matter field of CoSpheres once averaged over all possible stochastic realization, i.e. all possible value for each shape parameters \( v \), \( x \) and \( v_1 \) given \( R_1 \). We then study the shape of the mean average profiles according to \( R_1 \) and show that the central extrema progressively tends to the universal BBKS peak profile (Bardeen et al. 1986) for large \( R_1 \). For small \( R_1 \) however, the central extremum is strongly correlated to its cosmic environment through \( v_1 \) and \( R_1 \).

Using the spherical collapse model, we derive the exact non linear evolution of the compensation density distribution \( dP(\delta_1, R_1) \) for any redshift. We compute analytically the evolved moments \( \langle \delta_1^m | R_1 \rangle \) for both cosmic voids (central minimum) and central over densities. We compare our results with numerical simulation and show that the agreement is very good, even in the non linear regime.

This paper is organized as follow : in the first section we define precisely CoSpheres and their compensation radius \( R_1 \). We also discuss how such cosmic regions are detected in numerical simulation. In Sec. 2 we derive the statistical properties of these regions in the primordial Gaussian field, the radii distribution \( dP(R_1) \) together with the statistical study of the shape parameters. We discuss the properties of the mean averaged density profile at fixed compensation radius \( R_1 \). In the last section, Sec. 3, we study the dynamical properties of these distribution by using the Lagrangian Spherical Collapse and compare the results to numerical simulations at \( z = 0 \) in LCDM cosmology.

1 COSPHERES IN THE SKY

We study the statistical properties of CoSpheres. These cosmic structures are defined around extrema (minima or maxima) in the density field at any redshift (paper I). Around each extremum we define the concentric mass \( m(r) \) as the mass enclosed in the sphere of radius \( r \), from which we deduce the spherical mass contrast \( \Delta(r) \) as

\[
\Delta(r) := \frac{m(r)}{4\pi/3\rho_m r^3} - 1
\]

This profile is linked to the density contrast \( \delta(r) = \rho_m(r)/\bar{\rho}_m - 1 \) through

\[
\Delta(r) = \left[ \frac{3}{r} \int_0^r \frac{3}{u^2} \delta(\bar{u}) \, du \right]
\]

where \( \Delta'(r) = \delta(r) / \bar{v} \). As discussed in paper I, each extremum must be compensated on a finite scale. For each spherical profile, it exists a unique scale \( R_1 \) called compensation radius satisfying

\[
\Delta(R_1) = 0
\]

\( R_1 \) is defined as the smallest radius satisfying Eq. (3). This scale measures the size of the over (resp. under) massive region\(^1\) surrounding each maximum (resp. minimum). Since \( \bar{v} \propto -\Delta(r) \) in Newtonian regime, the mass contrast \( \Delta(r) \) drives the local gravitational collapse. The compensation radius separates the collapsing and the expanding regions.

These regions can be detected in numerical simulations. We use in this work, the numerical simulations from the “Dark Energy Universe Simulation” (DEUS) project, publicly available through the “Dark Energy Universe Virtual Observatory” (DEUVO) Database.\(^2\) These simulations consist of N-body simulations of Dark Matter (DM) for realistic dark energy models. For more details we refer the interested

reader to dedicated sections in Alimi et al. (2010); Rasera et al. (2010); Courtin et al. (2010); Alimi et al. (2012); Reverdy et al. (2015). We focus in this paper on the flat Λ CDM model with parameters calibrated against measurements of WMAP 5-year data (Komatsu et al. 2009) and luminosity distances to Supernova Type Ia from the UNION dataset (Kowalski et al. 2008).

The reduced Hubble constant is set to $h = 0.72$ and the cosmological parameters are $Ω_{DE} = 0.74$, $Ω_b = 0.044$, $n_s = 0.963$ and $σ_8 = 0.79$. All along this work, the reference simulation is chosen with $L_{box} = 2592 \text{ h}^{-1} \text{Mpc}$ and $n_{part} = 2048^3$. It provides both a large volume and a good mass resolution. Here the mass of one particle is $m_p = 1.5 \times 10^{11} \text{ h}^{-1} \text{M}_\odot$.

The construction procedure of numerical CoSpheres consists first in finding the position of local extremum. In the case of a central over-density we identify maxima with the center of mass of DM haloes. Haloes are defined by a Friend-of-Friend algorithm with a linking length $b = 0.2$. We considered in the reference simulation 200000 haloes with a mass $M_h \sim 3 \times 10^{13} \text{ h}^{-1} \text{M}_\odot$. Selecting haloes with a mass $M_h$ is equivalent to impose a threshold on the height of their progenitor, i.e. it selects local extrema with $\nu + v_0 = δ_c/σ_0(M_h)$ where $δ_c \approx 1.686$ for ΛCDM cosmology and $σ_0(M_h)$ is the fluctuation level.

For central under-densities we smooth the density field with a Gaussian kernel on a few number of cells. Minima are found by comparing the local density of each cell to its neighbours. The center of the cell is then identified with the position of the local minimum. The backward procedure is simplistic and assumes that the comoving position of each void is conserved during cosmic evolution. At any redshift, each void’s position is assumed to be the same than the one detected at $z = 0$.

From each extrema, we compute the concentric mass $m(r)$ from DM particles

$$m(r) = \sum_i m_p Θ[r - |x_i - x_0|]$$

where $m_p$ is the mass of one particle, $x_i$ the position of the $i^{\text{th}}$ particle and $x_0$ the position of the central extremum, $Θ(x)$ is the standard Heaviside distribution such as $Θ(x) = 1$ if $x > 0$ and 0 elsewhere.

The second step consists into building average profiles by stacking together individual profiles with the same compensation radius. For each $R_1$, we take at least 1000 profiles for both haloes and voids in order to insure a fair statistics. In Fig. 1 we show the resulting average profiles for both central over and under densities and several compensation radii at $z = 0$ in the reference simulation. As claimed before, the radial structure of these regions is symmetric; a central over (resp. under) massive core until $r = R_1$ surrounded by a large under (resp. over) massive compensation belt for $r > R_1$.

Numerical simulations can be used to follow the gravitational evolution of CoSpheres. By definition, these regions are detected at $z = 0$. For a central maximum, i.e. build from DM halo, we identify the position of its progenitor at higher redshift to the center of mass of its particles at $z = 0$. For each halo detected today, this procedure provides an estimated position of its progenitor at other redshift. These positions are used to define CoSpheres for any $z > 0$.

2 STATISTIC OF COSPHERES IN GAUSSIAN RANDOM FIELDS

In this section we study the statistical properties of CoSpheres in the framework of Gaussian Random Field (GRF) with appropriate constraints (paper I).

\begin{figure}[h]
\centering
\includegraphics[width=0.45\textwidth]{fig1a}
\includegraphics[width=0.45\textwidth]{fig1b}
\caption{Radial average mass contrast at $z = 0$ in the reference simulation. Each curve corresponds to a given compensation radius $R_1$ from 15 to 80 $h^{-1}\text{Mpc}$. Whereas each single individual profile is far from a smooth curve, stacked profiles display a global shape with well defined properties.}
\end{figure}
2.1 Gaussian Random Fields, the basics

Let us first recall the basic elements necessary for the derivation of average quantities in GRF. We consider here an homogeneous, isotropic random field whose statistical properties are fully determined by its power-spectrum (or spectral density) $P(k)$. It can be written as the Fourier Transform of the auto-correlation of the field $\xi(r) = \xi(|x_1 - x_2|) = \langle \delta(x_1) \delta(x_2) \rangle$

$$\xi(r) = \frac{1}{2\pi^2} \int_0^{+\infty} k^2 P(k) \sin(kr) \, dk$$

The Gaussianity of the field $\delta(x)$ leads to the joint probability $d\mathcal{P}_N = P[\delta(x_1), ..., \delta(x_N)] d\delta(x_1) ... d\delta(x_N)$ that the field has values in the range $[\delta(x_i), \delta(x_i) + d\delta(x_i)]$ for each position $x_i$. In this GRF model it is

$$d\mathcal{P}_N = \frac{1}{(2\pi)^N \det \mathcal{M}} \exp \left( -\frac{1}{2} \delta^T \mathcal{M}^{-1} \delta \right) \prod_{i=1}^{N} d\delta_i$$

where $\delta$ is the $N$ dimensional vector $\delta_i = \delta(x_i)$ and $\mathcal{M}$ is the $N \times N$ covariance matrix, here fully determined by the field auto-correlation $\mathcal{M}_{ij} := \langle \delta_i \delta_j \rangle = \xi(|x_i - x_j|)$

Furthermore, we are interested in deriving the properties of the field subject to a set of linear constraints $\mathcal{C} = \{C_1, ..., C_n\}$. Following Bertschinger (1987), each constraint $C_i$ can be written as

$$C_i[\delta] := \int W_i(x - x_0) \delta(x) dx = c_i$$

where $W_i$ is the corresponding window function and $c_i$ its value. For example, constraining the value of the field to a certain $\delta_0$ at some point $x_0$ leads to $W_i = \delta_p(x - x_0)$ and $c_i = \delta_0$. For $n$ constraints, the joint probability $d\mathcal{P}[\mathcal{C}]$ that the field satisfies these conditions reaches (van de Weygaert & Bertschinger 1996; Bertschinger 1987)

$$d\mathcal{P}[\mathcal{C}] = \frac{1}{\sqrt{(2\pi)^P \det \mathcal{Q}}} \exp \left( -\frac{1}{2} \mathcal{C}^T \mathcal{Q}^{-1} \mathcal{C} \right) \prod_{i=1}^{n} dc_i$$

where $\mathcal{Q}$ is the covariance matrix of the constraints defined through $\mathcal{Q} = (\mathcal{C}^T \mathcal{C})$.

2.2 The full joint Gaussian probability distribution

In this section we derive the full joint Gaussian probability to find a CoSphere with a given set of parameters in GRF. Since these regions are build around extremum, we must include the peak conditions derived by Bardeen et al. (1986). A local extrema located at $x_0$ is defined by three conditions

$$\delta(x_0) = 0$$

$$\eta_i = \frac{\partial \delta(x_0)}{\partial x_i} = 0$$

$$\zeta_{ij} = \frac{\partial^2 \delta(x_0)}{\partial x_i \partial x_j} = 0$$

where Eq. (12) gives the height of the peak in unit of the fluctuation level

$$\sigma_0 = \frac{1}{2\pi^2} \int_0^{+\infty} k^2 P(k) \, dk$$

wheras Eq. (13) imposes that the local gradient $\eta$ vanishes (since we consider extrema). Eq. (14) defines the Hessian matrix $\zeta$ of the density profile around the peak.

In addition to the peak condition, we must explicitly encode the compensation condition Eq. (3). This is achieved by adding the new constraints (paper I)

$$\mathcal{C}_R[\delta] := \int \Theta(R_1 - |x - x_0|) \delta(x) dx = \tilde{v}_0 = 0$$

$$\mathcal{C}_R[\delta] := \int \Theta(R_1 - |x - x_0|) \delta(x) dx = \bar{v}$$

where $\Theta$ is the Heaviside step function and $\bar{v}$ is the usual Dirac delta. Eq. (16) is the transposition of Eq. (3) in the form Eq. (10). The parameter $\tilde{v}$ is defined by $\Delta(R_1) = \tilde{v}_0$ and is set to 0 by definition of the compensation radius $R_1$. Eq. (17) defines the compensation density on the sphere of radius $R_1$ such that $\delta(R_1) := \delta_1 = \bar{v}_0$.

2.2.1 The full joint probability for spherically compensated peaks

Without any assumption on the symmetry, CoSpheres in primordial field are described by 12 independent scalars $(\nu, \tilde{v}, \nu_1, \eta_1, \nu_2, \eta_2, \zeta_{ij})$ with $i$ and $j$ running in $\{1, 2, 3\}$. The computation of the conditional probability Eq. (11) involves the correlation matrix $\mathcal{Q}$ between these 12 constraints. The introduction of two new degree of freedom makes the computation of $\mathcal{Q}$ more complicated than for a standard unconstrained peak. However, following Bardeen et al. (1986), we can simplify $\mathcal{Q}$ by introducing the reduced variables linked to the local curvature of the profile around the peak

$$x = \frac{\xi_{11} + \xi_{22} + \xi_{33}}{\sigma_0 \sqrt{\langle k^4 \rangle}}, \quad y = -\frac{\xi_{11} - \xi_{22} - \xi_{33}}{2\sigma_0 \sqrt{\langle k^4 \rangle}}, \quad z = -\frac{\xi_{11} - 2\xi_{22} + \xi_{33}}{2\sigma_0 \sqrt{\langle k^4 \rangle}}$$

where the various moments of $P(k)$ are given by

$$\langle k^{2n} \rangle := \frac{c_n}{\sigma_0^2} = \frac{1}{2\pi^2 \sigma_0^2} \int_0^{+\infty} k^{2+2n} P(k) \, dk$$

and

$$\lim_{r \to 0} \frac{\partial^2 \delta(r)}{\partial r^2} = -\frac{x}{3} \sigma_0 \sqrt{\langle k^4 \rangle}$$

With these variables, $\mathcal{Q}$ reduces to a partitioned matrix where the only non-diagonal terms are included in a $4 \times 4$ sub-matrix $\mathcal{Q}$. This sub-matrix encodes the new correlations
where we have already imposed the condition

\[ \langle J_1 \rangle = \langle W_1 \rangle \frac{\langle k^2 \rangle}{\langle k \rangle^2} \langle J_1 \rangle \]

\[ \langle W_1 \rangle \frac{\langle k^2 \rangle}{\langle k \rangle^2} \langle J_1 \rangle \]

\[ \langle J_1 \rangle = \langle W_1 \rangle \frac{\langle k^2 \rangle}{\langle k \rangle^2} \langle J_1 \rangle \]

where we used the following notation for the spherical Bessel functions evaluated at \( R_1 \):

\[ W_1 := \frac{\sin(kR_1) - kR_1 \cos(kR_1)}{(kR_1)^3} \]

\[ J_1 := \frac{\sin(kR_1)}{kR_1} \]

We can now rewrite Eq. (11) as

\[ d^2 \mathcal{P}(\tilde{v}, x, v_1, y, \eta, \zeta) \propto \frac{1}{\sqrt{|J|}} \exp \left[ -\frac{1}{2} \mathcal{F} \right] \mathcal{D} \]

where the superscript 12 indicates that this is a 12-dimensional quantity with the measure

\[ \mathcal{D} = dvdx dy dvz \prod_{\nu=4}^{\nu=6} d\zeta_{\nu} \]

with \( \zeta_4 = \zeta_{13}, \zeta_5 = \zeta_{13} \) and \( \zeta_6 = \zeta_{12} \) (Bardeen et al. 1986).

We now neglect the numerical factors which do not depend explicitly on \( R_1 \). The 2 form \( \mathcal{F} \) reduces to

\[ \mathcal{F} = \frac{x^2 C_x + v^2 C_v + v_1^2 C_{v_1} + 2(xx C_{xv} + xv_1 C_{xv_1} + v_1 v C_{vv})}{\Sigma^2(R_1)} \]

\[ + 15y^2 + 5\zeta^2 \]

where we have already imposed the condition \( \eta_1 = 0 \) (see Eq. 13) and \( \tilde{v} = 0 \) (see Eq. 16). The \( C_\nu \) functions (with \( \alpha = 0, x, v, v_1, xv, xv_1, v_1v_1 \)) depend also on \( R_1 \). Their explicit form is given in Appendix A. \( \Sigma^2(R_1) \) takes the form

\[ \Sigma^2(R_1) = C_0 + C_1 + C_2 + \frac{\langle k^2 \rangle}{\langle k \rangle^2} C_{xv} \]

Since we consider only spherical profiles, we marginalize over the asymmetry parameters \( y \) and \( z \). The integration of \( \mathcal{D} \) over \( y \) and \( z \) combined with the ordering condition \( |\zeta_1| \geq |\zeta_2| \geq |\zeta_3| \geq 0 \) then leads to the four-dimensional joint probability for the spherically compensated cosmic regions

\[ d^4 \mathcal{P}(x, v, v_1, \eta, \zeta) \propto \frac{f(x, v, v_1)}{\Sigma(R_1)} \exp \left[ -\frac{L(x, v, v_1)}{2} \right] dv dx dy dv_1 \]

with (Bardeen et al. 1986)

\[ f(x) = \frac{\sqrt{\pi}}{x^2 \sqrt{\pi}} \left[ e^{-x^2} \left( -\frac{8}{5} + \frac{x^2}{2} \right) + e^{-\frac{x^2}{4}} \left( \frac{8}{5} + \frac{31x^2}{4} \right) \right] \]

\[ + 15y^2 + 5\zeta^2 \]

This function is not modified here because it results from the integration over the \( y \) and \( z \) variables which are not correlated to \( v_1 \) nor \( \tilde{v} \). We define \( \mathcal{L} \) as

\[ \mathcal{L}(x, v, v_1) = \frac{x^2 C_x + v^2 C_v + v_1^2 C_{v_1} + 2 xx C_{xv} + xv_1 C_{xv_1} + v_1 v C_{vv}}{\Sigma^2(R_1)} \]

\[ + 2 x v C_{xv} + v_1 v C_{v_1 v_1} + v v C_{vv} \]

\[ \Sigma^2(R_1) \]

Note that \( \mathcal{L} \) depends on \( R_1 \) through \( \Sigma \) and the various \( C_\nu \) functions. When \( R_1 \) becomes very large, we recover the BBKS limit (see below Sec. 2.2.3) and \( \mathcal{L} \) reduces to its expression as derived in Bardeen et al. (1986). Finally, we map \( \tilde{v} \) to the compensation radius as

\[ d\tilde{v} = \frac{3v_1}{R_1} dR_1 \]

and we get the full joint Gaussian probability distribution of CoSpheres

\[ d^4 \mathcal{P}(x, v, v_1, R_1) \propto \frac{|v_1| f(x)}{R_1 \Sigma(R_1)} \exp \left[ -\frac{L(x, v, v_1, R_1)}{2} \right] dv dx dy dv_1 dR_1 \]

where both \( \Sigma(R_1) \) and \( \mathcal{L} \) depend on \( R_1 \).

2.2.2 The First Crossing Condition (FCC)

Our definition of \( R_1 \) (see Eq. 3) implicitly assumes that \( R_1 \) is the first crossing radius such that \( L(R_1) = 0 \). However, neither Eq. (3) nor the definition of \( v_1 \) insures it. For each \( R_1 \), there is a sub-domain for the shape parameters where the corresponding average mass contrast profile vanishes at some effective radius \( \tilde{R}_1 < R_1 \). This is typically the case for central peaks with high curvature \( x \). The true joint Gaussian probability must take this effect into account. In paper I we show that the average mass contrast profile corresponding to a set of shape parameters \( v, x \) and \( v_1 \) can be expressed as

\[ \Delta(r) = \sigma_0 \left[ |v| \Delta_v(r) + x \Delta_x(r) + v_1 \Delta_{v_1}(r) \right] \]

where each \( \Delta_{\nu}(r) \) function involves the compensation scale \( R_1 \) and the radius \( r \). This set of shape parameters is safe if it satisfies

\[ \forall r \in [0, R_1], \left\{ \begin{array}{ll} \Delta(r) > 0 & \text{if } v > 0 \\ \Delta(r) < 0 & \text{if } v < 0 \end{array} \right. \]

This defines the safe domain \( \mathcal{D}(R_1) \) for \( (v, x, v_1) \) where the first radius where \( \Delta(r) \) vanishes is \( \tilde{R}_1 \). If \( (v, x, v_1) \notin \mathcal{D}(R_1) \) there exist an effective \( \tilde{R}_1 < R_1 \) satisfying

\[ \Delta_v(\tilde{R}_1) + x \Delta_x(\tilde{R}_1) + v_1 \Delta_{v_1}(\tilde{R}_1) = 0 \]

This effective compensation radius is associated with a compensation density \( \tilde{v}_1 \) defined as

\[ \tilde{v}_1 = v \Delta_v(\tilde{R}_1) + x \Delta_x(\tilde{R}_1) + v_1 \Delta_{v_1}(\tilde{R}_1) \]

such that both \( \tilde{R}_1 \) and \( \tilde{v}_1 \) are functions of \( v, x, v_1 \) and \( R_1 \). The condition Eq. (31) defining the safe domain \( \mathcal{D}(R_1) \) can be translated to a simple restriction on the curvature \( x \)

\[ |x| < x_0(v, v_1, R_1) = \min \left( -|v| \frac{\Delta_v(r)}{\Delta_x(r)} - |v_1| \frac{\Delta_{v_1}(r)}{\Delta_x(r)}, \forall r < R_1 \right) \]
At fixed $R_1$, if $|x| \geq x_{\text{c}}(v, v_1, R_1)$, then this set of parameters \{$(v, v_1, R_1)$\} will contribute to \{$(v_\text{f}, v_1, R_1)$\} where $R_\text{f}$ and $v_1$ are the effective parameters defined in Eq. (32) and Eq. (33). In other words, for each $R_1$, there is a fraction of its parameter’s domain contributing to smaller $R_1 < R_\text{f}$ while a fraction of larger compensation radii with $R_1^* > R_1$ also contribute to this $R_1$. The full joint Gaussian probability can thus be formally decomposed in two parts

$$d^4\mathcal{P}_\text{tot}(v, x, v_1, R_1) = \delta(x - x_{\text{c}}(v, v_1, R_1)) d^4\mathcal{P}(v, x, v_1, R_1)$$

\[\text{direct contribution}\]

\[+ \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} dR_1^* d\nu_1^* d^4\mathcal{P}(v, x, v_1, R_1^*) \delta(D(\nu_1^* - \nu_1) \text{ contribution from higher compensation radii})\]

The first term accounts for peaks satisfying the first crossing condition (FCC) while the second one is the contribution from peaks with higher compensation radii whose effective compensation radius $\hat{R}_1$ equals $R_1$ and effective compensation density $\hat{\nu}_1$ equals $\nu_1$. Note that naturally, this indirect contribution term provides $x$ satisfying Eq. (34).

### 2.3 Statistical properties of the shape parameters in GRF

In this section we focus on the very large scale behaviour of the full joint Gaussian probability distribution, i.e. when $R_1 \rightarrow +\infty$. For clarity, let us assume a power-law matter power spectrum smoothed with a Gaussian kernel, $P(k) \sim k^n \exp(-k^2 R_1^2)$, where the power index $n$ is the effective power index at very small $k$. In the limit $R_1 \rightarrow +\infty$, the $C_\alpha$ parameters (see Appendix A) reduce to simple power laws

$$C_x \propto \left(\frac{R_1}{R_\text{f}}\right)^{-3-n}\quad (36)$$

$$\frac{C_x}{C_x} = 1, \quad \frac{C_{\nu_1}}{C_x} \propto \left(\frac{R_1}{R_\text{f}}\right)^2$$

$$\frac{C_{\nu_x}}{C_x} = -\nu, \quad \frac{C_{\nu_x}}{C_x} \propto \left(\frac{R_1}{R_\text{f}}\right)^{-1-n}, \quad \frac{C_{\nu_x}}{C_x} \propto \left\langle \frac{R_1}{R_\text{f}}\right\rangle^{-1-n}$$

$$C_0 \rightarrow \nu^2 - 1$$

where $\nu := (k^2) / (\langle k^2 \rangle)$. Using these limits, the exponential term $L$ simplifies to

$$L(x, v, v_1, R_1) = x^2 + x^2 - 2\gamma x v + 2\sqrt{2} \gamma R_1^2 \nu_1 + O(\nu_1^{-1-n})$$

The second concerns the term involving $v_1$. It depends explicitly on $R_1$ and contributes to an overall $\exp(-c\gamma R_1^2)$ factor in the full joint probability Eq. (35). For $R_1 \rightarrow +\infty$, combined with the $v_1$-pre-factor appearing in Eq. (35), it leads to a global $\delta(D(v_1))$ such that full joint probability distribution reduces to

$$d\mathcal{P}(v, x, v_1, R_1) \rightarrow +\infty \quad d\mathcal{P}_\text{bbks}(x, v, v_1) \times \frac{\delta(D(v_1))}{R_1^{-1-n/2}} d\nu_1 dR_1$$

This means that the statistical properties of the central extremum involving $x$ and $v$ reduce, for very large compensation radius, to the standard "unconstrained" peak statistic of BBKS with smaller central curvature satisfying Eq. (42).

We emphasize in Eq. (41) illustrates the progressive decoupling between the central peak and its environment. Large $R_1$ will be associated with universal central peaks whose local shape and properties are similar to BBKS.

### 2.3.1 The compensation radius probability distribution

Each extremum can be associated with a unique $R_1$ separating the collapsing and the expanding shells. The probability $d\mathcal{P}(R_1)$ to find a local extremum with $R_1$ and whatever the other shape parameters is obtained by marginalizing Eq.
We consider here a central maxima.

\[ \mathcal{J}_{0,0}(\nu, R_1) := \int_{\nu_0}^{\nu} dx \frac{d^4P_{\text{tot}}(x, x_1, \nu, R_1)}{d^3dR_1} \]  

(45)

where the integration on the local curvature \( x \) is done over \([0, x_\nu(x, \nu)]\) due to the FCC condition (see Sec. 2.2.2). Notice that the integration over \( \nu \) goes from \(-\infty\) to 0 since we consider here a central maxima.

On Fig. 2 we show this compensation radius probability \( dP(R_1) \) for \( \Lambda \)CDM cosmology in a Gaussian random field. We illustrate the effect of the central threshold \( \nu_0 \) defining the height of the central extremum \(|\nu| \geq |\nu_0|\). Increasing the central threshold favors larger compensation radii. This seems natural since higher central peaks are more likely compensated on large regions than smaller ones. This figure also shows typical wiggles in this distribution around \( R_1 \sim 100 \ h^{-1}\text{Mpc} \). This feature is probably related to the BAO. The enhanced correlation on this scale increases the probability to find Cospheres compensated around this particular radius.

\[ \frac{d^2P(\nu_1, R_1)}{d\nu_1 dR_1} = \int_{\nu_0}^{\nu} dx \frac{d^4P_{\text{tot}}(x, x_1, \nu_1, R_1)}{d^3dR_1} \]  

(46)

Note that \( \nu \) is integrated from \( \nu_0 \) to \(+\infty\) where \( \nu_0 \) is the lower threshold for the central height. The conditional probability \( dP(\nu_1|R_1) \) is derived from Bayes theorem

\[ \frac{dP(\nu_1|R_1)}{d\nu_1} = \frac{\int_{\nu_0}^{\nu} dx \frac{d^4P_{\text{tot}}(x, x_1, \nu_1, R_1)}{d^3dR_1}}{\int_{\nu_0}^{\nu} \mathcal{J}_{0,0}(\nu, R_1) d\nu} \]  

(47)

which describes the probability to get a compensated region with \( \nu_1 \) given \( R_1 \) normalized such that \( \int_{\nu_0}^{\nu} dP(\nu_1|R_1) = 1 \).

On Fig. 3 we plot the distribution of \( \delta_1 \) in a Gaussian random field with a comparison to numerical simulation, illustrating the excellent agreement between the theoretical expectation and the numerical results. As an illustration, if we neglect the dependence of \( x_\nu \) in term of \( \nu_1 \) and the second term in Eq. (35), \( \nu_1 \) follows a distribution of the form

\[ \frac{d^4P(\nu_1|R_1)}{d\nu_1} \sim |\nu_1| \exp \left[ -\frac{(\nu_1 - \tilde{\nu}_1)^2}{2\sigma^2} \right] \]  

(48)

where \( \tilde{\nu}_1 \) and \( \sigma \) are respectively the mean and dispersion value of the \( \nu_1 \) distribution and are both functions of \( R_1 \).

From Eq. (47) we compute the moments of \( \nu_1 \) given \( R_1 \), defined by

\[ \langle \nu_1^m | R_1 \rangle = \frac{\int_{\nu_0}^{\nu} \mathcal{J}_{0,m}(\nu, R_1) d\nu}{\int_{\nu_0}^{\nu} \mathcal{J}_{0,0}(\nu, R_1) d\nu} \]  

(49)

where \( \mathcal{J}_{0,m} \) generalizes the function defined in Eq. (45) as

\[ \mathcal{J}_{0,m}(\nu, R_1) := \int_{\nu_0}^{\nu} \nu_1^m \int_{\nu_0}^{\nu} dx \frac{d^4P_{\text{tot}}(x, x_1, \nu_1, R_1)}{d^3dR_1} \]  

(50)

On Fig. 4, we plot \( \langle \nu_1^m | R_1 \rangle \) as a function of the compensation radius \( R_1 \) in a Gaussian random field. \( \langle \nu_1^m | R_1 \rangle \) (red curve) admit a maximum for small compensation radius (here \( R_1 \sim 5 \ h^{-1}\text{Mpc} \) as we used a Gaussian smoothing scale \( R_f = 2 \ h^{-1}\text{Mpc} \) for the matter power spectrum) and slowly converges to 0.

\[ \frac{dP(\nu|R_1)}{d\nu} = \mathcal{J}_{0,0}(\nu, R_1) \]  

(51)

we deduce the moments of \( \nu \) constrained by its cosmic environment i.e. for a given compensation radius

\[ \langle \nu^m | R_1 \rangle = \frac{\int_{\nu_0}^{\nu} \nu^m \mathcal{J}_{0,0}(\nu, R_1) d\nu}{\int_{\nu_0}^{\nu} \mathcal{J}_{0,0}(\nu, R_1) d\nu} \]  

(52)

2.3.3 The height of the central peak \( \nu \)

The conditional probability distribution of the heigh \( \nu \) of the central extremum given \( R_1 \) is obtained by integrating the full joint probability distribution (see Eq. 35) over \( x \) and \( \nu_1 \),

\[ \frac{dP(\nu|R_1)}{d\nu} = \mathcal{J}_{0,0}(\nu, R_1) \]  

(51)

we deduce the moments of \( \nu \) constrained by its cosmic environment i.e. for a given compensation radius

\[ \langle \nu^m | R_1 \rangle = \frac{\int_{\nu_0}^{\nu} \nu^m \mathcal{J}_{0,0}(\nu, R_1) d\nu}{\int_{\nu_0}^{\nu} \mathcal{J}_{0,0}(\nu, R_1) d\nu} \]  

(52)
and in particular the average value for \( \nu \) obtained for \( n = 1 \)

\[
\langle \nu | R_1 \rangle = \frac{\int_{\nu_0}^{+\infty} \nu \mathcal{J}_{2,0}(\nu) d\nu}{\int_{\nu_0}^{+\infty} \mathcal{J}_{2,0}(\nu) d\nu}
\]  

(53)

As it can be seen in Fig. 4, \( \langle \nu | R_1 \rangle \) strongly depends on \( R_1 \) for small compensation radius while it progressively tends to its asymptotic value. As shown in Sec. 2.2.3, it converges to the standard value \( \langle \nu \rangle \) computed by Bardeen et al. (1986).

Small inhomogeneous regions (small \( R_1 \)) are associated with lower central extremum, describing smoothed inhomogeneities while higher extremum (or deeper voids) are more likely to sit in larger over massive (resp. under massive) regions. As discussed in Sec. 2.2.3, the convergence toward the standard BBKS case illustrates the progressive decorrelation between the central peak and its large scale cosmic environment.

### 2.3.4 The curvature distribution \( x \)

Finally we evaluate the statistical properties of the local curvature \( x \) around a central extremum. Following the same development as before, we derive the various moments

\[
\langle x^n | R_1 \rangle = \frac{\int_{\nu_0}^{+\infty} \nu^n \mathcal{J}_{2,n}(\nu, R_1) d\nu}{\int_{\nu_0}^{+\infty} \mathcal{J}_{2,0}(\nu, R_1) d\nu}
\]  

(54)

with the average of \( x \) given by

\[
\langle x | R_1 \rangle = \frac{\int_{\nu_0}^{+\infty} \nu \mathcal{J}_{2,1}(\nu, R_1) d\nu}{\int_{\nu_0}^{+\infty} \mathcal{J}_{2,0}(\nu, R_1) d\nu}
\]  

(55)

We show on Fig. 4 the behavior of \( \langle x | R_1 \rangle \) as a function of \( R_1 \). For large compensation radii, it converges to its modified BBKS value (see Sec. 2.2.3) and remains almost constant for a wide range of \( R_1 \). Again we observe on BAO scale some wiggles for \( \langle \nu | R_1 \rangle \) and \( \langle x | R_1 \rangle \) relating the peaks parameters and the compensation radius.

### 2.4 The mean average profile with a given compensation radius \( R_1 \) in GRF

#### 2.4.1 The profile at fixed \( R_1 \)

In the primordial Gaussian field, average profiles of CoSpheres are determined by four independent - but correlated - scalars: \( \nu, x, \nu_1 \) and \( R_1 \). At fixed compensation radius \( R_1 \), the other shape parameters \( X = \{ \nu, x, \nu_1 \} \) can be considered as stochastic variables with constrained probabilistic distributions \( dP(X | R_1) \) as computed in the previous sections. Since the average density and mass contrast profiles are linear in the shape parameters (see paper I and Eq. (56)), one can define the mean average profile at a fixed compensation radius as the profile whose shape parameters are averaged over their distribution, thus reaching

\[
\frac{\langle \delta \rangle (r) }{\sigma_0} = \langle \nu | R_1 \rangle \delta_\nu (r) + \langle x | R_1 \rangle \delta_x (r) + \langle \nu_1 | R_1 \rangle \delta_{\nu_1} (r)
\]  

(56)

where brackets mean an average on stochastic realization of the field and bar means an average over the possible values for the free shape parameters. The mass contrast profile reaches (paper I)

\[
\frac{\langle \Delta \rangle (r) }{\sigma_0} = \langle \nu | R_1 \rangle \Delta_\nu (r) + \langle x | R_1 \rangle \Delta_x (r) + \langle \nu_1 | R_1 \rangle \Delta_{\nu_1} (r)
\]  

(57)

This profile describes the spherically compensated matter distribution resulting from stacking every possible realization at fixed \( R_1 \). On Fig. 5 we show the mass contrast profiles \( \Delta \) for various compensation radii in ACDM cosmology. We retrieve the various properties of CoSpheres described before: (i) smaller central maxima (low \( \nu \)) are associated with narrow compensation radius with a deep compensation density \( \delta_1 \), (ii) higher central maxima (high \( \nu \)) are located in larger over massive regions with a high \( R_1 \) and smoother...
density contrast \( \Delta_1 \) and (iii) when \( R_1 \) increases, central peaks become undistinguishable on small scales \( (r \ll R_1) \) and tend to the standard BBKS profiles. In other words, for large \( R_1 \), different environments with various compensation radii can be associated with very similar central profiles.

The whole of the previous discussion can be directly transposed to the symmetric case of a central minima, seeding cosmic void.

2.4.2 On the characteristic elbow

One particular feature of the mean average profile, besides the fact that they are fully determined by one single parameter \( R_1 \), is the existence of a characteristic elbow. This bend appears around \( r \sim 10 \ h^{-1}\text{Mpc} \) in Fig. 5 but it also shows up in numerical profiles as can be seen in Fig. 1b. This elbow is a result of the progressive decorrelation between the central peak and its surrounding environment as discussed in Sec. 2.2.3.

While \( R_1 \) increases, the central extremum tends to an universal shape as expected from BBKS. This elbow appears as the transition between small "BBKS" scales and larger ones involved with the compensation property. This characteristic does not appear in standard void profiles when build from their effective size \( R_{eff} \) as in Hamaus et al. (2014). This is likely due to the fact that voids with the same \( R_{eff} \) may have very different compensation radii. Stacking together profiles with the same \( R_{eff} \) may erase this feature. On the other hand, this elbow does not appear in evolved profiles build from central over densities as in Fig. 1a despite existing in the primordial Universe (see Fig. 5). This vanishing follows from the non linear gravitational evolution of these profiles, altering their shape on small scales.

3 NON LINEAR GRAVITATIONAL EVOLUTION OF COSPHERE IN \( \Lambda \)CDM COSMOLOGY

In the previous section we discussed the statistical properties of the shape parameters of CoSpheres within the primordial GRF. These results stand under the Gaussian assumption which can be safely assumed at high redshift. In this section we study the dynamical evolution of these quantities during the non linear collapse of the matter field. As shown in paper I, the adapted formalism for the gravitational collapse of these regions is the Lagrangian spherical collapse model (Padmanabhan 1993; Peacock 1998). It describes the Lagrangian evolution of concentric shells without shell-crossing or caustics formation.

3.1 Spherical Lagrangian collapse in \( \Lambda \)CDM cosmology

We recall the dynamical equations for the Lagrangian collapse suited for our study. In the following, a Greek letter \( \chi \) will denote a comoving quantity while a Latin character \( r \) designates a physical length. These quantities are related by \( r = \chi \times a \) with a the homogeneous scale factor normalized as \( a(t_0) = 1 \) today. We also denote every initial quantity by the "i" label, e.g. \( \chi_i \) is the initial comoving position of one shell. Initial conditions are taken deep in the matter dominated era where The Gaussian assumption for \( \delta(x) \) stands. We define the dimensionless Lagrangian displacement for each shell

\[
\mathcal{R}(\chi_i, \tau) = \frac{\chi(\tau)}{\chi_i} \tag{58}
\]

with \( \chi(t) \) the comoving radius of the shell at some time \( t \).

The mass conservation in the absence of shell crossing leads to the relation

\[
\frac{1 + \Delta}{1 + \Delta_i} = \mathcal{R}^{-3} \tag{59}
\]

where \( \Delta_i \) is the initial mass contrast for this shell, i.e. \( \Delta_i = \Delta(\chi) \) and \( \Delta \) its evolved mass contrast. In order to simplify the dynamical equation, we introduce the affine parameter \( \tau \) defined through

\[
\frac{d\tau}{d\log(a)} := \sqrt{\frac{\Omega_m}{2}} \tag{60}
\]

which can be integrated to give \( \tau(a) \) in the \( \Lambda \)CDM model, with the definition \( \tau(a_i) = 0 \)

\[
\tau(a) = \frac{\sqrt{2}}{3} \left[ \text{arctanh} \left( \Omega_m^{-1/2} \right) - \text{arctanh} \left( \Omega_m^{-1/2} \right) \right] \tag{61}
\]

With this new parametrization, the equation of motion driving the evolution of each individual shell reaches (paper I)

\[
\frac{\partial^2 \mathcal{R}}{\partial \tau^2} + \frac{1}{\sqrt{2\Omega_m}} \frac{\partial \mathcal{R}}{\partial \tau} = \mathcal{R} - 1 + \Delta_i \tag{62}
\]

To close our system we need to specify the initial conditions at \( \tau = 0 \). They are fixed by assuming that the dynamics follows the Zel’dovich evolution at very high redshift, leading to (paper I)

\[
\left\{ \begin{array}{c}
\mathcal{R}(t_i) = 1 \\
\frac{\partial \mathcal{R}}{\partial \tau}(t_i) = -\sqrt{\frac{3}{2\Omega_m}} \Delta_i f(t_i)
\end{array} \right. \tag{63}
\]

MNRAS 000, 1–77 (2017)
where $f$ is the linear growth rate (Peebles 1980) and $f(t_i)$ is evaluated at the initial time defined by $\tau = 0 \Leftrightarrow t = t_i$. Eq. (62) is valid for any cosmology with a quintessence field sourcing dark energy and possibly a time varying e.o.s parameter $w$. The affine parameter $\tau$ is then still defined by Eq. (60) but Eq. (61) is no longer true (Alimi & de Fromont 2017). We extend also Eq. (62) for theories beyond GR in de Fromont & Alimi (2017b).

3.2 Dynamical evolution of the compensation radius probability distribution

The particular scale $R_1$ is by definition conserved in comoving coordinates, i.e. $R_1(t) \propto a(t)$. In other terms, since the mean density enclosed in the sphere of radius $R_1$ equals the background density, this scale evolves as the scale factor of the Universe. Since $R_1$ is conserved, its probability distribution must also be conserved during the gravitational evolution. In principle, merging or creation of local extrema could modify this probability distribution. However, such effects are expected to occur on small scales, and since we consider sufficiently large value for $R_1$ ($R_1 \gtrsim 5 \sim 7$ $h^{-1}$Mpc), the probability distribution $dP(R_1)$ will not be affected.

On Fig. 6 we show the measure of its pdf $dP(R_1)/dR_1$ at various redshifts from $z = 8$ to $z = 0$ in the numerical simulation. We also show the theoretical expectation from Eq. (43) computed within GRF. This figure illustrates two points. Firstly, the compensation radius pdf does not evolve during the cosmic evolution except on very small scales ($R_1 \leq 5$ $h^{-1}$Mpc) where our reconstruction procedure may be inaccurate (see Sec. 1). On larger scales however, neither the shape nor the amplitude are affected, confirming that this distribution is conserved during cosmic history.

On the other hand, the GRF expectation (see Eq. 43) fits the measured distribution with a very good agreement. This distribution thus appears as a good way to probe the early universe. However, since the initial power spectrum $P(k)$ is independent from the e.o.s parameter for DE $w$, this probability distribution does not probe $w$ neither $\sigma_8$, the amplitude of the power spectrum, but may probe $\Omega_m$ and the various quantities describing the primordial Universe as the scalar index $n_s$ on very large scales. These cosmological dependences are discussed in Alimi & de Fromont (2017).

Note however that the wiggles predicted by theoretical prediction around $R_1 = 100$ $h^{-1}$Mpc do not appear in numerical data. This may be due to the finite number of our simulation ($L_{box} \approx 2592$ $h^{-1}$Mpc) and the fact that on such scale, we are dominated by the cosmic variance (Rasera et al. 2014).

3.3 The evolution of the compensation density $\delta_1$

$\delta_1$ is defined on the sphere of radius $R_1$. It is a fundamental Eulerian quantity and its probability distribution can be computed analytically in the primordial GRF (see Sec. 2.3.2). $\delta_1$ is directly measurable from the matter profile. In paper I we showed that during the non linear evolution, it follows a simple dynamics, corresponding to a one-dimensional Zel’’dovich collapse

$$\delta'_1 = \delta_1 \frac{D(t)}{D(t) - 1}$$

(64)

![Figure 6. The compensation radius probability distribution $dP(R_1)$ for $\Lambda$CDM cosmology computed from 10000 profiles build around haloes at various redshift ($z = 8$ to $z = 0$) in the reference simulation (blue lines). This figure has been obtained from 10000 haloes of mass $M_h = 3.0 \pm 0.075 \times 10^{13}$ $h^{-1}$M$_\odot$. The shaded region around each curve is the Poisson noise computed in radial bins of size $dR_1 = 3.5$ $h^{-1}$Mpc. The red line is the initial Gaussian distribution given by Eq. (43). The conservation of $R_1$ insures the conservation of its probability distribution. The height of the central threshold $v_0$ has been chosen in agreement with the halo masses ($3.0 \times 10^{13}$ $h^{-1}$M$_\odot$) used to construct the compensated regions.](image-url)
In term of the primordial moments in Gaussian random field and central maxima, these moments can be simply rewritten despite being a mute parameter, we prefer to keep the notation $\delta_i^t$ in the integral to highlight the fact that this average is evaluated at any time and not only in the initial conditions.

\[
\langle \delta_i^t | R_1 \rangle (t) = \int_{-1}^{1} \left( \delta_i^t \right)^n dP(\delta_i^t | R_1)
\]

where the integration is done over $\delta_i^t$. Mapping $\delta_i^t$ to its corresponding value in the initial conditions $\delta_i$ leads to

\[
\langle \delta_i^n | R_1 \rangle (t) = \int_{-1}^{1} \left( \frac{\dot{D}(t) \delta_i}{1 - \delta_i (\dot{D}(t) - 1)} \right)^n dP(\delta_i | R_1)
\]

In Appendix B we show that for both central minima and central maxima, these moments can be simply rewritten in term of the primordial moments in Gaussian random field

\[
\langle \delta_i^n | R_1 \rangle (t) = \sum_{k=0}^{n} \frac{\dot{D}(t)^n}{(\dot{D}(t)-1)^k} \left( \delta_i^t \right)^{n-k} \langle \delta_i^k | R_1 \rangle
\]

In particular, for $n = 1$ we get

\[
\langle \delta_i | R_1 \rangle (t) = \dot{D}(t) \sum_{k=0}^{\infty} \left( (\dot{D}(t)-1)^k \left( \delta_i^t \right)^{k} \right)
\]

\[\text{Figure 7. Evolved probability density function } dP(\delta_1 | R_1)/d\delta_1 \text{ at } z = 0 \text{ in the } \Lambda \text{CDM cosmology from haloes. The full line curves corresponds to the exact evolution given by Eq. (67). The shaded regions are the measured distributions for two different compensation radius in the reference simulation. The dashed curves are the Gaussian prediction, i.e. the linear evolution of the primordial distribution. This figure illustrates the non linearity of the local gravitational process but also the possibility to reproduce the evolved distribution from the exact collapse.}\]

\[\text{Figure 8. Redshift evolution of the first conditional moment of } \delta_1 \text{ at fixed } R_1 \text{, i.e. } \langle \delta_1 | R_1 \rangle \text{ for } R_1 = 20 \ h^{-1}\text{Mpc}. \text{ The red curve is the non linear solution derived from Lagrangian spherical dynamics Eq. (71), the dashed red curve is the linear solution } \langle \delta_1 | R_1 \rangle (t) = D(t)|\dot{D}(t)| \langle \delta_1 | R_1 \rangle \text{ and the numerical data are in blue (points with corresponding error bars). The agreement between numerical and theoretical computation from Eq. (71) is very good for all redshift (here the x axis is the scale factor } a = 1/(t+1). \text{ The full blue line and the dashed line are the small } \delta_1 \text{ expansion from Eq. (72) and Eq. (74). At low redshift, all the non linear terms beyond the second order term } \langle \delta_1 | R_1 \rangle \text{ have to be taken into account to reproduce the numerical results.}\]

\[\text{At } t = t_i, \text{ since } \dot{D}(t_i) = 1, \text{ the only non zero contribution comes from the } k = 1 \text{ term leading to } \langle \delta_1 | R_1 \rangle. \text{ Expanding Eq. (71) we have}\]

\[
\langle \delta_1 | R_1 \rangle (t) \approx \dot{D} \langle \delta_1 | R_1 \rangle + \dot{D}(\dot{D} - 1) \langle \delta_1^2 | R_1 \rangle + \ldots
\]

\[\text{The first term is the linear evolution while higher terms account for the corrections to this simple dynamics. Note that Eq. (71) is different from the evolution of the mean which would be}\]

\[
\langle \delta_1 | R_1 \rangle (t) = \frac{\langle \delta_1 | R_1 \rangle \cdot \dot{D}(t)}{1 - \langle \delta_1 | R_1 \rangle \cdot (\dot{D}(t) - 1)}
\]

\[\text{whose small } \dot{D}(t) \text{ expansion is}\]

\[
\langle \delta_1 | R_1 \rangle (t) \approx \dot{D} \langle \delta_1 | R_1 \rangle + \dot{D}(\dot{D} - 1) \langle \delta_1 | R_1 \rangle^2 + \ldots
\]

\[\text{The first linear term remains unchanged while the second one differs by } \langle \delta_1^2 | R_1 \rangle - \langle \delta_1 | R_1 \rangle^2. \text{ In Fig. 8 we show the measure of } \langle \delta_1 | R_1 \rangle (t) \text{ in the numerical simulations together with the exact evolution Eq. (71) and the various approximations Eq. (72) and Eq. (74) for } R_1 = 20 \ h^{-1}\text{Mpc}. \text{ We also show the linear prediction } \langle \delta_1 | R_1 \rangle = D(t) \langle \delta_1 | R_1 \rangle. \text{ It turns out that the non linear prediction fits very well the measured evolution on the whole range of redshifts.}\]

\[\text{The possibility to predict precisely the distribution of the compensation density at any non linear redshift opens again new possibilities for cosmology and will be deeply studied in Alimi & de Fromont (2017); de Fromont & Alimi (2017b).}\]
4 DISCUSSION AND CONCLUSION

In this paper, we derived the main statistical properties of CoSpheres as introduced in paper 1 both in the primordial GRF and in the structured Universe until $z = 0$.

Within the Gaussian field, CoSpheres are fully determined by a unique compensation radius and a set of shape parameters $v$, $x$ and $\nu$. This formalism can be seen as a physical extension of the original BBKS work by taking explicitly into account the large scale matter field around the local extremum. This extension describes the correlation between local extremum and their large scale environment.

In the framework of GRF, we derive the full joint Gaussian probability for the four parameters $R_1$, $v$, $x$ and $\nu$ (see Eq. 35) by taking into account the appropriate domain for the curvature parameter $x$ in order to ensure the correct definition of $R_1$ (see Sec. 2.2.2). Interestingly, as studied in Sec. 2.2.3, the very large scale limit $R_1 \rightarrow +\infty$ reduces to the standard BBKS statistics for the central extrema (Bardeen et al. 1986). Physically, it describes the limit where the central extremum is completely decorrelated from its surrounding cosmic environment. In other words, The statistical distribution of $v$ or $x$ are no more affected by $R_1$ when $R_1$ becomes very large.

Marginalizing the full joint probability over the shape parameters $v$, $x$ and $\nu$ leads to the distribution $dP(R_1)$ (see Eq. 43) which gives the probability to find a CoSphere with a given $R_1$. Since each single $R_1$ is a comoving quantity, its pdf $dP(R_1)$ is also expected to be conserved in comoving coordinates during the whole cosmic evolution. This is confirmed by Fig. 6 where we compare the $R_1$ distribution around DM haloes (central extremum) at various redshifts with the Gaussian prediction (red curve). Since the Gaussian field is exactly symmetric, this distribution can also be transposed without any change to the complementary case of central minimum, seeding cosmic voids. In Fig. 9 we show the compensation radius distribution $dP(R_1)$ at various redshift for central minima. This figure has been obtained by finding minimum in the density field smoothed with a Gaussian kernel on $R_1 = 5 \, h^{-1}\text{Mpc}$ at $z = 0$ and assuming that their position do not change with redshift (profiles are computed around the same position for each $z$). Once again, the Gaussian prediction (red curve) fits the measured distribution on all available scales.

As in Fig. 6, the BAO-like wiggles around $R_1 = 90 \, h^{-1}\text{Mpc}$ expected from theory do not appears clearly on numerical data. As previously discussed in Sec. 3.2, this slight discrepancy between theoretical and numerical results may be due to the cosmic variance which dominates on these scales due to the size of our simulation box (Rasera et al. 2014).

We emphasize that this distribution is suited to model the distribution of cosmic void sizes once identified as spherically compensated regions. This approach is fundamentally different from other attempts to model void statistics such as in Sheth & Weygaert (2004); Furlanetto & Piran (2006); Achitouv et al. (2015). These approach are based on the excursion set theory Press & Schechter (1974); Bond et al. (1991) while our formalism identifies the size of a void to its compensation radius. The improvement of our approach is the ability to define correctly the size of such cosmic structure and to be able to model its properties from first principles. However, our model assumes that we are indeed able to find this radius in observable data, which is far from being obvious.

Apart from the compensation radius distribution, we derived the statistical properties of the shape parameters of CoSpheres and particularly the conditional probability distribution of each shape parameter at fixed $R_1$. We computed their conditional moment and discussed the correlation between the central peak and its surrounding cosmic environment. More precisely, we have shown that whilst $R_1$ increases, the peak parameters $v$ and $x$ progressively tend to their asymptotic BBKS value while $\nu$ vanishes. Small central extremum (small value of $|v|$) are associated with narrow compensation radii with a high compensation density $v_1$. On the other hand, higher peaks are more likely to sit in large inhomogeneous regions with a small compensation density. Once again, this discussion is valid for both central maximum and minimum, describing cosmic voids.

Using the spherical collapse model and the conservation of $R_1$ we then derived the evolved conditional distribution for $\delta_1$ at fixed $R_1$. This leads to the evolved moments $\langle \delta_1^4 | R_1 \rangle$ at $z = 0$ whose expression can be computed analytically. The comparison with numerical simulation are in a very good agreement with the Lagrangian prediction (see Fig. 6 and Fig. 7). In the opposite the Eulerian dynamical evolution fails to reproduce these quantities, even on "large scales", e.g. $R_1 = 40 \, h^{-1}\text{Mpc}$.

The statistical properties of the compensation scalars $R_1$ and $\delta_1$ are thus particularly interesting since they can be directly measured in numerical simulations or otherwise from observational data and can be used as new cosmology probes. This is investigated in Alimi & de Fromont (2017) and de Fromont & Alimi (2017b).

The fundamental interest of CoSpheres for cosmology
is thus based on two main properties. The first one is the conservation of the compensation radius $R_1$ in comoving coordinates, i.e. the fact that that $R_1(t) \propto a(t)$. This fundamental feature implies the conservation of its probability distribution $dP(R_1)$ during the whole cosmic history and allows in principle to probe directly the properties of the primordial Gaussian Universe. This property allows to evaluate at $z = 0$ the statistics of the shape parameters describing both the small scale extremum and its large scale environment. The second fundamental property is the exact symmetric treatment of CoSpheres defined from central maximum or minimum. This formalism provides a physically motivated model for cosmic voids and offers an alternative approach for describing their statistical properties.

APPENDIX A: COEFFICIENTS $C_\alpha$

In this appendix we give the explicit expressions of the $C_\alpha$ coefficients appearing in Eq. (24)

\[
\frac{C_\alpha}{\langle k^4 \rangle} = -\langle j_1^2 \rangle \left( \langle W_1^2 \rangle + 2 \langle j_1 \rangle \langle W_1 \rangle \langle W_1 J_1 \rangle - \langle W_1 J_1 \rangle^2 \right) + \langle j_1^2 \rangle \left[ \langle W_1^2 \rangle - \langle W_1 \rangle^2 \right] \quad (A1)
\]

\[
C_\gamma = -\langle j_1^2 \rangle \left( \langle k^2 W_1 \rangle^2 - \langle k^4 \rangle \langle W_1 J_1 \rangle \right) + 2 \langle k^2 j_1 \rangle \langle k^2 W_1 \rangle \langle W_1 J_1 \rangle + \langle W_1 \rangle \langle j_1^2 \rangle (k^4 - \langle k^2 J_1 \rangle^2) \quad (A2)
\]

\[
C_\nu = -\langle k^2 W_1 \rangle^2 + 2 \langle k^2 \rangle \langle k^2 W_1 \rangle \langle W_1 \rangle - \langle k^2 \rangle^2 \langle W_1 \rangle^2 + \langle k^4 \rangle \left[ \langle W_1^2 \rangle - \langle W_1 \rangle^2 \right] \quad (A3)
\]

\[
\frac{C_\nu W}{\sqrt{\langle k^4 \rangle}} = \langle j_1^2 \rangle \left( \langle k^2 W_1 \rangle \langle W_1 \rangle - \langle j_1^2 \rangle \langle k^2 \rangle \langle W_1 \rangle^2 + \langle j_1 \rangle \langle k^2 J_1 \rangle \langle W_1 \rangle \right) + \langle W_1 \rangle \langle j_1 \rangle \left( \langle k^2 W_1 \rangle - \langle W_1 \rangle \langle k^2 \rangle \langle W_1 \rangle \right) \quad (A4)
\]

\[
\frac{C_\nu W}{\sqrt{\langle k^4 \rangle}} = \langle k^2 J_1 \rangle \langle W_1 \rangle^2 - \langle j_1 \rangle \langle k^2 W_1 \rangle \langle W_1 \rangle + \langle W_1 \rangle \left( \langle k^2 W_1 \rangle - \langle W_1 \rangle \langle k^2 \rangle \langle W_1 \rangle \right) \quad (A5)
\]

\[
C_{\nu W} = \langle k^2 J_1 \rangle \langle k^2 W_1 \rangle - \langle k^2 \rangle \langle k^2 J_1 \rangle \langle k^2 W_1 \rangle \langle W_1 \rangle + \langle j_1 \rangle \left( \langle k^2 W_1 \rangle^2 - \langle k^4 \rangle \langle W_1 \rangle^2 \right) + \langle W_1 \rangle \left( \langle k^4 \rangle \langle W_1 \rangle - \langle k^2 \rangle^2 \langle W_1 \rangle \right) \quad (A6)
\]

We also introduce $C_0$ defined by

\[
C_0 = \left( \langle j_1 \rangle \left( \langle k^2 W_1 \rangle - \langle k^2 J_1 \rangle \langle W_1 \rangle \right) \right)^2 + \left( \langle k^2 \rangle^2 - \langle k^4 \rangle \right) \left( \langle j_1^2 \rangle \langle W_1 \rangle^2 - \langle W_1 J_1 \rangle^2 \right) \quad (A7)
\]

Linked to the determinant of the correlation sub-matrix $\hat{Q}$

\[
\Sigma^2(R_1) = C_0 + C_X + C_V + 2 \frac{\langle k^2 \rangle^2}{\sqrt{\langle k^4 \rangle}} C_{\nu W} \quad (A8)
\]
Note that all these coefficients are functions of $R_1$.

**APPENDIX B: COMPUTING THE EVOLVED MOMENTS OF THE COMPENSATION DENSITY**

We now compute the evolved moments $\langle \delta^m_i | R_1 \rangle (t)$ for both central minimum and maximum. We show that in both cases it gives

$$\langle \delta^m_i | R_1 \rangle (t) = \sum_{k \geq 0} \hat{D}(t)^m (1 - \hat{D}(t))^k \left( -\frac{n}{k} \right) \langle \delta^{i+k} | R_1 \rangle$$  \hspace{1cm} (B1)

where the various moments $\langle \delta^{i} | R_1 \rangle$ are computed within the Gaussian field at some time $t_i$ and $\hat{D}(t) = D(t)/D(t_i)$.

**B1 Central minima, i.e. cosmic voids**

For central minimum seeding cosmic voids, the compensation density $\delta_1$ is positive. Using the notations of Sec. 3.3, $\delta_i^1$ is the evolved compensation density and $\delta_1$ its corresponding value in the primordial field. These quantities are linked through Eq. (64) and Eq. (65). Since we consider finite values of $\delta_i^1$ today, this implies that the corresponding primordial values must satisfy $\delta_1 \leq \delta_i^1 (t) \equiv 1/(\hat{D}(t) - 1)$ (see Eq. 64). The moments today are given by

$$\langle \delta^m_i | R_1 \rangle (t) = \int_0^{\infty} \left( \delta_i^1 \right)^m dP(\delta_i^1 | R_1)$$  \hspace{1cm} (B2)

Using the mapping Eq. (64) it leads to

$$\langle \delta^m_i | R_1 \rangle (t) = \int_0^1 \frac{\hat{D}(t) \delta_1}{1 - \delta_1 (\hat{D}(t) - 1)}^m dP(\delta_1 | R_1)$$  \hspace{1cm} (B3)

$$= (\sigma_0 \hat{D}(t))^m \int_0^{1/\epsilon(t)} \left( \frac{\nu_1}{1 - \nu_1 \epsilon(t)} \right)^n dP(\nu_1 | R_1)$$  \hspace{1cm} (B4)

where $\delta_1 = \sigma_0 \nu_1$ and $\epsilon(t) = \sigma_0 (\hat{D}(t) - 1)$. Since $\nu \in [0, 1/\epsilon(t)]$, we can use a Maclaurin expansion of the $1 - \nu_1 \epsilon(t)$ term, leading to

$$\langle \delta^m_i | R_1 \rangle (t) = \hat{D}(t)^m \sum_{k \geq 0} (-1)^k (\hat{D}(t) - 1)^k \left( -\frac{n}{k} \right)$$

$$\times \int_0^{1/\epsilon(t)} (\sigma_0 \nu_1)^{n+k} dP(\nu_1 | R_1)$$  \hspace{1cm} (B5)

Using the primordial moments $\langle \delta^{i} | R_1 \rangle = \sigma_0^m \left( \nu_1^m | R_1 \right)$ we get the final result as recalled in Eq. (B1).

**B2 Central maximum**

For central maximum, the computation necessitates a careful treatment. We start from

$$\langle \delta^m_i | R_1 \rangle (t) = \int_{-\infty}^0 \left( \frac{\hat{D}(t) \delta_1}{1 - \delta_1 (\hat{D}(t) - 1)} \right)^m dP(\delta_1 | R_1)$$  \hspace{1cm} (B6)

Using Eq. (65), it is clear that if $\delta_1 \geq -1$, then for any time $t$ we have $\delta_i^1 \geq -1$. However, we cannot use here a Maclaurin expansion since the term $\nu_1 \epsilon(t) = \delta_1 (\hat{D}(t) - 1)$ is no more included in its convergence radius, i.e. it can take values larger than 1 ($|\nu_1 \epsilon(t)| > 1$). We thus introduce the new variables $x = \delta_1 + 1$ and $\eta(t) = (\hat{D}(t) - 1)/\hat{D}(t)$, both included in $[0, 1]$. Eq. (B6) transforms to

$$\langle \delta^m_i | R_1 \rangle (t) = \int_0^1 \left( \frac{x - 1}{1 - x \eta(t)} \right)^n dP(x - 1 | R_1)$$  \hspace{1cm} (B7)

after a Taylor expansion in term of $\eta(t)$ and switching back to $\delta_1$ we get

$$\langle \delta^m_i | R_1 \rangle (t) = \sum_{k \geq 0} (-\eta(t))^k \left( -\frac{n}{k} \right) \langle \delta^{i+k} | R_1 \rangle$$  \hspace{1cm} (B8)

Since $\delta_1 \in [-1, 0]$, we expand also the term $(1 + \delta_1)^k$ term,

$$\langle \delta^m_i | R_1 \rangle (t) = \sum_{k \geq 0} (-\eta(t))^k \left( -\frac{n}{k} \right) \sum_{p=0}^k \left( \frac{k}{p} \right) \langle \delta^{i+p} | R_1 \rangle$$  \hspace{1cm} (B9)

We simplify this expression by reordering and collecting terms with the same contribution,

$$\langle \delta^m_i | R_1 \rangle (t) = \sum_{m \geq 0} \left( \sum_{k \geq m} (-\eta(t))^k \left( -\frac{n}{k} \right) \left( \frac{k}{m} \right) \right) \langle \delta^{m+n} | R_1 \rangle$$  \hspace{1cm} (B10)

Using again $\eta(t) = (\hat{D}(t) - 1)/\hat{D}(t)$ together with the relation

$$\forall a \in [-1, 1], \sum_{k \geq m} a^k \left( -\frac{n}{k} \right) \left( \frac{k}{m} \right) = \frac{a^m}{1 + a^{m-n}}$$  \hspace{1cm} (B11)

where $a = (1 - 1/\hat{D}(t)) = -\eta(t)$. We finally recover the same expression Eq. (B1) which holds for both central minima and central maxima.
